Col. 1 gives the drop in electromotive force of the cell

on the addition of potassium chloride at a concentration of *c* mols per liter.

Col. 2 gives the electromotive forces of the cells

<sup>1</sup> Thus, a concentration of 0.06 *M* salt in 0.1 *M* hydrochloric acid is compared with a concentration of 0.16 *M* salt.

as obtained from the plot X of the previous communication.

Col. 3 gives the electromotive forces of the cells

obtained by subtracting the values in Col. 2 from those in Col. 1.

Col. 4 gives the electromotive forces of the cells

obtained from  $E_i + E_i$  in Table II.

Now, as has been stated under the discussion of the general method here employed, if the activity of the chlorine ion in 0.1 *M* hydrochloric acid is equal to the activity of the chlorine ion in 0.1 *M* potassium chloride, then the values for the cells in Cols. 3 and 4 should be identical. As can readily be seen, there is a striking agreement between the values obtained even up to a salt concentration of 3 *M*. The widest deviation between the two series of results is 0.00076 volt at a salt concentration of 0.400 *M*. Furthermore, it is to be noticed that at every concentration of salt, the electromotive force of the cell

is greater than that of the cell

This deviation may be due to two causes; firstly, the X-plot of the previous communication may be faulty; secondly, the ion-activity of the hydrochloric acid may be greater than the ion activity of the potassium chloride at 0.1 *M* concentration. Since the widest deviations occur in the more dilute solutions and since the values in Col. 4 are in every case greater than those in Col. 3, there is great likelihood that the ion activity of the acid is greater than that of the salt.

**4. Further Discussion of the Results. Final Calculation of the Electromotive Forces of the Cells.—**

There is as yet no reliable value for the activity of the hydrogen and chlorine ions in 0.1 *M* hydrochloric acid. From the data obtained by Jahn<sup>1</sup> on the cells

and by Ellis<sup>2</sup> on the cells

the latter has calculated the activity coefficient<sup>3</sup> of 0.1 *M* hydrochloric acid. In this calculation, the assumption was made that at an acid con-

<sup>1</sup> *Z. physik. Chem.*, 33, 545 (1900).

<sup>2</sup> *THIS JOURNAL*, 38, 737 (1916).

<sup>3</sup> The activity coefficient is equal to the activity divided by the concentration.

centration of 0.00167, the activity coefficient equalled the conductance viscosity ratio. Ellis obtained in this manner the value 0.843 for the activity coefficient, which makes the hydrogen ion activity 0.0843. More reliable calculations have been made by Ellis on the activity coefficient of 0.1 *M* potassium chloride from the osmotic pressure calculations of Bates<sup>1</sup> and the electromotive force measurements of MacInnes and Parker.<sup>2</sup> The values 0.732 and 0.727 for the activity coefficients are obtained from these two sources. If we take the ion-activity of 0.1 *M* potassium chloride to be 0.0730, then there is reason to believe that the ion-activity of 0.1 *M* hydrochloric acid is less than 0.0843. Ellis was aware of the provisional nature of this value.

According to the formula of Lewis and Sargent,<sup>3</sup> the liquid potential at the surface of a 0.1 *M* potassium chloride solution and a 0.1 *M* hydrochloric acid solution is -0.0284. Recent measurements of the cell

obtained by Lewis and Sebastian,<sup>4</sup> give the value -0.0284. This argues that there is little, if any, difference between the ion activities of the acid and the salt at this concentration.

From the results reported in this paper, it is thought that the activity of the ions in 0.1 *M* hydrochloric acid is greater than in 0.1 *M* potassium chloride but only slightly greater. If 0.0730 be accepted to represent the ion-activity of the salt, there is reason to assume that the ion-activity of the acid is 0.0755. The arbitrary nature of this choice is realized; it simply fits in with the large amount of evidence obtained by the author.

The extent of this correction can best be shown by Table IV and the plots in Fig. 1. Table IV contains the following:

(1) Salt concentration (*c*).

(2) The values of Col. A were obtained on the assumption that the ion activities of 0.1 *M* hydrochloric acid equalled the ion activities of 0.1 *M* potassium chloride. In other words, the electromotive forces of the cells

(*E*<sub>t</sub> + *E*<sub>h</sub>, Table II) were subtracted from the drop in electromotive forces of the cell

on the addition of potassium chloride (Col. 2, Table III). A in Fig. 1 is the plot of these values. Here, the electromotive forces are plotted against the salt concentration (*c*) in gram equivalents per liter.

<sup>1</sup> THIS JOURNAL, 37, 1421 (1915).

<sup>2</sup> *Ibid.*, 37, 1445 (1915).

<sup>3</sup> *Ibid.*, 31, 363 (1909).

<sup>4</sup> Lewis and Randall, *Ibid.*, 36, 1973 (1914).

(3) The column headed "dotted line" and corresponding to the dotted line in Fig. 1 was obtained as follows:

a. It was assumed that the ion-activity of the acid was 0.0755 and the salt 0.0730.

b. The chlorine ion-activities of the acid-salt mixtures were assumed to be equal to those of the salt solution plus 0.0025 at the different concentrations. This should be a good approximation.

Fig. 1.

c. From this data, the electromotive forces of the cells

$\text{Hg} \mid \text{HgCl}, \text{KCl in HCl (0.1 M)} \parallel \text{HCl (0.1 M)}, \text{HgCl} \mid \text{Hg}$   
 were calculated. By subtracting these values from the drops in electro-  
 motive force of the cell

on the addition of potassium chloride of concentration ( $c$ ), the electromotive forces of the cells

are obtained. This gives the final data on the electromotive forces of the last of these cells as obtained from the measurements in this paper.

(4) The Col. X, corresponding to X in Fig. 1, represents the electromotive forces of this last series of cells as obtained from the Plot X of the earlier communication.

(5) The last column represents the difference between the values under "dotted line" and X.

TABLE IV.

Conc. of salt ( $c$ ).	A.	Dotted line.	X.	Difference.
0.060	0.00033	0.00002	-0.00010	0.00012
0.100	0.00027	-0.00011	-0.00015	0.00004
0.120	0.00026	-0.00017	-0.00020	0.00003
0.200	0.00037	-0.00017	-0.00030	0.00013
0.240	0.00020	-0.00038	-0.00040	0.00002
0.400	0.00001	-0.00065	-0.00075	0.00010
0.600	-0.00058	-0.00128	-0.00125	-0.00003
0.900	-0.00162	-0.00236	-0.00225	-0.00011
1.200	-0.00335	-0.00413	-0.00375	-0.00038
1.800	-0.00726	-0.00808	-0.00775	-0.00033
2.400	-0.01147	-0.01230	-0.01200	-0.00030
3.000	-0.01638	-0.01721	-0.01640	-0.00081

A very close agreement is obtained except at the higher concentrations of salt. In no case is the difference more than 1 millivolt. This may be due to an error in the values obtained in the previous communication. The large increase in the hydrogen ion activity in the more concentrated solutions would tend to diminish the liquid potential between the acid-salt solutions and the solution of saturated potassium chloride there used. This effect would act in such a way as to increase the electromotive force of the cell and thus render the electromotive force decrease of the Plot X too small. We cannot at present be entirely certain of this, for at these high concentrations an error may have been introduced in assuming that the cation transference number of potassium chloride is 0.495 throughout the complete range of concentrations. The evidence offered in this paper would tend to prove that this value varies slightly, if at all. However, if the cation transference number decreases with increasing salt concentration, there will result a smaller difference between the Plot X and the dotted line.

5. The Ion Activities of Solutions of Potassium Chloride in 0.1 M Hydrochloric Acid.—Table V gives these ion activities calculated from the data thus obtained. The hydrogen ion activities are calculated from the electromotive forces in Table IV. Up to a concentration of

0.600 *M* salt, these have been obtained from the values given in Col. X; at salt concentrations higher than this, they have been obtained from the means of the values of Col. X and Col. "dotted line." The chlorine ion activities have been obtained by adding 0.0025 to the values given in Table II. The last column gives the free energy transfer of one gram ion of hydrogen from a solution of 0.1 *M* hydrochloric acid to a solution of 0.1 *M* hydrochloric acid containing potassium chloride at the concentration designated.

TABLE V.

Conc. of salt ( <i>c</i> ).	Hydrogen ion activities.	Chlorine ion activities.	Free energy transfer.
0.000	0.0755	0.0755	...
0.060	0.0758	0.1126	-9.65
0.100	0.0759	0.1361	-14.47
0.120	0.0761	0.1508	-19.30
0.200	0.0765	0.1957	-28.95
0.240	0.0767	0.2208	-38.60
0.400	0.0777	0.3076	-72.37
0.600	0.0793	0.4216	-120.6
0.900	0.0826	0.5861	-222.0
1.200	0.0880	0.7480	-382.0
1.800	0.1027	1.0785	-763.3
2.400	0.1211	1.4357	-1172.0
3.000	0.1452	1.8122	-1621.0

Since an error of 0.00025 volt corresponds to an error of 1% in the ion activity and since there is still an element of guess-work in the calculation of these values, an accuracy of less than 1% is not claimed.

### Summary.

#### 1. Measurements of the cells

and

up to a concentration of 3 *M* potassium chloride have been made.

2. From these, if the ion activities of 0.1 *M* potassium chloride and 0.1 *M* hydrochloric acid are known, the electromotive forces of the cells

can be calculated.

3. The measurements here recorded, along with those of an earlier communication, indicate that if the ion activity of 0.1 *M* potassium chloride is 0.0730, then the ion activity of 0.1 *M* hydrochloric acid is 0.0755.

4. From these two values, and the measurements of the above cells, the hydrogen and chlorine ion activities of solutions of potassium chloride at different concentrations in 0.1 *M* hydrochloric acid have been computed.

[CONTRIBUTION FROM THE CHEMICAL SECTION, IOWA AGRICULTURAL EXPERIMENT STATION.]

## ESTIMATION OF CALCIUM IN ASH OF FORAGE PLANTS AND ANIMAL CARCASSES.

By S. B. KUZIRIAN.

Received June 24, 1916.

An accurate as well as a rapid method for the estimation of calcium in forage plants and animal carcasses in agricultural experiment stations is of prime importance in studying the relationship between the growing plant or animal on the one hand and the soil or food supply on the other.

Having had occasion in this laboratory to make a large number of calcium determinations on samples of forage plants and animal carcasses, the disadvantages and inconveniences of the methods in common use soon became apparent. In the course of these analyses the method described in this paper was found to be superior both in regard to accuracy and convenience.

Thompson and Morgan<sup>1</sup> attempt the precipitation of calcium as oxalate in the presence of large excess of phosphoric acid in acetic acid solution. McCrudden<sup>2</sup> likewise tries to estimate the calcium without first removing the phosphoric acid.

The separation of phosphoric acid as mercurous,<sup>3</sup> stannic,<sup>4</sup> bismuthic,<sup>5</sup> silver,<sup>6</sup> etc., phosphates with the subsequent removal of these precipitants by some suitable analytical operations is too tedious, requiring prolonged time for execution. These methods are, therefore, out of consideration for general use in experiment stations.

The basic acetic method is the one which has come into most common use, having been adopted as official by the Association of Official Agricultural Chemists. The conditions to be observed with this method are of such a nature, that it is difficult to get concordant results in determinations of manganese, calcium, magnesium and the alkalis. The main objection to this process is the prolonged evaporation which is necessary to reduce a large volume of filtrate into 50 to 75 cc. The action of ammonia salts upon the glass beaker at 80 to 90° is not altogether negligible.

**A More Accurate and Rapid Method.**—Shedd's<sup>7</sup> method, though more convenient and rapid, tends to give higher results due to contamination

with molybdenum. When, however, the following procedure, which is a slight modification of Shedd's process, is adopted, excellent results are obtained. The modification consists essentially in boiling the calcium oxalate precipitate for 30 minutes on a hot plate, and filtering through a Gooch; then, instead of dissolving this precipitate with hydrochloric acid and reprecipitating with dilute ammonia, which operation seems to be insufficient completely to remove adhering traces of molybdenum,<sup>1</sup> it is ignited to convert the oxalates into oxides, preferably in an electric furnace. It is then dissolved in dilute hydrochloric acid, filtered, some ammonium chloride and ammonia added, and boiled until the odor of ammonia is faint. The precipitated iron and aluminium are removed and the calcium precipitated as oxalate, at this stage of the process, calcium being entirely free from molybdenum salts.<sup>2</sup>

The results shown in Table I were obtained with solutions containing known amounts of calcium and phosphorus. The phosphorus was removed in each case as ammonium phosphomolybdate, according to directions given in the Official Methods<sup>3</sup> (Volumetric Optional) and titrated to make sure that its removal was complete. The estimation of calcium according to the above method was then attempted and the following results were obtained:

TABLE I.—ANALYSIS OF KNOWN SOLUTION FOR CALCIUM AND PHOSPHORUS.

No. of the experiment.	P <sub>2</sub> O <sub>5</sub> taken (as Na <sub>2</sub> HPO <sub>4</sub> ), g.	CaO taken (as Ca(NO <sub>3</sub> ) <sub>2</sub> ), g.	CaO found, g.	Error, g.
1	0.0207	0.0283	0.0283	0.0000
2	0.0207	0.0283	0.0285	+0.0002
3	0.0207	0.0283	0.0283	0.0000
4	0.0207	0.0283	0.0283	0.0000
5	0.0207	0.0283	0.0283	0.0000
6	0.0207	0.0566	0.0566	0.0000
7	0.0207	0.0283	0.0282	-0.0001
8	0.0207	0.0283	0.0283	0.0000

The ease with which closely agreeing duplicates can be obtained when ash of forage plants is analyzed for calcium is shown in Table II. Numbers 1 and 2 in each case are duplicates of the same sample.

<sup>1</sup> On testing qualitatively a series of 8 results obtained according to Shedd's method, all gave indications of molybdenum. The sulfide test was found to be most satisfactory, being sensitive to a small fraction of a milligram of MoO<sub>3</sub>. In all cases calcium oxides were dissolved in hydrochloric acid, made ammoniacal, colorless ammonium sulfide added, digested, filtered and the filtrate made acid with hydrochloric acid. Sometimes a development of a blue coloration on addition of ammonia sulfide indicates a reduced condition of molybdenum.

<sup>2</sup> When two series of eight each were tested for molybdenum similarly, tests were negative in all cases.

The carcasses of some newly born pigs were ashed after air drying and dissolved in nitric acid, the phosphoric acid precipitated as ammonium phosphomolybdate and the filtrate analyzed for calcium in the same way. Following are the results obtained:

TABLE III.—ANALYSIS OF PIG CARCASSES<sup>2</sup> FOR CALCIUM.

<sup>1</sup> 2-gram samples taken.

<sup>2</sup> Ashing of the pig samples was done in platinum dishes. No calcium acetate or magnesium nitrate was added during ashing as it was found to be unnecessary.

<sup>3</sup> The weight of the air-dried sample taken in each case was 0.5 g.

When iron and aluminium were removed according to the description of Shedd<sup>1</sup> and tested for molybdenum in a series of four determinations the test was positive. Because of the fact that iron is titrated with permanganate after fusion with potassium bisulfate and reduction with nascent hydrogen, some complications may arise, preventing accurate results.

More reliable and accurate results of all basic ions in ash of forage plants and animal carcasses are obtained if the excess of molybdenum after the removal of  $P_2O_5$  as ammonium phosphomolybdate, is removed as sulfide according to Fresenius.<sup>2</sup> In short, the filtrate is made slightly ammoniacal, digested with colorless ammonium sulfide, carefully acidified with 12% hydrochloric acid, warmed to  $45^\circ$  to flocculate the molybdenum sulfide and filtered through a Schleicher & Schüll filter (blue label). The clear filtrate thus obtained is boiled to expel hydrogen sulfide and after further filtration is ready for basic analysis. The fact that a perfect separation and gravimetric estimation of iron and aluminium can be effected with the use of this method, makes it highly commendable. Moreover, if manganese is present in traces, it may easily be tested for and estimated. Some work was undertaken in this laboratory to show the advisability of substituting this method for the separation and estimation of basic ions in ash in place of the official methods, giving special consideration to the time required and also accuracy. Aliquots of a solution of calcium nitrate of known strength were mixed with a solution of disodic hydrogen phosphate and the phosphorus removed as phosphomolybdate. From the filtrate thus obtained, molybdenum was removed as sulfide according to directions given above. The calcium was precipitated as oxalate and ignited into oxide. Following are the results obtained under these conditions:

TABLE IV.—ESTIMATION OF CALCIUM AFTER REMOVAL OF MOLYBDENUM AS SULFIDE.

The time required in this case is much shorter than when basic acetate method is used, three hours being sufficient to bring one series of six, each

<sup>1</sup> O. M. Shedd, *Bur. of Chem., Bull.* 152, pp. 63, 64.

<sup>2</sup> Fresenius' *Quant. Chem. Anal.*, 1, 464.

having one duplicate, to the condition where calcium is ready for precipitation as oxalate.

### Summary.

A more rapid and accurate method is recommended for the determination of calcium in the ash of agricultural products. It consists essentially in removing the phosphorus as ammonium phosphomolybdate from an acid solution of the ash, and precipitation of calcium from the filtrate as calcium oxalate, either directly or after the removal of the excess of molybdenum as sulfide. Since no advantage was found in removing the molybdenum, it is recommended that this step be omitted.

A comparison of this method with the so-called basic acetate method in common use brings out the following points in its favor:

1. It yields more accurate and concordant results than the basic acetate method.
2. No attention need be given to the maintenance of exact neutrality of the solution.
3. The volume of the filtrate resulting from the precipitation of phosphorus can be kept reasonably small, so that no evaporation is necessary.
4. The time required for the determination is greatly shortened.
5. Phosphorus and calcium may be determined in the same aliquot.

AMES, IOWA.

## [CONTRIBUTION FROM THE CHEMISTRY DEPARTMENT OF THE UNIVERSITY OF ILLINOIS.] A SYSTEMATIC SEPARATION OF THE ANIONS OF GROUP I. ANIONS WHOSE SILVER SALTS ARE INSOL- UBLE IN NITRIC ACID.<sup>1</sup>

By H. C. P. WEBER AND H. A. WINKELMANN.

Received August 17, 1916.

The customary methods for the examination and separation of the acids depend mainly upon various group reactions, followed by specific tests for one or the other anion, combined with a process of elimination based upon the results of the analysis for the cations. For a limited number of anions special methods of separation have been worked out in detail, as for instance for certain of the acids containing sulfur. The literature on the separation of the halogens Cl, Br, I, is quite voluminous and in this particular case a choice of various satisfactory methods of separation is possible. On the whole these methods are, however, limited in scope and very little work has been done upon systematic methods for the separation of the anions.<sup>2</sup>

<sup>1</sup> Portions of this work were submitted by Mr. H. A. Winkelmann in partial fulfillment of the requirements for the degree of Master of Science in Chemistry in the Graduate School of the University of Illinois, June, 1915.

<sup>2</sup> The lack of such a systematic procedure is shown particularly by the errors and confusion resulting from the customary method of attack in the hands of students

The classification of acids into groups according to their reactions with silver and barium salts, frequently used in texts on qualitative analysis is ascribed to Bunsen in 1878, and is used practically unchanged. In 1900 Abegg and Herz<sup>1</sup> described, very briefly, a separation of the anions based upon the solubility of the calcium, barium and zinc salts and the volatility of various acids.

Quite recently A. A. Noyes,<sup>2</sup> published the most comprehensive scheme of separation of the anions so far elaborated. The fundamental idea of this method is the separation of the volatile and nonvolatile acids in various stages by distillation after addition of phosphoric acid. The more volatile acids, such as hydrocyanic acid, are collected in the first distillate, the less volatile in the second. The various portions are then examined for specific reactions of one or the other acid, without attempting to effect a further separation. The method is, in many respects, ideal and very effective, and a very great improvement upon the method of trial and failure indicated above.

In cases in which the nature of the mixture is such that interaction between the various constituents is possible, the prolonged heating during distillation will hasten and extend decomposition, with resulting decrease of directness or certainty in the results.<sup>3</sup>

The part of the investigation here described has to do with the first group of acids, in the following classification:

I. Anions which give silver salts insoluble in dilute nitric acid, but whose barium salts are soluble in water or acids.

II. Anions which give silver salts difficultly soluble in neutral solution, but readily soluble in dilute nitric acid, and whose barium salts are readily soluble.

III. Anions which give silver and barium salts insoluble in water alone, but soluble in the presence of dilute nitric acid.

IV. Anions which give salts of silver and barium readily soluble under all conditions.

V. Anions which give silver salts soluble in water, but whose barium salts are insoluble, even in the presence of nitric acid.

first confronted with the problem of recognizing, and distinguishing between the various negative radicals in an unknown mixture. While they obtain a fairly comprehensive view of the relations between the various metallic elements in their reactions, this is not true of the nonmetallic elements.

<sup>1</sup> *Z. anorg. Chem.*, 23, 236 (1900).

<sup>2</sup> *THIS JOURNAL*, 34, 609 (1912).

<sup>3</sup> The fact that each distillation with phosphoric acid entails destruction of the distillation flask does not involve more than a slight inconvenience in individual cases; where the method is, however, to be applied repeatedly by large numbers of students, this factor does become one which it is desirable to eliminate.

The anions included in this first group are  $\text{Cl}^-$ ;  $\text{Br}^-$ ;  $\text{I}^-$ ;  $\text{CN}^-$ ;  $\text{CNS}^-$ ;  $\text{Fe}(\text{CN})_6^{\text{III}}$ ;  $\text{Fe}(\text{CN})_6^{\text{IV}}$ ;  $\text{S}^-$ .

The first step in the problem consisted in the examination of the solubility data of the salts of the various anions, either in neutral, acid or alkaline solutions and in the presence of various salts. While it was a simple matter to find numbers of insoluble salts, the compounds available rapidly narrow down in number, either because they are not suitable for purposes of separation, or because the solubilities referred to pure salts in equilibrium with pure water, conditions which are not applicable always to the conditions of an analysis. For this reason a number of the cases examined as promising, but found to be unsatisfactory, are briefly described as a matter of record. The effect of the complications introduced in the course of analysis is shown by the results tabulated under these and various other metals further on.

**Ferrocyanides and Ferricyanides.**—The plan which first suggested itself was to add metallic zinc to the mixture of the silver salts of the acids. The silver salts would thus be reduced with the production of metallic silver and the corresponding zinc salts. The zinc ferrocyanide and ferricyanide being insoluble, would remain with the reduced silver and unused zinc, the remaining zinc salts being left in solution. This method lost in sensitiveness as a result of the occlusion of some of the other anions by the metallic silver or zinc. In addition,<sup>1</sup> metallic zinc, when acting on potassium ferricyanide, will reduce the same, yielding some ferrocyanide, and in part replacing iron in the complex.

This procedure would have been more in harmony with the steps to be anticipated in the succeeding groups, since the first group could thereby be removed as a whole, but was not found feasible. The difficulty was overcome by adding zinc nitrate to the solution before adding silver nitrate. The insoluble zinc ferrocyanide and ferricyanide are precipitated, leaving the remaining acids of the first group in solution, from which they are precipitated by silver nitrate. Experiments performed to determine the sensitiveness of this method showed that in a solution containing dilute nitric acid, 0.05 mg. of ferricyanide, or ferrocyanide, in 10 cc. total volume, gave a decided precipitate, while 0.02 mg. could still be detected by an experienced observer. The separation of the two zinc salts was found to be readily effected by means of ammonium hydroxide, and will be described under the general procedure.

**The Remaining Anions.**—Having precipitated the silver compounds of  $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ,  $\text{CN}^-$ ,  $\text{CNS}^-$ , and  $\text{S}^-$ , the next step was to determine upon a process of separation and identification. The following steps were investigated for their usefulness:

*A. Ammonium Hydroxide.*—Since ammonium hydroxide is a good sol-

<sup>1</sup> vide G. McP. Smith, *Z. anorg. Chem.*, **82**, 65 (1913).

vent for some silver salts, the possibility of its use for the separation was examined. Silver iodide and sulfide were found to be insoluble under all conditions. The solubility of the silver salts under examination depends considerably upon conditions, as is well known, making necessary a careful control of the variables. For example, silver chloride is easily soluble in dilute ammonium hydroxide, whereas the bromide is but slightly so, but its solubility increases materially with the concentration of the ammonia. The thiocyanate is soluble only in concentrated ammonia. The ammonium cyanide, on the other hand, is very unstable, so that even if a separation is obtained, there is danger of decomposition in subsequent manipulations.

One of the fundamental objections to this method is the unreliability of results which depend upon extraction of a more soluble substance from an admixture containing less soluble substances. This is never possible with mathematical precision, and, unless the differences in solubility are very great, it is not even possible for practical purposes. Given large quantities of two constituents, for instance silver bromide and silver iodide, such a method gives decided results. But at the extremes of the range of mixtures, the results are of necessity erroneous. Thus a large quantity of iodide will prevent solution of small percentages of bromides, and conversely, small percentages of iodide will dissolve with the larger portion of bromide. Methods of separating the silver halides by means of ammonium hydroxide do not seem to have obtained wide application, although several have been described. For these reasons, the method was abandoned after a brief examination of its possibilities.

*B. Lead Salts.*—The behavior of the lead salts of this group of acids was examined with the view to separating iodine as lead iodide, after the reduction of the silver salts. The following table shows the behavior of lead acetate added to a neutral and acid solutions of the anions:

TABLE I.—BEHAVIOR OF LEAD ACETATE WITH VARIOUS SALTS<sup>1</sup> (VOL. 10 Cc.).

	Solution neutral.					Solution acid (1-2 cc. dil. HNO <sub>3</sub> ).				
	1 mg.	3 mg.	5 mg.	7 mg.	10 mg.	1 mg.	3 mg.	5 mg.	7 mg.	10 mg.
KCl.....	+	+	+	+	+	—	—	—	—	—
KBr.....	+	+	+	+	+	—	—	—	—	—
KI.....	+	+	+	+	+	—	—	—	+	+
KCN.....	+	+	+	+	+	—	—	—	—	—
KCNS.....	+	+	+	+	+	—	—	—	—	—

The results given in Table I show that this salt does not offer a satisfactory means of separation, since in neutral solutions a precipitate was obtained in every case, while in an acid solution, 7 mg. of iodide yielded only a slight precipitate and 10 mg. only a fair one. Even if the lead iodide separation had been practicable, the lead would again have to be removed

<sup>1</sup> In this and subsequent tables a plus sign indicates a positive test and a minus sign a negative result.

after proceeding with another step. Such an extra step increases the liability of losing small amounts of the acid, which was considered an added disadvantage in the use of lead.

*C. Mercurous Salts.*—The insoluble halide compounds of univalent mercury were next examined for their usefulness. One milligram of chloride or bromide ion in 10 cc. of a solution acidified with nitric acid gave, as anticipated, a decided precipitate with mercurous nitrate. Corresponding or larger quantities of the iodides, cyanides or thiocyanates gave precipitates from neutral solutions which readily redissolved upon acidification or addition of excess  $\text{HgNO}_3$ . In fact, even the mercurous chloride dissolves in a large excess of mercurous nitrate in an acidified solution. In the hope of separating the constituents of the silver precipitate by treatment with mercurous nitrate,  $\text{AgCl}$ ,  $\text{AgBr}$ ,  $\text{AgI}$ ,  $\text{AgCN}$  and  $\text{AgCNS}$  were digested with  $\text{HgNO}_3$ . The precipitates were found to be reduced, the presence of mercurous chloride and bromide in the precipitate being indicated by the blackening of the residue by ammonia. The remaining three anions were found in the mercurous solution. Part of the chloride and of the bromide were, however, also in solution, the recovery of the cyanide ion was not satisfactory and the method involved subsequent removal of mercury for further steps. This procedure was therefore abandoned in favor of the formate reduction.

*D. Formate Reduction.*—In order to effect a separation of the precipitated silver salts, various reducing agents were investigated. Copper and metallic zinc reduce all of the silver compounds with the exception of the sulfide. Formaldehyde in alkaline solution acts in the same manner. Formates in acid solution give slow and incomplete reduction. It was soon found that with proper control of the alkalinity a satisfactory separation of chlorine could be obtained. The iodide of silver is the most resistant and even with the greatest concentration of alkali, silver iodide is practically unaffected. With solutions containing 15% of sodium hydroxide the reduction of silver chloride to metallic silver is very rapid, 200 mg. of silver chloride being completely reduced by warming a few minutes, whereas the bromide is only very slightly affected. In a solution which contains about 8% of sodium hydroxide and sodium formate, silver chloride was completely reduced in 10 minutes' boiling, while the bromide is unaffected even after much longer treatment. The cyanides and thiocyanates were reduced under the same conditions. Cyanides caused some difficulty by dissolving in the known fashion in the alkali, so that the filtrate from the silver residue contained some silver cyanide in addition to sodium cyanide. This caused some difficulty in the succeeding manipulations, which was later overcome by removing the silver cyanide from the silver chloride, bromide, iodide, and thiocyanate before reduction. This can be very effectively done by treatment with a

solution of a mercuric salt, without dissolving any of the other silver compounds, which behavior furnishes, at the same time, a very satisfactory method of isolating and detecting the cyanide radical. The reaction depends upon the fact that mercuric cyanide is dissociated to an abnormally low extent into cyanide ion, as the well-known anomalous behavior of mercury cyanide indicates. If silver cyanide is digested with mercuric nitrate or sulfate it immediately dissolves, or conversely, in the presence of mercuric salts cyanides do not precipitate silver salts. This behavior is most pronounced with cyanides, the remaining anions of this group precipitating the corresponding salts of silver even in the presence of mercury, provided certain precautions are observed.

In connection with these experiments the ferri- and ferrocyanide of silver were also subjected to reduction by means of formates in the presence of alkalis, with the view to include these two ions in the silver precipitate for further treatment. This would then have avoided the precipitation of these two anions by means of the zinc before adding silver nitrate. The procedure was not however applicable. The two silver salts were reduced, but the alkaline filtrate gave either uncertain, or negative, tests for ferrocyanide or ferricyanide. Here, as with such reducing agents as copper and zinc, the complex cyanide radical suffers disruption yielding, among other things, the cyanide ion. This behavior made it necessary to remove the complex cyanides at the beginning of the separation.

Applying, then, sodium formate as a reducing agent to the mixture of silver salts, after dissolving silver cyanide by means of a mercuric salt, causes reduction of silver chloride and silver thiocyanate, with the formation of metallic silver in the residue, and the corresponding sodium salts in solution. From this solution the thiocyanate can readily be precipitated as cuprous thiocyanate under the proper conditions, and the filtrate from this precipitate tested for chloride by means of silver nitrate.

The residue from the reduction contains metallic silver and any silver bromide, iodide and sulfide originally present.

**Cuprous Salts.**—The original procedure which was developed entailed the separation of chloride, bromide, cyanide and thiocyanate after the silver salts had been converted into the corresponding sodium salts by means of reduction with formate. The precipitation of copper thiocyanate is a well-known quantitative method. It remained to be seen how the chloride and bromide behaved under the conditions of separation. It was found that, in the presence of sulfurous acid, 100 mg. of chloriae or bromine (as potassium salts) are held in solution. Under the same conditions 0.02 mg. of CN or CNS give a decided precipitate.<sup>1</sup>

<sup>1</sup> While working on this method a paper by Curtman and Wickoff, *THIS JOURNAL*, 37, 298 (1915), appeared, treating the determination of bromides in the presence of cyanides, thiocyanates and ferricyanides. The results there were in harmony with

While this gave a satisfactory separation from bromine the question of separation of the cyanide and thiocyanate still remained, and caused considerable difficulty. The cobalt and nickel salts offered some hope for a separation but were rejected after trial. The cyanide may be converted into Prussian blue in one part of the solution and the characteristic ferric thiocyanate reaction obtained in another, but this was not all that could be desired, particularly when both constituents were present in rather large quantities. Fortunately, later work showed that the removal of the cyanide at an earlier stage of the procedure eliminated this difficult separation and this was therefore accepted as a welcome simplification of the process.

As a consequence of these results the best procedure was decided to consist in limiting this separation by means of cuprous salts to the removal of thiocyanates from chlorides. This process can be conveniently and accurately carried out and the other anions are provided for at other stages of the procedure.

#### PROCEDURE.

##### Precipitation of Ferricyanides and Ferrocyanides.

**Procedure I.**—Add one to three cc. of dilute nitric acid to a nearly neutral mixture of acids, and *immediately* enough zinc nitrate to insure complete precipitation of the ferricyanide and ferrocyanide and shake the solution vigorously. Completeness of the precipitation is indicated by a noticeable change in the character of the precipitate, which is colloidal at first but coagulates more readily when excess of precipitant is present. When sufficient ferricyanide is present to color the solution, there is a fairly sharp end point, consisting in the discharge of the yellow color. When not enough zinc nitrate is present the solutions are colloidal; an excess of zinc nitrate to insure complete precipitation of the ferricyanide and ferrocyanide is advantageous. One to two grams of ammonium nitrate hasten coagulation of the colloidal precipitate and should be added if difficulty is experienced in filtering.

Heating the solution should be avoided, since it increases the tendency of the precipitate to become colloidal, and would cause loss of hydrocyanic acid. Ageing always favors the separation of colloidal precipitates, and should the precipitate run through the filter, which for this case should be a fairly close-grained one, it may be set aside for a short period and will then usually be found to have changed sufficiently to permit satisfactory filtration. The *same effect* may be obtained more rapidly by shaking the suspended precipitate energetically in a stoppered flask. Shaking, in effect, simply hastens the ageing of the colloid and is very  
our experience and showed that 2 mg. of bromine could be detected in the presence of as much as 500 mg. of the other constituents by applying the cuprous salt separation previous to the test.

effective in producing a precipitate which does not run through the filter.

When iodides and ferricyanides are both present, iodine will be liberated slowly. This does not interfere with the subsequent detection of iodine. In order, however, to check appreciable reduction of the ferricyanide to ferrocyanide the zinc nitrate should be added immediately, or, preferably, the nitric acid should be added first to the zinc nitrate and the two reagents added to the solution in one operation.

After washing the zinc precipitate on the filter several times with a few cubic centimeters of a dilute ammonium nitrate solution (rejecting all but the first washing), pour 10 cc. of a warm 3% NaOH solution through the filter. This is sufficient for quantities up to 200 mg. of each of the two salts, which dissolve, yielding the alkali ferri- and ferrocyanide and sodium zincate. Add to the resulting solution 5 cc. of a 5% ammonium nitrate solution, a few drops of zinc nitrate solution to provide excess zinc ion, and shake vigorously. The zinc ferrocyanide is precipitated as a gelatinous white precipitate. This precipitate is quite characteristic. It may, if desired, be further characterized by the conversion into the cupric or ferric ferrocyanide. The red cupric ferrocyanide is to be preferred, since it is just as sensitive and cannot be confused with the ferrous ferricyanide as the ferric ferrocyanide may. In either case, the ferrocyanide of zinc is dissolved in a small quantity of NaOH solution, the copper or iron is added and the solution then acidified. This is preferable to acidifying first, particularly when only small quantities are present, since the zinc ferrocyanide, when once formed, is not converted into the copper or iron salt very rapidly.

The ferricyanide is identified by acidifying the filtrate from the zinc ferrocyanide with dilute hydrochloric acid, and adding 1-2 cc. of potassium iodide solution (which should not give free iodine upon acidification), and 0.5-1 cc. of  $\text{CHCl}_3$  or  $\text{CCl}_4$ . The ferricyanide is reduced, giving free iodine in the  $\text{CHCl}_3$  layer.

The voluminous nature of these zinc precipitates adapts them particularly well to quantitative approximations. A series of seven precipitates obtained in the regular course of analysis and varying from 100 to 1 mg. in approximately even steps, were correctly estimated by four out of five observers entirely unused to the method. The same thing is true of the ferricyanide of zinc.

The iodide reaction develops rather slowly with small quantities (0.5 mg.) of ferricyanide but it is recommended in preference to the test with ferrous iron.

A ferric salt gives with a ferrocyanide a blue precipitate of ferric ferrocyanide, but not with ferricyanide. A ferrous salt gives with a ferricyanide a similar blue precipitate of ferric ferrocyanide. It gives with ferrocyanide a white precipitate of ferrous ferrocyanide when no ferric salt is present, but a blue one after exposure to the air. In order to distinguish the ferricyanide from ferrocyanide with a ferrous salt the solution must be fresh, that is, free from ferric salt. The reaction with potassium iodide is to be preferred for the reason that there is no possibility of confusion with ferro-

cyanide due to faulty separation. When applying this test for small quantities, it is necessary to bear in mind that commercial iodides usually contain traces of iodates and will consequently give traces of free iodine on acidification. A reagent which will not liberate iodine upon acidification may very conveniently be made by boiling a neutral, or but faintly acid, solution of potassium iodide with metallic magnesium.

The oxidation of iodides by ferricyanides is slow, and in testing for small quantities, time must be given for the iodine to be liberated. As in the case of ferrocyanide, a fairly accurate quantitative estimation can be made even by one unused to the method when amounts from 100 to 1 mg. are used.

The results obtained during experimentation on the above separation are given in Table II.

$\text{K}_3\text{Fe}(\text{CN})_6$ ....	+	+	+	+	+	+	+	+

### Precipitation of Silver Salts.

**Procedure II.**—The filtrate from the zinc precipitation is treated with silver nitrate until no further precipitate forms. If cyanides are present in appreciable quantities the disappearance of the odor of hydrocyanic acid indicates completeness of precipitation. A slight excess of silver nitrate is added, the precipitate is coagulated by shaking, and the solution is removed by decantation or filtration. The precipitate is washed with distilled water containing a few drops of nitric acid until the washings are practically free from silver. Reject all but the first washings. The solution contains the acids of subsequent groups. The precipitate is examined for  $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ,  $\text{CN}^-$ ,  $\text{CNS}^-$ , and  $\text{S}^-$ .

### Separation of Cyanide.

**Procedure III.**—To the precipitated silver salts contained in a beaker, after having removed excess of water, add 2 cc. of a 2 molar solution of mercuric acetate containing 5% of acetic acid. Digest 15 minutes on the steam bath (the solution may be permitted to evaporate to dryness). Add 2 cc. of a 2 molar sodium acetate solution and dilute to 20 cc. and filter. The filtrate contains the cyanide as a complex mercury compound.  $\text{H}_2\text{S}$  is passed into this until mercury has been completely precipitated and the mercuric sulfide is removed by filtration. The filtrate is made alkaline with a few drops of sodium hydroxide, enough ammonium polysulfide is added to color the solution yellow (2–5 drops are sufficient unless very large quantities of cyanides are present) and it is then digested on the steam bath, preferably until the liquid has evaporated.

Enough dilute sulfuric acid is added to decompose the excess polysulfide. In the filtrate from this, which now contains thiocyanic acid, the blood-red color of ferric thiocyanate is obtained upon addition of ferric salts. (See Table VI.)

All of the halogen salts of silver dissolve in mercuric salts with the formation of highly complex mercuric compounds. Thus, in a solution containing one mol of  $\text{Hg}(\text{NO}_3)_2$  and one mol of  $\text{HNO}_3$ , 7 g. per liter (0.05 mol) of silver chloride, 7 g. (0.04 mol) of silver bromide and 25 g. (0.11 mol) of silver iodide will dissolve.<sup>1</sup>

The compounds formed are, according to the conditions, any one or all of the following:  $\text{HgHgCl}_4$ ,  $\text{HgHgCl}_2(\text{NO}_3)_2$ ,  $\text{AgHgCl}_2(\text{NO}_3)_2$ . As may be noted on comparing the remaining halides, the complex formation increases toward the iodide, *i. e.*, as the acid grows weaker. With the very weak hydrocyanic acid the complex formation is very much greater still, the  $\text{CN}^-$  being used up quantitatively to form either the  $\text{Hg}(\text{CN})_4^{2-}$  or the  $\text{Hg}(\text{CN})_3^-$  ion.<sup>2</sup> If, instead of using mercuric salts of the strong acids, the acetate is used the complex cyanide alone is formed, *i. e.*, only silver cyanide and not the chloride dissolves. (A trace of chloride, and more iodide, dissolves if a slight amount of acetic acid is present, either added or from hydrolysis, but this is completely stopped by the addition of sodium acetate to the solution, so that not even 0.2 mg. of iodine dissolves in 300 times as much mercuric acetate.) In effect, then, mercuric acetate is less complex than mercuric cyanide and more so than the remaining halogen compounds and this makes the separation possible. The addition of the sodium acetate after digestion with the acid solution of mercuric acetate is necessary to precipitate the last traces of the other halides.

For the final characterization of the cyanide, the thiocyanate conversion works well, 0.1 mg. being detected without difficulty. Removal of mercury from the solution by means of more electropositive metals and conversion of the cyanide into ferrocyanide gave erratic results under the conditions prevailing and is not to be recommended here.

### Separation of Chloride and Thiocyanate.

**Procedure IV.**—To the washed silver salts, from which the cyanide has been removed (excess water should be decanted), add 10–15 cc. of an 8% sodium hydroxide solution and 1 g. of sodium formate and boil a short time in a covered receptacle (5 to 10 minutes). Dilute to 20 cc., decant or filter and test the filtrate for chlorine and thiocyanate as follows: very nearly neutralize the solution with dilute sulfuric acid, completing the neutralization with sulfurous acid. To the acid solution, which should smell decidedly of  $\text{SO}_2$ , add copper sulfate solution drop by drop until no more copper thiocyanate is precipitated. Filter, dissolve the precipitate in hydrochloric acid and add a ferric salt to obtain the red ferric thiocyanate. To the filtrate from the cuprous thiocyanate add dilute nitric acid equivalent in quantity to the sulfurous acid previously added, heat until the  $\text{SO}_2$  is driven off and add silver nitrate until no more silver chloride forms. (See Table VI.)

The precipitation of thiocyanates by copper in a reducing solution is very nearly complete, only  $5 \times 10^{-4}$  g. dissolving in a liter. If desired, a separate portion of the solu-

<sup>1</sup> Morse, *Z. physik. Chem.*, **41**, 707 (1902).

<sup>2</sup> Sherfill, *Ibid.*, **43**, 705 (1903); **47**, 103 (1904).

tion may be tested for thiocyanate directly with a ferric salt. If found present it must first be removed before testing for chloride.

Formic acid reduces silver chloride to metallic silver much more readily than it does the bromide or the iodide. The speed of reduction varies considerably with the concentration of the sodium hydroxide. For this reason the solution should not be allowed to concentrate to an appreciable extent while heating. For the reduction it is advisable to prepare a reducing solution containing 8 g. NaOH and 10 g. of  $\text{H.COONa}$  (chlorine free) per 100 cc. and to use 20 cc. of this solution. With the concentrations given, silver chloride is completely reduced in 10 minutes' vigorous boiling, while silver bromide is not affected. With a 15% sodium hydroxide solution and as much as a half hour's boiling silver bromide is partially reduced (a few per cent of 200 mg. for instance) while silver iodide is not appreciably reduced even in 33% NaOH on long extended boiling. The silver thiocyanate behaves toward the reduction as the chloride does, forming sodium thiocyanate, which dissolves, and metallic silver.

### Separation of Bromide and Iodide.

**Procedure V.**—The precipitate which remains contains silver bromide, iodide (and sulfide) and in addition the metallic silver resulting from the previous reduction. It is covered with a few cubic centimeters of concentrated ammonia and metallic copper in powder form (molecular copper) is added. The reduction of the bromide and iodide is instantaneous, the corresponding cuprous salts going into solution. If a precipitate of basic copper salts is formed more  $\text{NH}_4\text{OH}$  must be added. Silver sulfide remains behind. The filtrate is neutralized with sulfurous acid and an excess of dilute sulfuric acid is added. If iodine is present white copper iodide is precipitated. This is collected on the filter (shake precipitate to coagulate) and the iodine, after dissolving the cuprous iodide in hydrochloric acid, is liberated by chlorine water (or  $\text{HNO}_2$ ,  $\text{H}_2\text{O}_2$  or  $\text{FeCl}_3$ ) and dissolved in carbon tetrachloride giving a violet color.

To the filtrate from the copper iodide, which contains the bromide, nitric acid is added and the solution is warmed until most of the  $\text{SO}_2$  has been driven off. Addition of silver nitrate then causes formation of yellowish silver bromide. (See Table VI.)

The precipitation of copper as cuprous iodide is a well-known quantitative method, the solubility of  $\text{Cu}_2\text{I}_2$  in water being only  $3 \times 10^{-4}$  g. per liter. Under the same conditions 100 mg. of bromine are not precipitated. The characterization of the precipitate is hardly necessary unless it is feared that the thiocyanate was not completely removed in the previous step, or unless unusually large quantities of bromide were taken.

### Detection of Sulfide.

**Procedure VI.**—The silver residue from the reduction contains the sulfide. It is completely dissolved in nitric acid. The silver sulfide dissolves with formation of sulfuric acid, which, after dilution to 100 cc. is precipitated as white barium sulfate upon addition of barium nitrate.

# Numerical Data.

TABLE IV.

Rate and completeness of reduction with copper powder.

200 mg. (8 millimols) Cl<sup>-</sup>, Br<sup>-</sup>, I<sup>-</sup>, CN<sup>-</sup>, CNS<sup>-</sup> as the silver salts, freshly precipitated and washed. Various ions were taken separately.

Set. 1. Copper, about equal in volume to the silver precipitate and distilled water. The silver salts are reduced rapidly to metallic silver.

Set. 2. Same as 1, and 1 cc. of conc. ammonia added. The reduction is very rapid (less than 10 minutes). The residues of silver and copper after washing dissolved without a trace of residue in dilute nitric acid. If air is excluded during the operation the ammonia solution contains the cuprous compounds.

Set. 3. Same as 1 but carried out in presence of dilute sulfuric acid. Reduction takes place much more slowly and is not complete, even on long standing.

Set 4. Similar trials with Pb as reducing agent gave unsatisfactory results.

TABLE V.

## Mercuric salt separation of cyanides.

Solubility of silver salts.—To 5 cc. of 0.5 M HgNO<sub>3</sub> about 1 cc. of 1.5 M AgNO<sub>3</sub> was added. In order to obtain a precipitate, 2.5 mg. Cl<sup>-</sup>, 0.8 mg. Br<sup>-</sup>, 4 mg. I<sup>-</sup>, no pptd. CN<sup>-</sup>, 1 mg. CNS<sup>-</sup> were added before a precipitate formed. Addition of sodium acetate caused immediate precipitation of the dissolved silver salt, except in the case of AgCN.

Similar behavior was noted with HgSO<sub>4</sub> + H<sub>2</sub>SO<sub>4</sub> solution.

To 20 cc. of 0.2 M mercuric acetate a few drops of acetic acid and silver nitrate was added. In order to obtain a precipitate the following amounts of halogen were necessary: 0.4 mg. Cl<sup>-</sup>; 0.5 mg. Br<sup>-</sup>; 0.6 mg. I<sup>-</sup>; no ppt. w. CN<sup>-</sup>; 0.2 mg. CNS<sup>-</sup>. To the same solution 2 cc. 2 M sodium acetate were added. Precipitates were obtained with 0.04 mg. Cl<sup>-</sup>; 0.04 mg. Br; 0.02 mg. I<sup>-</sup>; no ppt. w. CN<sup>-</sup>; 0.01 mg. CNS<sup>-</sup>. The precipitates obtained under the last conditions were practically as strong as the blanks obtained without HgC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> in distilled water.

TABLE VI.

Sets of solutions constituted as shown in Table VII were prepared and analyzed by H., J., and W., the contents being unknown to the analyst at the time. Since the results were uniformly correct they are not reproduced in detail. In Solution B chlorine was found in small amounts in every instance. This error is only an apparent one however, since the other salts present, while of high grade commercial quality were not chlorine-free. Thus no sample of cyanide was found during the course of the work which did not contain chlorine. In solution C, which contained 80 mg. I, one analyst reported a trace of bromine. In Solution H, ferrocyanide was twice reported although not added. Reduction of the ferricyanide by the hydriodic acid present, or a content of ferrocyanide in the ferricyanide, accounts for this. Otherwise the results obtained were correct.

### Summary.

A procedure is described in which any mixture of the ions Cl<sup>-</sup>, Br<sup>-</sup>, I<sup>-</sup>, CN<sup>-</sup>, CNS<sup>-</sup>, FeCy<sub>6</sub><sup>≡</sup>, FeCy<sub>6</sub><sup>≡</sup> may be systematically separated with quantitative approximation.

Data in support of the proposed methods are furnished. The separations given are adequate when the respective ions form 0.01 to 0.0001 of the total, varying somewhat with the ion in question.

The procedure may be represented schematically by Table VIII, in which the compounds listed are empirical designations and an underscored substance indicates a precipitate. The numbers indicate the corresponding procedure:

<sup>1</sup> For convenience in these tables, ferrocyanide is designated by Focy and ferricyanide by Ficy.

### LEAD ARSENATES.

#### A STUDY OF THE FACTORS CONTROLLING THE REACTIONS OF LEAD NITRATE AND LEAD ACETATE WITH DISODIUM ARSENATE.

By G. ENNIS SMITH.

Received June 30, 1916.

Since Moulton<sup>1</sup> in 1893 first demonstrated the economic value of lead arsenate, numerous publications have appeared discussing the different compounds of lead and arsenic acid. These have dealt chiefly with the methods of preparation, the composition, some of the physical properties, and their efficiency as insecticides. While it has been generally stated that the composition varies with the source, mode of preparation, concentration, temperature, and every other conceivable condition that may vary in the production, yet there has been no attempt to define how these factors cause the variation; in fact, there has been a general evasion of even stating the direction and the extent to which the composition is influenced by the different factors.

The object of this paper will be to attempt to define the conditions in the production of lead arsenate that regulate the composition, and when the conditions are varied to demonstrate the influence that the variation will exert on the reaction, and on the composition of the resulting products.

It is not considered necessary to give a historical review of literature on lead arsenates as that has been given in a recent volume<sup>2</sup> of *THIS JOURNAL*. In general the various investigators have contended that the reaction of lead nitrate and disodium arsenate can be represented in the main by the equation

though the composition of the resulting lead arsenate would indicate that there was slight deviation and that the reaction of lead acetate with disodium arsenate can be represented closely by the equation

While working on another problem with commercial lead arsenates, some experiences suggested that the reactions given by the various investigators were not correct and that there might be a movable equilibrium in the products of the reactions, and thus a study of this problem was undertaken. Before reliable results could be obtained, however, it was necessary to prepare pure samples, at least of the lead and sodium compounds which may be components of the systems to be examined.

<sup>1</sup> Mass. Board, *Agr. Report*, 41, 282 (1893).

<sup>2</sup> Tartar and Robinson, *THIS JOURNAL*, 36, 1843 (1914).

### Experimental.

**Preparation of the Lead Compounds.**—Tartar and Robinson<sup>1</sup> claimed that they had prepared pure diplumbic arsenate, and a basic lead arsenate of a constant composition by the reaction of diplumbic arsenate with ammonium hydroxide. They stated that triplumbic arsenate is not formed under the ordinary aqueous conditions employed in the manufacture of commercial lead arsenate and that the precipitates obtained from the reactions of lead acetate and lead nitrate with disodium arsenate are mixtures of diplumbic arsenate and the basic lead arsenate.

When the results of Tartar and Robinson were examined it was observed that there was a great discrepancy. They claim that the composition of the basic lead arsenate, produced by the reaction of diplumbic arsenate with ammonium hydroxide, may be represented closely by the formula  $21\text{Pb}_3(\text{AsO}_4)_2 \cdot 2\text{Pb}(\text{OH})_2 \cdot 10\text{H}_2\text{O}$ . There are 65 Pb atoms and 42 As atoms in this formula and as the number of Pb and As atoms is identical in diplumbic arsenate, then it must be concluded that an amount corresponding to 23 atoms As or 35.38% of the arsenic of diplumbic arsenate has gone into solution. In outlining a method for a quantitative determination of diplumbic arsenate by the same reaction of diplumbic arsenate with ammonium hydroxide, they state that "the amount of soluble arsenic calculated as  $\text{As}_2\text{O}_5$  and then multiplied by the factor 7.6034, gives the amount of lead hydrogen arsenate," which would indicate that 39.71% of the arsenic of the diplumbic arsenate has gone into solution. On account of this discrepancy the reaction of diplumbic arsenate with ammonium hydroxide was studied.

The diplumbic arsenate was prepared from solutions of lead nitrate and disodium arsenate of equimolar proportions (concentration 0.01 *M*); when the precipitate had formed one-half the molecular proportion of nitric acid was added. After standing eighteen hours the supernatant liquid was decanted and the precipitate was then washed by decantation, first with water acidulated with nitric acid, then with distilled water, and dried at 110°. This is a modification of the method suggested by Tartar and Robinson. (The reason for the modification will be discussed later on.) By this method two samples were prepared which, on analysis, showed an arsenic content of 33.08% and 33.1% of  $\text{As}_2\text{O}_5$ , respectively, which would indicate that there had been a fairly complete isolation of diplumbic arsenate. When prepared in this manner diplumbic arsenate takes the form of comparatively large, transparent, crystalline plates, showing a general rhombohedral direction when seen through the microscope.

Weighed samples of the diplumbic arsenate were digested with a 5% solution of ammonium hydroxide on a steam bath for three hours. They

<sup>1</sup> *Loc. cit.*

were then filtered, washed, and dried at  $110^{\circ}$ . The amount of soluble arsenic in the filtrate, the loss in weight of the samples, and the lead and arsenic content of the dried insoluble residue were determined. It was noted that the soluble arsenic approached 40% of the arsenic of the diplumbic arsenate, therefore, in the products of the reaction the ratio of the soluble arsenic to the insoluble arsenic approaches two to three. Thus it may be that the reaction can be represented by the following equation:

TABLE I.

Analyses of the Products of the Reaction of Diplumbic Arsenate with Ammonium Hydroxide.

	Soluble arsenic in filtrate. Per cent.	Loss of wt. of the lead compound. Per cent.	Insoluble residue.	
			Lead as PbO. Per cent.	Arsenic as $\text{As}_2\text{O}_5$ . Per cent.
Sample No. 1.....	39.9	15.22	74.98	23.43
Sample No. 2.....	39.94	15.28	75.05	23.46
Theoretical for $\text{Pb}_5\text{OH}(\text{AsO}_4)_3$ .....	40.00	15.32	75.924	23.463
As found by Tartar and Robinson.....	39.71 <sup>1</sup>	.....	74.72 <sup>2</sup>	23.43 <sup>2</sup>
Theoretical for $21\text{Pb}_3(\text{AsO}_4)_2 \cdot 2\text{Pb}(\text{OH})_2 \cdot 10\text{H}_2\text{O}$ .....	35.38	.....	74.2	24.694
Theoretical composition of $\text{PbHAsO}_4$ .....	.....	.....	64.292	33.113

These results would indicate that the reaction can be represented by the above equation and that the formula  $\text{Pb}_5\text{OH}(\text{AsO}_4)_3$  more closely represents the insoluble product of the reaction of diplumbic arsenate with ammonium hydroxide, than the formula suggested by Tartar and Robinson.

The results of the lead determination do not correspond very closely with the theoretical, but it is generally accepted that the method of the Association of Official Agricultural Chemists for the determination of lead gives low results. For this reason, in this paper, more emphasis will be laid on the arsenic determination, and the results of the lead determination will be given only where it is considered to be essential. It might be inferred from the lead determination that it was a hydrated compound. Instead of carrying out a lengthy investigation of the lead determination, it was decided to determine the loss of weight of the lead compound during the reaction, to find out if it corresponds to the theoretical decrease in weight when diplumbic arsenates is converted into the compound,  $\text{Pb}_5\text{OH}(\text{AsO}_4)_3$ . The results of that determination show that it is not a hydrated compound, which is substantiated by the results of the arsenic determination. The formula may be written  $3\text{Pb}_3(\text{AsO}_4)_2 \cdot \text{Pb}(\text{OH})_2$ , which would indicate that it is a tritri-plumbic lead hydroxyarsenate but the formula  $\text{Pb}_5\text{OH}(\text{AsO}_4)_3$  is preferred and the compound will be referred to in this paper as the lead hydroxyarsenate. The com-

<sup>1</sup> Calculated from the factor 7.6034.

<sup>2</sup> The average of four samples.

pound occurs as a fine amorphous powder and does not show any definite structure when seen under the microscope.

**Preparation of the Sodium Compounds.**—Disodium arsenate occurs as two well-defined salts, which are generally represented, respectively, by the formulas  $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O}$  and  $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$ . The compound  $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O}$  crystallizes out of solution of disodium arsenate at low temperatures and is efflorescent. The compound  $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$  crystallizes out of solution of disodium arsenate at temperatures above  $18^\circ$  and is not efflorescent.<sup>1</sup>

Samples of both these salts were prepared. Disodium arsenate is prepared commercially in the presence of an excess of sodium carbonate, and the salt, as it is put onto the market, is generally alkaline.

The crystals of  $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O}$  were prepared by saturating a solution at  $0^\circ$  with the fairly pure disodium arsenate and then adding a small amount of arsenic acid until the solution was neutral to phenolphthalein. During the crystallization the solution was kept at a low temperature. The crystals obtained in this manner were further purified by recrystallization three or four times, the precaution being taken not to use heat to dissolve the crystals. The crystals obtained in this manner were efflorescent and were only slightly alkaline with phenolphthalein.

The crystals of  $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$  were prepared by taking part of the solution that had been neutralized for the production of the crystals  $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O}$ , heating the solution to boiling and allowing the salt to crystallize from the warm solution and then recrystallize from warm solutions. The crystals obtained in this manner were not efflorescent and were decidedly alkaline with phenolphthalein.

Sodium nitrate, sodium acetate and sodium baborate were prepared by recrystallization of the so-called pure commercial salts.

**The Reaction of Diplumbic Arsenate with Sodium Baborate.**—The reaction of diplumbic arsenate with sodium baborate was examined, using the sample of diplumbic arsenate that had been isolated from all other compounds. The lead arsenate and the solution of sodium baborate were shaken intermittently for two days and then filtered. The soluble arsenic in the filtrate and the loss of weight of the lead compound were determined.

5 g. Sodium baborate.....					

<sup>1</sup> Fresenius, *J. prakt. Chem.*, 56, 30.

When sodium silicate and the sodium compounds of the higher fatty acids were used very similar results were obtained. With the latter compounds, when the diplumbic arsenate was added in excess the fatty acids were precipitated.

When diplumbic arsenate is converted into lead hydroxyarsenate, pyroarsenic acid ( $\text{H}_4\text{As}_2\text{O}_7$ ) is eliminated from the lead compounds, which corresponds to 40% of the arsenic of the diplumbic arsenate and can be represented by the following:

If diplumbic arsenate should be converted into triplumbic arsenate, orthoarsenic acid ( $\text{H}_3\text{AsO}_4$ ) is eliminated from the lead compounds, which corresponds to 33.33% of the arsenic of the diplumbic arsenate and can be represented thus:

The above results then show:

(1) That the diplumbic arsenate has been converted into lead hydroxyarsenate.

(2) That when diplumbic arsenate is converted into lead hydroxyarsenate, 40% of the arsenic of diplumbic arsenate has changed to a soluble arsenic compound as has been previously demonstrated.

(3) That a free acid has been formed.

It will be demonstrated later that the ratio of the soluble arsenic to the free acid approaches one  $\text{HAsO}_4$  to two H.

Thus it can be inferred that the reactions of diplumbic arsenate with the sodium salts of weak acids can be represented by the following:

In each of the three reactions given above, the free acid is to a great extent thrown out of solution or has a very low degree of dissociation, therefore the reactions tend towards completion in that direction. Naturally the next step would be to study the reactions of diplumbic arsenate with sodium nitrate and sodium acetate, which are by products in the manufacture of lead arsenate. Then the reactions to be studied can be represented by the following:

The results of Tartar and Robinson indicate that lead arsenate prepared from aqueous solutions is a mixture of diplumbic arsenate and lead hydroxyarsenate, which is corroborated by the results obtained in the examination of the reaction of diplumbic arsenate with sodium biphosphate, and by other results which will be brought forward later; therefore, if a definite point of equilibrium could be established in the above systems, the products of the reactions of lead nitrate and lead acetate with disodium arsenate could accurately be defined as when disodium arsenate is added in excess, the products of the reactions are identical with the components of the systems which are to be studied.

**Reaction of Lead Nitrate with Disodium Arsenate. Point of Equilibrium.**—The mixtures were placed in bottles which were then attached to a shaker and intermittently shaken for the period stated in the tables. After the shaking the mixtures were filtered and the soluble arsenic and acidity in aliquot parts of the filtrate were determined.

To ascertain if the composition of the lead arsenate, produced by the reaction of lead nitrate with disodium arsenate agreed with that calculated from the concentrations of the system when they had come to an equilibrium, unless otherwise stated, the solutions of lead nitrate and disodium arsenate were placed in a container and attached to a shaker and were shaken until the composition became constant.

TABLE III.

Temperature.	Initial concentrations.		Concentrations at equilibrium.		
	PbHAsO <sub>4</sub> . Mol.	NaNO <sub>3</sub> . Mol.	Period. Days.	HNO <sub>3</sub> . Mol.	Na <sub>2</sub> HAsO <sub>4</sub> . Mol.
10–16°.....	0.01	0.008	5	0.00004	0.0000175
	0.1	0.08	5	0.00004	0.0000175
	Pb <sub>2</sub> OH(AsO <sub>4</sub> ) <sub>2</sub> . Mol.	Na <sub>2</sub> HAsO <sub>4</sub> . Mol.	HNO <sub>3</sub> . Mol.		
10–16°.....	0.002	0.004	0.008	60	0.00005
	0.02	0.04	0.08	60	0.00005

It was noted that the amounts of the concentration of HAsO<sub>4</sub> to the concentration of H<sup>+</sup> were approximately in the proportion of 1 to 2. With varying conditions there was a wide variation from this ratio, the variation being constant under similar conditions. As a study of the equation shows that the amount of soluble arsenic accurately defines the progress of the reaction, and as it can be more accurately determined than the acidity, the results of the soluble arsenic determination were adopted to designate the point of equilibrium when it was approached from PbHAsO<sub>4</sub> and NaNO<sub>3</sub>. The possibility of error being introduced into the system with these samples was also practically *nil*.

When the equilibrium was approached from Pb<sub>2</sub>OH(AsO<sub>4</sub>)<sub>2</sub>, Na<sub>2</sub>HAsO<sub>4</sub> and HNO<sub>3</sub>, as the large amount of soluble arsenic introduced into the system was reduced to a low concentration, the experimental error in its

determination was greatly multiplied. And as the acidity gave constant results, then, when the concentration of the acid approached within experimental error of the concentration of the acid, when the equilibrium was approached from  $\text{PbHAsO}_4$  and  $\text{NaNO}_3$ , it was assumed that the systems had come to an equilibrium.

When the equilibrium was approached from  $\text{PbHAsO}_4$  and  $\text{NaNO}_3$ , constant results could readily be obtained and the system came to an equilibrium in a relatively short period; but when it was approached from  $\text{Pb}_5\text{OH}(\text{AsO}_4)_3$ ,  $\text{Na}_2\text{HAsO}_4$  and  $\text{HNO}_3$ , the rate of reaction was extremely slow. This was probably due to the physical condition of the lead hydroxyarsenate. That this is a factor will be apparent when the "Progress of the Reaction" is discussed. It was very difficult to obtain corroborative results and it was only after each component was thoroughly examined that constant results could be obtained.

The above results show that the following equation represents the concentrations of the components of the system when it has arrived at an equilibrium at stated concentration and temperature:

**The Effect of the Concentration of the Disodium Arsenate on the Equilibrium.**—The influence of increasing the concentration of disodium arsenate would be to move the equilibrium in the direction

and, therefore, there would be a tendency to produce more diplumbic arsenate. If the disodium arsenate does function in this manner then the effect is masked by other influences.

If, in the presence of an excess of disodium arsenate in the system, lead nitrate is added, if the excess is only slight, the lead compounds of the arsenic acids are distributed in practically the same ratio as the other lead compounds of the system; from this it might be inferred that the sodium compounds were in an equilibrium which can be represented thus:

in which case, under certain conditions, the effect of the concentration of the disodium arsenate would be an effect of a much lower order than its mass action.

The compounds,  $\text{Na}_3\text{AsO}_4$ ,  $\text{Na}_2\text{HAsO}_4$  and  $\text{NaH}_2\text{AsO}_4$ , are all alkaline to congo red and methyl orange and these indicators can be used to indicate the completion of the following reaction at low temperatures:

If solutions of disodium arsenate are made strongly acid, using either

of these two indicators, and are then heated, they become decidedly alkaline, and when cooled, become acid again.

It is not intended in this paper to make a detailed examination of the movable equilibrium of the sodium compounds, but this phenomenon has been mentioned because it can be readily seen that it will give an insight into the influence of disodium arsenate upon the equilibrium and upon the products of the reaction of lead nitrate and disodium arsenate.

While it was found that a slight excess of neutral disodium arsenate did not affect the equilibrium, yet a slight excess of solutions of the compound  $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$  always moved the equilibrium in the direction

The system must produce more acid to neutralize the alkalinity of the disodium arsenate before it can proceed to an equilibrium; therefore, more lead hydroxyarsenate would be produced.

TABLE IV.

Composition of Lead Arsenates.

	$\text{As}_2\text{O}_5$
Prepared from 0.1 mol $\text{Pb}(\text{NO}_3)_2$ and 0.1 mol $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$ ...	33.08
Prepared from 0.1 mol $\text{Pb}(\text{NO}_3)_2$ and 0.2 mol $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$ ...	32.00

These results disproved the contention of Holland and Reed<sup>1</sup> that the influence of an excess of the alkaline disodium arsenate ( $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$ ) would be to produce a compound approaching nearer to the theoretical composition of diplumbic arsenate.

It is worthy of note that while the alkalinity of the excess of disodium arsenate exerts such an influence on the equilibrium and on the composition of lead arsenate, yet the effect of the alkalinity is not apparent when the arsenate is completely precipitated. This may be due to the alkalinity being neutralized by the acidity of the lead nitrate solution or to the distribution of the arsenic acids before and after precipitation.

**The Effect of the Concentration of the Lead Nitrate on the Reaction.**—The methods by which the point of equilibrium was established cannot be used when there is an excess of lead nitrate, as the soluble arsenic is eliminated and general acidimetric methods are not applicable in the presence of the lead compound. From the arsenic content of the resulting lead arsenates the point of equilibrium could be established, but that would not be very satisfactory, as it is possible that the limit of error in the determination of the arsenic content might be greater than the influence of the lead nitrate.

A probable indication of the influence of the lead nitrate upon the reaction might be obtained from a study of the solution of the compound. When lead nitrate is dissolved in dilute solutions there is a turbidity and the solution becomes acid; this is due to hydrolysis, which may be represented in part by the following:

<sup>1</sup> Mass. Agr. Exp. Sta., 24th Ann. Report, p. 201.

As none of the general titration methods can be used to determine the acidity of the lead nitrate solution, a rather crude colorimetric method was employed to obtain a rough approximation of the acidity of the solution. Strips of litmus paper were dipped, for a short interval, simultaneously into lead nitrate solutions and acid solutions of known strength. The acidity of the solution being fairly great, an excess would tend to produce more diplumbic arsenate but a measure of the acidity is also a measure of the amount of the hydroxy compound. The tendency of this hydroxy compound would be to produce more lead hydroxyarsenate, thus an excess of lead nitrate solution exerts two influences which are directly opposed to each other. Each may offset the effect of the other, in which case an excess of lead nitrate would not affect the composition of the precipitate.

As the solubilities of diplumbic arsenate and lead hydroxyarsenate are only very slight, as long as these compounds are in contact with the solution, their active masses can be considered constant. Therefore, an in-

<sup>1</sup> The altitude of the Chemistry laboratory of the Montana Experiment Station is 4910 feet above sea level.

crease in the amounts of the lead arsenates in the system would not affect the equilibrium.

An increase in the concentration of the sodium nitrate would be expected to move the equilibrium in the direction

At low temperatures, although the concentration of the sodium nitrate was increased ten and one hundred fold, there was the same amount of soluble arsenic produced. It is probable that the influence of a variation in the concentration of the sodium nitrate at low temperatures is so slight that it cannot be detected by the methods used. The results show that as the temperature rises the influence of a variation in the concentration of the sodium nitrate becomes apparent.

In the production of lead arsenate, when the reaction has come to an equilibrium, as the concentration increases, the relative amount of lead hydroxyarsenate will decrease. Therefore, as the concentration increases the composition of the resulting lead arsenate will approach nearer to the theoretical composition of diplumbic arsenate. This is not in accord with the deductions of other investigators. The error in their conception was due to the fact that the products of the reaction were not allowed to come to an equilibrium, and that the progress of the reaction in dilute solutions, within certain limits, is faster than in the more concentrated.

As the temperature rises the equilibrium moves in the direction

and more lead hydroxyarsenate is formed; therefore, as the temperature rises the composition of the resulting lead arsenate will recede from the theoretical composition of diplumbic arsenate. There are probably two factors that cause the movement of the equilibrium Pt: the depression of the dissociation of the acid and the tendency of the sodium compounds of the system to become more alkaline as the temperature rises.

**The Effect of Washing Away the Soluble Products.**—In Table VI the calculated compositions of the precipitates at different concentrations are given, which represent the compositions of the precipitates as they exist before they have been isolated from the soluble products of the reactions. The results have shown that when the concentration of the sodium nitrate is decreased the systems attain to the same concentrations of soluble arsenic and acid. After each removal and addition of the washing fluid the concentrations of soluble arsenic and acid have been greatly reduced. Therefore, as the concentration of sodium nitrate still remains relatively great, the system will tend to produce more soluble arsenic and acid and the reaction will proceed in the direction

and more lead hydroxyarsenate will be formed which will be proportional to the rate at which the concentration of the sodium nitrate is reduced

by the removal of the washing fluid. While the increased amount of lead hydroxyarsenate produced is comparatively small, yet it is sufficient to materially alter the composition of the precipitate. It would probably be an economic advantage to use a slightly acidulated water as the washing fluid in the commercial production of lead arsenate. There is a loss of disodium arsenate by each addition of the washing fluid when distilled water is used. This loss is greatly multiplied on account of the general alkalinity of the average water supply. If sufficient nitric acid were added to neutralize the alkalinity of the water and leave a slightly acid solution, the loss of soluble arsenic would be reduced to a minimum.

**Progress of the Reaction.**—Various investigators claim that the reaction between lead nitrate and disodium arsenate takes place as represented by the equation

and some have added that a same amount of the tribasic arsenate is formed due to a secondary reaction. While this equation, to a certain extent, represents the initial and final stages, it does not represent the reaction as it actually takes place.

It has been pointed out that diplumbic arsenate occurs in comparatively large crystalline plates and that lead hydroxyarsenate is a very fine amorphous precipitate. When solutions of lead nitrate and disodium arsenate are mixed, the precipitate as it first appears is extremely fine and then quickly changes to a relatively large flocculent crystalline precipitate. The transformation is too rapid to be a physical change due to the growth of the crystal by solution, as the diplumbic arsenate is only very slightly soluble. While the precipitate clings together, a microscopic examination shows that the change is not due to the coagulating power of sodium nitrate. It is contended that there has been a reaction between the precipitate and the solution and that the compound which is precipitated is lead hydroxyarsenate which reacts with disodium arsenate and the nitric acid of the solution, the reaction proceeding to an equilibrium, as in the system that has been studied.

The course of the reaction between lead nitrate and disodium arsenate can probably be represented by the following:

Attempts were made to regulate the progress of the reaction. If the influence of the action of the solution upon the precipitate could be retarded then it might be possible to isolate the precipitate in an initial stage of the reaction. When the precipitates were produced at infinite dilutions (under 0.001) and the solution decanted as soon as the pre-

precipitate had settled, then washed and dried, it was found that the precipitates were composed practically of pure lead hydroxyarsenate.

TABLE VII.

Composition of Precipitate from Lead Nitrate and Disodium Arsenate at Infinite Dilution.

	Lead as PbO.	Arsenic as $\text{As}_2\text{O}_5$ .
Sample 1.....	74.6	23.52
Sample 2.....	74.2	23.94

Although the progress of the reaction is rapid in the concentrated solutions, it was found that in infinitely dilute solutions the progress was extremely slow. This is probably due to the condition of the lead hydroxyarsenate, which might account for the slow rate of reaction when the equilibrium was approached from  $\text{PbOH}(\text{AsO}_4)_3 \cdot 2\text{Na}_2\text{HAsO}_4$  and  $4\text{HNO}_3$ .

When the attempt was made to isolate diplumbic arsenate it was thought advisable to avoid the production of lead hydroxyarsenate in such a condition that it would not be readily acted upon by the solution. As it seemed probable that this might occur if it was endeavored to prepare diplumbic arsenate by re-precipitating with ammonium hydroxide, lead arsenate that had been dissolved with nitric acid, as suggested by Tartar and Robinson, the previously mentioned modification was adopted.

**The Reaction of Lead Acetate with Disodium Arsenate.**—The same methods as were used in the examination of the reaction of lead nitrate with disodium arsenate were employed to examine the reaction of lead acetate with disodium arsenate.

	Lead as PbO.	Arsenic as $\text{As}_2\text{O}_3$ .
Sample No. 1.....	74.9	23.26
Sample No. 2.....	74.3	23.9

These results show that the progress of the reaction of lead acetate with disodium arsenate is similar to the progress of the reaction of lead nitrate with disodium arsenate and can be represented by the following:

The results also show that, when the reaction of lead acetate with disodium arsenate has come to an equilibrium, the resulting lead arsenate is composed principally of diplumbic arsenate. As the reaction of lead acetate with disodium arsenate has been employed so extensively for the commercial production of lead arsenate and has also been studied by numerous investigators, it appears to be remarkable that the fact has been so completely overlooked that there was a reaction between the precipitate as it was formed and the solution. Haywood and McConnell<sup>1</sup> appear to be the only investigators that have found it was possible to produce a lead arsenate by the reaction of lead acetate with disodium arsenate that was composed principally of diplumbic arsenate, though they make no mention of how their results were obtained.

There has been no attempt in this paper to derive the equilibrium constants. Before these can be obtained with any degree of accuracy it will probably be necessary to make a more thorough examination of the influence of the sodium compounds on the equilibrium and also to attain the point of equilibrium of the systems within a narrower range of temperature than has been attempted in this investigation.

### Conclusions.

In the reactions of lead nitrate and lead acetate with disodium arsenate:

The lead arsenates produced are mixtures of diplumbic arsenate,  $\text{PbHAsO}_4$ , and lead hydroxyarsenate,  $\text{Pb}_5\text{OH}(\text{AsO}_4)_3$ .

The products of the reactions at low temperatures, when the reactions have come to an equilibrium, whether lead acetate or lead nitrate is used, consist principally of diplumbic arsenate.

The products of the reactions at infinite dilutions (less than 0.001 mol) whether lead acetate or lead nitrate is used, consist principally

<sup>1</sup> U. S. Dept. Agr., Bur. Chem., *Bull.* 131.

of lead hydroxyarsenate if the precipitates are filtered immediately after the precipitation.

The precipitate that is first formed is lead hydroxyarsenate; diplumbic arsenate is produced by a secondary reaction.

As the excess of the alkaline disodium arsenate increases greater amounts of lead hydroxyarsenate are produced.

As the concentration increases, when the reactions have come to an equilibrium, the relative amount of diplumbic arsenate increases.

As the temperature rises more lead hydroxyarsenate is formed.

From the determination of the point of equilibrium in the systems

the composition of the resulting lead arsenate of the respective reactions can be calculated.

## THE ARSENATES OF LEAD.

[FIRST PAPER.]

By C. C. McDONNELL AND C. M. SMITH.

Received July 22, 1916.

Arsenate of lead, until comparatively recent years, was of no commercial importance; however, since it was first recommended as an insecticide,<sup>1</sup> it has come into very extensive use, and several thousand tons are used annually for the destruction of certain leaf-eating insects. Fourteen U. S. patents<sup>2</sup> relating to commercial processes for its production have been issued. Despite its large and increasing use and importance, the chemical and physical properties of the several arsenates of lead have not been very thoroughly investigated. Most of the recent work has been directed toward determining what products result from the reaction between lead nitrate or lead acetate, and disodium hydrogen arsenate,  $\text{Na}_2\text{HAsO}_4$ , which compounds have been widely recommended for its preparation for spraying purposes.

The references in the literature concerning the preparation and properties of the arsenates of lead are based mostly upon the work of the earlier chemists, Berzelius, Mitscherlich, Wittstein, Graham, H. Rose, and Salkowski, whose conclusions are somewhat contradictory, and

<sup>1</sup> Report Mass. Board of Agr., 1893, p. 282.

<sup>2</sup> Nos. 870,915, 892,603, 903,389, 929,952, 1,014,742, 1,056,340, 1,064,023, 1,064,639, 1,100,673, 1,100,686, 1,141,920, 1,169,114, 1,172,741, 1,175,565.

frequently misquoted by more recent writers. The latter condition has been due in part no doubt to changes in nomenclature.

The older investigators recognized "neutral" lead arsenate (which term was applied indiscriminately to both dilead orthoarsenate and lead pyroarsenate) and "basic" or "sub" arsenate (later designated trilead arsenate). The naturally occurring mineral now known as mimetite was for many years regarded as "sub" arsenate of lead until the researches of V. Rose<sup>1</sup> and Wöhler<sup>2</sup> showed it to be lead chloroarsenate of the formula  $\text{Pb}_4(\text{PbCl})(\text{AsO}_4)_3$ .

The work of the more recent investigators will be considered under the several subheadings.

Arsenic acid, as is well known, forms several distinct classes of salts—orthoarsenates, derived from orthoarsenic acid,  $\text{H}_3\text{AsO}_4$ , which are subdivided into mono-, di- and tri-metallic salts; pyroarsenates, derived from pyroarsenic acid,  $\text{H}_4\text{As}_2\text{O}_7$ ; and metarsenates, derived from metarsenic acid,  $\text{HAsO}_3$ .

Representatives of all of these classes are found among the various metallic arsenates, and, theoretically, lead should also form corresponding compounds.

**Monolead Orthoarsenate**,  $\text{PbH}_4(\text{AsO}_4)_2$ .—One might naturally suppose that monolead arsenate would result from the interaction of solutions of lead nitrate or acetate and a monoalkali arsenate, such as potassium dihydrogen arsenate,  $\text{KH}_2\text{AsO}_4$ .<sup>3</sup> However, this does not occur, at least at moderate dilutions. Under such conditions we invariably obtained dilead arsenate,  $\text{PbHAsO}_4$ , with simultaneous liberation of free acid in the solution, according to the following equation:

Likewise, dilead arsenate is formed when arsenic acid is permitted to react with lead nitrate at ordinary dilutions. These facts suggested that monolead arsenate is unstable in moderately acid media, but might exist at higher acid concentrations. When 20 g. of dilead arsenate were boiled for two hours with 50% arsenic acid and the liquid filtered off, the latter was found to contain but a trace of lead, and the residue, after washing with 95% alcohol (in which arsenic acid is readily soluble), was found to have been practically unchanged. When the arsenic acid concentration was raised to 86%  $\text{H}_3\text{AsO}_4$ , transposition took place. 400 g. of 86% arsenic acid were brought to boiling (about 130 °), and pure dilead arsenate was added in successive small portions. The first few additions dissolved completely, and 7 g. went into solution before a permanent

<sup>1</sup> *Neues Allgemeines Journal der Chemie*, 3, 65 (1804).

<sup>2</sup> *Ann. Phys. Chem.*, 4, 161 (1825).

<sup>3</sup> Commercial potassium arsenate is the dihydrogen salt,  $\text{KH}_2\text{AsO}_4$ , although frequently labeled  $\text{K}_2\text{HAsO}_4$ .

residue remained. A total of 10 g. was added and the heating continued for several minutes. The solution was then filtered through asbestos and allowed to stand until cold, when a bulky mass of moderate sized crystals had deposited. They were separated from the mother liquor as well as possible by centrifuging, then washed with absolute alcohol and dried at  $110^{\circ}$ . Analysis showed this compound to be monolead orthoarsenate (a).

By the addition of a small amount of nitric acid to the boiling arsenic acid solution a larger yield of this material may be obtained. One such experiment, using a solution containing 86% arsenic acid and 2% nitric acid, gave a product of almost theoretical composition (b).

	Found. (a).	Found. (b).	Calc. for $\text{PbH}_4(\text{AsO}_4)_2$ .
Lead oxide, $\text{PbO}$ .....	45.03%	45.59%	45.62%
Arsenic oxide, $\text{As}_2\text{O}_5$ .....	47.42	47.14	47.01
Water of constitution (by ignition).....	7.55	7.34	7.37
	100.00	100.07	100.00

The concentration at which the change from di- to monolead arsenate takes place was determined approximately by using arsenic acid of various concentrations. It was found that 93, 91, 88 and 86%  $\text{H}_3\text{AsO}_4$  deposited monolead arsenate, while concentrations of 80%  $\text{H}_3\text{AsO}_4$ , or less, gave dilead arsenate, showing that the transition concentration lies somewhere between 80 and 86% arsenic acid.

*Properties.*—Under the microscope the monolead arsenate prepared as described was seen to consist entirely of long, narrow, rhomboidal plates. The acute angle at the end is  $68^{\circ}$  (measured by rotating stage). They are biaxial, probably negative, and extinguish at an angle of  $8^{\circ}$  with reference to the longer edge. The minimum index of refraction, normal to the face upon which the crystals naturally lie, is about 1.75, and the birefringence is very strong. (These results indicate that they are mono- or triclinic, probably the latter, as the normal to the crystal did not coincide with any one of the three ether axes.)

The specific gravity, determined on 2.5 g. of material, using a 25 cc. specific gravity bottle and benzene as the liquid, was found to be 4.46 at  $15^{\circ}$  compared with water at the same temperature.

Chemically, monolead arsenate is very unstable. In contact with water it gives up arsenic acid immediately; 0.5 g. treated with 100 cc. of water for 3 hours at room temperature gave 21.89% soluble  $\text{As}_2\text{O}_5$ . The same proportions boiled for 5 minutes gave 22.91% soluble  $\text{As}_2\text{O}_5$ . The lead dissolved was practically *nil* in both cases, showing that water causes complete decomposition of monolead arsenate into dilead arsenate and arsenic acid. The crystals which had been treated with water retained their shape, as shown by microscopical examination, but were almost

without exception of a brown color, and nearly opaque, with the appearance of having been fractured throughout.

Monolead arsenate, when heated very slowly, begins to lose water at  $140^{\circ}$ . Heated at  $150^{\circ}$  for 7 hours it lost approximately one half its total content, corresponding to one molecule of water. Upon further heating at this temperature it continued to lose weight slowly, but the entire theoretical amount was not lost after heating 5 hours a day for three successive days, nor after three additional 5-hour periods at  $210^{\circ}$ . Total loss during this heating, 6.83%. When heated over a low flame below redness it lost 7.34% (theory for water of constitution, 7.37%). Heated to fusion it was partially reduced and lost  $\text{As}_2\text{O}_3$ , which could be seen escaping from the crucible.

**Dilead Orthoarsenate,  $\text{PbHAsO}_4$ .**—The material derived from orthoarsenic acid by the replacement of two of the hydrogen atoms by lead has been known by various names, such as neutral lead arsenate, acid lead arsenate, bibasic lead arsenate, lead hydrogen arsenate, diplumbic hydrogen arsenate, diplumbic arsenate, and simply lead arsenate. It would seem that dilead arsenate is sufficiently specific; in fact, in commercial usage when the term "lead arsenate" is used it is generally this compound that is meant. It is by far the most important arsenate of lead. The formula may be expressed as  $\text{Pb}_2\text{H}_2(\text{AsO}_4)_2$ , or, since its molecular weight is not known, simply  $\text{PbHAsO}_4$ .

There are numerous references in the literature to the preparation and properties of this material. They are, however, in some cases, contradictory.

Berzelius (*Neues Journal für Chemie und Physik*, 23, 174 (1819); *Ann. chim. phys.*, [2] 11, 229 (1819)) states that it is produced when a solution of nitrate of lead is added to a solution of arsenate of soda with the precaution that the whole amount of the arsenic acid be not precipitated, and describes the product (*Lehrbuch der Chemie*, 3, 72 (1845)) as a white powder, insoluble in water, soluble in  $\text{HCl}$  and  $\text{HNO}_3$ , melting at white heat to an opaque yellowish mass.

Mitscherlich (*Ann. chim. phys.*, 19, 368 (1821)).—Lead acetate completely decomposes the bin-arsenates ( $\text{M}'\text{H}_2\text{AsO}_4$ ), for the arsenate of lead is insoluble in acetic acid. The precipitate is ordinarily the neutral salt (dilead arsenate), but one can never be sure that the neutral salt is not mixed with the sub-salt (trilead arsenate). Distinguished from the sub-salt by melting easily and crystallizing on cooling.

Wittstein, "Entymologisch Chemisches Handwörterbuch," 2, 929 (1847).—Neutral lead arsenate precipitates as a white insoluble powder when lead acetate is mixed with neutral arsenates of the alkalis. It melts at white heat to a yellow non-transparent glass.

H. Rose, "Ausführliches Handbuch der Analytischen Chemie," 1, 381 (1851).—A solution of nitrate or acetate of lead produces in solutions of arsenic acid, or alkali arsenates, an immediate white precipitate of lead arsenate, soluble in nitric, insoluble in acetic acid; does not crystallize when melted before the blowpipe. In certain cases the lead arsenate may contain more lead and be, therefore, more basic (*Ibid.*, 2, 406).

Gmelin, "Handbook of Chemistry," trans. by Watts, 5, 173 (1851).—It is formed by the slow action of arsenic acid and air upon metallic lead; also by the precipitation of lead chloride with arsenic acid. Soluble in hydrochloric acid.

Salkowski, *J. prakt. Chem.*, 104, 160 (1868).—Produced by the addition of neutral sodium arsenate to lead acetate as long as a precipitate forms. Crystalline. Converted to lead pyroarsenate upon ignition.

Duvillier, *Compt. rend.*, 81, 1251 (1875).—If a boiling solution of arsenate of lead in nitric acid be diluted with water it quickly deposits little plates of dilead arsenate.

Goguel, "Mémoires de la Société des Sciences Physiques et Naturelles de Bordeaux," Ser. [5] 1, 135 (1896).—By the addition of concentrated arsenic acid to a boiling solution of lead nitrate containing about 1% nitric acid obtained crystals in micaceous leaflets, unctuous to the touch, insoluble in water, soluble in dilute nitric acid; water of constitution lost above 200°; not further decomposed at red heat. Optical measurements of the crystals showed them to belong to the monoclinic system.

De Schulten, *Bulletin de la Société Française de Mineralogie*, 27, No. 6, 113 (1904).—Well formed monoclinic crystals of dilead arsenate were obtained by the slow addition of a 0.3% solution of ammonia to a hot nitric acid solution of lead arsenate. Sp. gr. 6.076 at 15°. Optical and goniometric measurements are given.

Holland and Reed (Mass. Agr. Expt. Station, 24th Ann. Report, Part I, 204 (1912)) state that acid lead arsenate of theoretical composition is readily prepared from nitrate of lead and sodium arsenate, provided dilute solutions are employed and the sodium salt added carefully in excess (10%).

Tartar and Robinson (THIS JOURNAL, 36, 1846 (1914)).—Pure dilead arsenate was obtained as a white amorphous powder by the addition of dilute ammonia, with constant stirring, to a saturated solution of lead arsenate in nitric acid until three-fourths of the nitric acid used was neutralized. Sp. gr. 5.786.

The most frequently quoted method for the production of dilead orthoarsenate is the reaction between solutions of lead acetate, or nitrate, and the "neutral" arsenate of soda,  $\text{Na}_2\text{HAsO}_4$ . R. E. Curry and T. O. Smith,<sup>1</sup> after a phase rule study, conclude that "in the system disodium hydrogen arsenate, lead nitrate and water there exists at 25° only one compound, lead hydrogen arsenate;" however, F. J. Smith,<sup>2</sup> Pickering<sup>3</sup> Haywood<sup>4</sup> and Tartar and Robinson<sup>5</sup> have noted that the action between lead nitrate and disodium arsenate is not constant, resulting in a product usually slightly more basic than dilead arsenate. Experiments made by us are in agreement with the latter view. (It should be noted that Curry and Smith worked with very dilute solutions.) Using lead acetate and disodium arsenate in suitable proportions we have obtained a material even more basic than trilead arsenate.

Mitscherlich used as his source of arsenic the "binarsenates" of ammonia, soda, and potash, by which he meant salts of the type  $\text{M}'\text{H}_2\text{AsO}_4$ , and not those of the type  $\text{M}'_2\text{HAsO}_4$ , as is stated in several later quotations of his work. We have found that if lead nitrate or acetate in moderately

<sup>1</sup> THIS JOURNAL, 37, 1685 (1915).

<sup>2</sup> Mass. State Board of Agr., 45th Ann. Report, 357 (1897).

<sup>3</sup> J. Chem. Soc., 91, 310 (1907).

<sup>4</sup> Bur. Chem., Bull. 105, 165 (1907).

<sup>5</sup> Loc. cit.

strong solutions is precipitated by means of an excess of monopotassium arsenate, dilead arsenate is produced, which, when dried, is a very bulky, amorphous powder, of practically theoretical composition. The use of very dilute solutions results in the formation of a crystalline product having a silky appearance.

Arsenic acid in conjunction with lead acetate or nitrate, as stated by H. Rose, is as efficient as the method just described for making a pure product and the tendency to crystallization is greater owing to the greater acidity of the solution.

The few experiments made by us on the reaction between lead chloride and arsenic acid, gave, instead of dilead arsenate (which Gmelin states is so formed), a chloroarsenate approximating to natural mimetite,  $\text{Pb}_4(\text{PbCl})(\text{AsO}_4)_3$ , as we have shown in a previous paper.<sup>1</sup> It may be that under certain conditions dilead arsenate would also deposit from such solutions. In a number of experiments with saturated lead chloride and soluble arsenates (0.04 mol  $\text{As}_2\text{O}_5$  per l.), a lead chloroarsenate was always obtained, except that when a solution of lead chloride was added to potassium or sodium dihydrogen arsenate, the latter in excess, pure dilead arsenate was precipitated.

We first obtained crystals by placing a solution of cold dilute nitric acid, saturated with dilead arsenate, under a bell jar by the side of an open dish of concentrated ammonia. The slow absorption of the ammonia vapors neutralized the acid and precipitated dilead arsenate in the form of long, slender, glistening crystals. A pure crystalline product was also obtained by adding a dilute solution of ammonium acetate to a solution of dilead arsenate in boiling nitric acid. We found the method of Duvillier to be the most satisfactory for producing a pure crystallized compound, as it permits of successive recrystallizations. On pouring a solution of nitric acid (1 : 4) saturated at the boiling point with dilead arsenate into about six times its volume of boiling water, a mass of beautiful crystals separated, consisting of very thin plates of sufficient size to be visible to the eye. The analysis of this product gave results in practical accord with theory.

	Found.	Theory for $\text{Pb}_2\text{HAsO}_4$ .
Lead oxide, $\text{PbO}$ .....	64.20%	64.29%

Water of constitution (by diff.).....	2.67%	2.58%
	<hr/> 100.00%	<hr/> 100.00%

When the nitric acid solution was allowed to cool without dilution a smaller crop of much larger crystals was obtained, some being as large as  $1 \times 1 \times 0.03$  mm.

*Properties.*—Goguel and de Schulten both described the product as occurring. *Am. J. Sci.*, [4] 42, 139 (1916).

curing in monoclinic leaflets, tabular parallel to the plane of symmetry, the latter containing the optic axes. The crystals in both cases had an acute angle of about  $84^\circ$ . Goguel states that extinction occurred at  $21-22^\circ$ , while de Schulten gives for this measurement  $38^\circ$ , both in reference to the obtuse angle of the crystal. Those prepared by us had an acute angle of  $85^\circ$  and extinguished at  $29^\circ$  within the obtuse angle. They are optically positive and the birefringence is quite high.

The determination of the density of two lots of dilead arsenate crystals, using a 10 cc. specific gravity bottle, 6 g. of material, and water<sup>1</sup> as the liquid, gave sp. gr. 15/15 6.042 and 6.053, agreeing with the value 6.076 as given by de Schulten. A determination made on 4.5 g. of amorphous material, using benzene as the liquid, gave sp. gr. 15/15 5.93. Tartar and Robinson<sup>2</sup> report a value of 5.786. (The results obtained on the crystalline compound are no doubt more nearly correct.)

Dilead arsenate is very little soluble in water; 5 g. boiled for 6 hours under a reflux condenser with 200 cc. of water gave but 4 mg. of  $\text{As}_2\text{O}_5$  in solution. Cold water has even less effect. Experiments being conducted by C. C. McDonnell and J. J. T. Graham (the results of which have not yet been published), show that long-continued exposure to constantly changing water brings about decomposition, both lead and arsenic dissolving, but the latter at a relatively greater rate, leaving the residue more basic than dilead arsenate.

Upon heating, dilead arsenate loses its water of constitution and is converted into the pyroarsenate. Experiments made by heating small portions at various constant temperatures in an air oven, showed that the temperature of conversion to pyroarsenate is within a few degrees of  $280^\circ$ . The material used in these tests did not lose its crystalline appearance. It melts at a bright red heat and on cooling crystallizes to lead pyroarsenate.

**Trilead Orthoarsenate,  $\text{Pb}_3(\text{AsO}_4)_2$ .**—It is stated by Berzelius<sup>3</sup> that trilead arsenate is formed by the action of ammonia on "neutral" lead arsenate ( $\text{PbHAsO}_4$ ), and<sup>4</sup> when a neutral arsenic acid salt ( $\text{M}'_2\text{HASO}_4$ ) is mixed with neutral lead acetate. Mitscherlich<sup>5</sup> says it is produced by the addition of neutral lead salts to a solution of an arsenate, the latter in excess; and<sup>6</sup> by the addition of lead acetate in excess to bi-arsenates ( $\text{M}'\text{H}_2\text{AsO}_4$ ), with subsequent boiling. Graham<sup>7</sup> claims to have produced it by the addition of lead acetate to subarsenate of soda ( $\text{Na}_3\text{AsO}_4$ ).

<sup>1</sup> The action of water on dilead arsenate is so slight that no error is here introduced.

<sup>4</sup> *Lehrbuch der Chemie*, 3, 72 (1845).

<sup>5</sup> *Ann. chim. phys.*, 19, 363 (1821).

<sup>6</sup> *Ibid.*, p. 368.

<sup>7</sup> *Philosoph. Trans. Royal Society*, 123, 266 (1833).

The double decomposition between soluble arsenates and lead salts has been used by a number of more recent investigators. Holland and Reed,<sup>1</sup> using disodium arsenate and lead acetate, obtained, under restricted conditions, a product containing lead and arsenic in the proper ratio for trilead arsenate. Tartar and Robinson,<sup>2</sup> however, state that pure trilead arsenate cannot be prepared by the reaction of these two compounds. Our work, as well as the observations of others, shows that the compound resulting from such reactions varies with changing conditions. In a series of experiments the reactions between the two lead salts, nitrate and acetate, and the two arsenates  $\text{Na}_2\text{HAsO}_4$  and  $\text{Na}_3\text{AsO}_4$  were studied, first with lead salt in excess and then with arsenate in excess, the concentrations employed being 0.4 mol  $\text{PbO}$  and  $\text{As}_2\text{O}_5$ , respectively, per liter. The results are here tabulated.

Salt in excess.	Precipitant.	Molecular ratio $\frac{\text{PbO}}{\text{in precipitate As}_2\text{O}_5}$
$\text{Pb}(\text{Ac})_2$	$\text{Na}_2\text{HAsO}_4$	3.29
$\text{Pb}(\text{Ac})_2$	$\text{Na}_3\text{AsO}_4$	3.36
$\text{Pb}(\text{NO}_3)_2$	$\text{Na}_2\text{HAsO}_4$	2.19
$\text{Pb}(\text{NO}_3)_2$	$\text{Na}_3\text{AsO}_4$	3.14
$\text{Na}_2\text{HAsO}_4$	$\text{Pb}(\text{Ac})_2$	2.96
$\text{Na}_2\text{HAsO}_4$	$\text{Pb}(\text{NO}_3)_2$	2.12
$\text{Na}_3\text{AsO}_4$	$\text{Pb}(\text{Ac})_2$	3.25
$\text{Na}_3\text{AsO}_4$	$\text{Pb}(\text{NO}_3)_2$	3.27

An inspection of this table shows that the only case in which the molecular ratio is very close to 3.00 is in the reaction between lead acetate and excess disodium arsenate. In two cases a product approximating to dilead arsenate was obtained and in all the others basic compounds or mixtures having molecular ratios from 3.14 to 3.36 resulted.

According to Tartar and Robinson the action of aqueous ammonia on dilead arsenate produces, instead of trilead arsenate, a basic arsenate, to which they ascribe the formula  $21\text{Pb}_3(\text{AsO}_4)_2 \cdot 2\text{Pb}(\text{OH})_2 \cdot 10\text{H}_2\text{O}$ . As a result of phase rule experiments (results to be published shortly), we have found that ammonia does change dilead to trilead arsenate, but the latter has a very limited range of existence, and with slight excess of ammonia is converted to a basic arsenate. We have prepared this basic arsenate in crystalline form. All of its properties indicate that it is hydroxy mimetite containing, however, one molecule of water of crystallization,  $\text{Pb}_4(\text{PbOH})(\text{AsO}_4)_3\text{H}_2\text{O}$ . It will be more fully described in a subsequent paper on the basic arsenates of lead.

When small portions of litharge are added to molten lead pyroarsenate combination takes place with incandescence, showing that a chemical reaction, and not merely solution, is taking place. A mixture of dilead arsenate (or pyroarsenate) and litharge in theoretical proportions to form

<sup>1</sup> *Loc. cit.*, p. 203.

<sup>2</sup> *Ibid.*, p. 1847.

trilead arsenate fuses with difficulty before the blast lamp, but can be rendered fluid in a furnace. The melt solidifies to a light yellowish brown, crystalline mass, which is easily broken up. No single crystals were revealed, even after breaking up and examining with the microscope. Most of the pieces were irregularly twinned throughout their mass, giving a speckled appearance when viewed in parallel polarized light. Practically all of the clear transparent pieces appeared to be perpendicular to the acute bisectrix, giving a poor figure very little different from a uni-axial cross. Birefringence low and positive. Specific gravity 7.32 at 15°.

Small portions fused before the mouth blowpipe and allowed to form into hanging drops, on cooling assumed polyhedral forms somewhat resembling crystals of garnet. They were dark brown, iridescent and opaque. The faces were of a resinous luster, somewhat conchoidal in appearance and probably are not true crystallographic faces.

**Lead Metarsenate,  $\text{Pb}(\text{AsO}_3)_2$ .**—Metarsenates in general may be prepared from monoarsenates by ignition. Monolead arsenate loses its water of constitution completely below a red heat and forms lead metarsenate. We also produced it directly from its constituents. When solid arsenic acid and litharge ( $\text{PbO}$ ) or red lead ( $\text{Pb}_3\text{O}_4$ ), in the correct proportion to form lead metarsenate, are heated, the mixture fuses very readily to a rather thin liquid. When permitted to cool slowly, and undisturbed, the melt solidifies at a dull red heat to a transparent glassy mass, very brittle and devoid of crystalline structure. When, however, this material is broken up and the lumps again heated until semiliquid, the whole mass becomes crystalline almost immediately. A product prepared in this way analyzed as follows:

	Found.	Theory for $\text{Pb}(\text{AsO}_3)_2$ .
Lead oxide, $\text{PbO}$ .....	49.75%	49.25%
Arsenic oxide, $\text{As}_2\text{O}_5$ .....	47.12%	50.75%
Arsenious oxide, $\text{As}_2\text{O}_3$ .....	2.65%	.....
	<hr/> 99.52%	<hr/> 100.00%

It is seen that the arsenate has been partially reduced to arsenite, and this occurred even when red lead was used in an attempt to prevent the reduction. A similar experiment, using lead nitrate, produced the same compound. It also contained some arsenite (3.54%  $\text{As}_2\text{O}_3$ ).

**Properties.**—Crystallized lead metarsenate appears to consist of hexagonal tablets. Pieces viewed perpendicular to these tablets were dark under crossed nicols, but gave no recognizable interference figure, even when 1 mm. or more in thickness. All pieces which showed any interference color at all were of an intense blue, regardless of their thickness. This may be the ultra-blue mentioned by Dana<sup>1</sup> as being sometimes seen in minerals such as Danburite, which have very low birefringence.

<sup>1</sup> "Textbook of Mineralogy," p. 428 (1906).

The specific gravity, determined with about 10 g. of material in benzene, was 6.42, referred to water.

Lead metarsenate is decomposed by water. The amorphous glassy material takes up moisture quickly from the air, becoming opaque, but the crystallized product is less readily attacked. Some material powdered to pass a No. 100 sieve was allowed to stand in contact with water at room temperature for 42 hours when it gave only 1.96% soluble  $\text{As}_2\text{O}_5$  and 2.60%  $\text{As}_2\text{O}_3$  (the latter represents the total  $\text{As}_2\text{O}_3$  in the preparation). Boiling for 10 minutes gave practically the same result. However, when ground to an impalpable powder, decomposition into dilead arsenate and arsenic acid occurs almost completely. One gram treated with 100 cc. of water at about  $70^\circ$  for 40 hours gave 21.34%  $\text{As}_2\text{O}_5$  and 2.59%  $\text{As}_2\text{O}_3$  in the solution.

**Lead Pyroarsenates.**—It is theoretically possible to have two lead pyroarsenates, with the formulas  $\text{PbH}_2\text{As}_2\text{O}_7$  and  $\text{Pb}_2\text{As}_2\text{O}_7$ . Pyroarsenic acid and pyroarsenates cannot exist in aqueous solution, and lead pyroarsenates are not obtained by double decomposition. All of our work was therefore confined to ignition methods.

**Monolead Pyroarsenate,  $\text{PbH}_2\text{As}_2\text{O}_7$ .**—This may be regarded as the semidehydration product of monolead orthoarsenate,  $\text{PbH}_4(\text{AsO}_4)_2 = \text{PbH}_2\text{As}_2\text{O}_7 + \text{H}_2\text{O}$ . As a matter of fact, monolead arsenate loses approximately one-half of its water of constitution rapidly at  $150^\circ$  and the remainder is expelled with much more difficulty, as previously noted under monolead arsenate. This is proof that dehydration takes place in steps, and indicates that monolead pyroarsenate is formed as an intermediate product.

Brünnich and F. Smith<sup>1</sup> claim to have found this compound in commercial lead arsenates. Their results, however, are not conclusive and it does not appear, from the properties of this compound, that it could exist in a commercial lead arsenate paste or be isolated from a dry mixture which might contain it by the method employed by these authors.

**Dilead Pyroarsenate,  $\text{Pb}_2\text{As}_2\text{O}_7$ .**—There is a conflict in the literature concerning methods of making this compound. According to Dammer<sup>2</sup> it may be prepared by the action of arsenic acid and air on metallic lead, also by the precipitation of lead nitrate with ammonium, potassium or sodium diarsenates, giving as the reference for the latter statement the work of Berzelius and Mitscherlich. Upon consulting the original articles it was found that Berzelius<sup>3</sup> obtained a product of the percentage composition corresponding to pyroarsenate, but he had ignited the material resulting from the precipitation of lead nitrate by sodium arsenate. Mit-

<sup>1</sup> *Queensland Agric. J.*, 26, 333 (1911).

<sup>2</sup> *Handbuch der Anorganischen Chemie*, 2, Pt. 2, 566 (1894).

<sup>3</sup> *Neues Journal für Chemie und Physik*, 23, 174 (1818).

scherlich<sup>1</sup> quotes Berzelius' results just given and<sup>2</sup> states that "neutral" lead arsenate results by the interaction of lead acetate and "bi-arsenates." The statement by Luther and Volck<sup>3</sup> that lead pyroarsenate results from the action of arsenic acid on basic lead carbonate, and Volck<sup>4</sup> that lead pyroarsenate may occur in lead arsenate pastes, are not supported by experimental proof.

Lefevre,<sup>5</sup> by saturating fused potassium metarsenate with litharge, produced lead pyroarsenate in the form of transparent orthorhombic leaflets.

The simplest means of producing lead pyroarsenate is to heat pure dilead orthoarsenate to about 300°. It may also be made by fusing a mixture of PbO and As<sub>2</sub>O<sub>5</sub>, or Pb(NO<sub>3</sub>)<sub>2</sub> and NH<sub>4</sub>H<sub>2</sub>AsO<sub>4</sub> in equivalent amounts. Fusion always results in a slight reduction to arsenite.

*Properties.*—Lead pyroarsenate melts before a blast lamp, becoming quite fluid, and solidifies on cooling to a light yellow crystalline mass, which is easily broken and powdered between the fingers, probably owing to pronounced cleavage in the crystals. The crushed material when examined under the polarizing microscope showed no well formed crystals but a predominance of irregular pieces almost perpendicular to one optic axis. Such pieces, whenever they had any straight edges, showed slightly inclined extinction. They were biaxial and positive, with medium birefringence.

The specific gravity, determined on about 55 g. of material in benzene, was found to be 6.85 referred to water.

Lefevre states<sup>6</sup> that lead pyroarsenate crystals slowly became opaque under the action of water. We found that when finely powdered it rapidly absorbs water when moistened. Amorphous dilead arsenate, heated to redness but not fused, lost 2.73%. When moistened and allowed to stand for three days and then dried at 110°, it regained 2.29%. A second moistening and drying resulted in a further gain of 0.29% or a total of 2.58%, which is the theoretical amount of water of constitution in dilead arsenate.

### Summary.

1. Monolead arsenate has been prepared and its physical and chemical properties described for the first time.
2. The methods of preparing crystalline dilead arsenate have been reviewed, and its physical and chemical properties more fully investigated.
3. Crystallized trilead arsenate has been prepared.

<sup>1</sup> *Ann. chim. phys.*, [2] 19, 360 (1821).

<sup>2</sup> *Ibid.*, p. 368.

<sup>3</sup> U. S. Patent No. 903,389.

<sup>4</sup> *Science*, 33, 868 (1911).

<sup>5</sup> *Ann. chim. phys.*, [6] 27, 25 (1892).

<sup>6</sup> *Loc. cit.*

4. Lead metarsenate has been made and its physical and chemical properties described.

5. Dilead pyroarsenate has been prepared in crystalline form, and certain of its physical and chemical properties determined.

## THE EFFICIENCY OF CALCIUM CHLORIDE, SODIUM HYDROXIDE AND POTASSIUM HYDROXIDE AS DRYING AGENTS.

BY GREGORY P. BAXTER AND HOWARD W. STARKWEATHER.

Received August 19, 1916.

In a recent paper upon the efficiency of certain drying agents, Baxter and Warren<sup>1</sup> make the statement that Dibbitts<sup>2</sup> found the aqueous vapor pressures of the lowest hydrate of calcium chloride to be 0.29 mm., 2.17 mm., and 3.50 mm. at 0°, 24° and 30°, respectively. Our attention has been called by Dr. W. F. Hillebrand to the fact that these figures refer to a hydrate containing 26% of water. As we have been unable to discover reliable data upon the drying efficiency of anhydrous calcium chloride,<sup>3</sup> the matter has been investigated experimentally. We have found the efficiency of this salt to be far greater than the above values indicate. In addition we seized the opportunity to test two other common drying agents, fused sodium and potassium hydroxides.

The air current method was employed, the details of the apparatus and procedure being essentially identical with those described by Baxter and Warren. Calcium chloride was prepared in an anhydrous condition by fusion in an open platinum dish.<sup>4</sup> While still warm it was crushed to pieces the size of a small pea and packed in a glass stoppered U-tube about 15 mm. in diameter, the column of salt being about 30 cm. long.<sup>5</sup> In most of the experiments the air was passed over a 20% solution of sodium hydroxide to ensure an excess of moisture before being conducted through the calcium chloride tube. After a considerable amount of moisture had been absorbed by the calcium chloride, in a few experiments the air was first dried by means of concentrated sulfuric acid in order that the equilibrium might be approached from the reverse side. The

<sup>1</sup> THIS JOURNAL, 33, 340 (1911).

<sup>2</sup> *Z. anal. Chem.*, 15, 159 (1876).

<sup>3</sup> See however, Marden and Elliott, *J. Ind. Eng. Chem.*, 7, 320 (1915).

<sup>4</sup> The calcium chloride was undoubtedly basic after fusion. It is, however, unlikely that the basic impurity was present in quantity sufficient to affect the results even if of a greater efficiency than the neutral salt.

<sup>5</sup> In the paper by Baxter and Warren it is erroneously stated that the column of salt was 30 mm. long, as in reality it was ten times this length.

results with calcium chloride at  $0^{\circ}$  and  $25^{\circ}$  were very consistent and satisfactory, but the first experiments at  $50^{\circ}$  showed gradually higher values for succeeding experiments. Fearing that the chloride had by this time absorbed so much water that its efficiency had been impaired, the salt was again fused. While the results then became more nearly concordant, irregularities still persisted, until the layer of active salt was doubled to about 70 cm. by inserting a second U-tube containing the fused salt. The results then showed the most satisfactory agreement. In order to find out whether the layer of chloride had been sufficiently long at the lower temperatures, additional experiments, Nos. 4, 5, 13, 14, were carried out at the lower temperatures with the longer layer, with results identical with the earlier ones.

The attempt was made to weigh the phosphorus pentoxide tube in which the water was absorbed to hundredths of a milligram, by using a No. 10 Troemner balance and gold plated weights carefully standardized by the Richards method. No claim is made, however, that the accuracy

is greater than a tenth of a milligram. It was repeatedly shown that the tube remained constant in weight within this amount for periods of fourteen to sixteen hours.

No blank experiments were considered necessary, since in the runs with potassium hydroxide the gain in weight of the tube was scarcely perceptible.

While three points are obviously insufficient to define a curve exactly, since the plot of the logarithm of the vapor pressure against the reciprocal of the absolute temperature is very nearly a straight line it seems worth while to point out that the preceding averages can be represented by the modification of the Antoine<sup>1</sup> formula

$$\log v. p. = 8.614 - \frac{3234}{T + 58}$$

The desiccating efficiency of sodium hydroxide was determined in the same manner as that of calcium chloride, using the two tubes (70 cm.) of drying agent. The sodium hydroxide was fused in a silver dish and broken up while still warm. Apparently the greater part of the water was absorbed by the first 5 cm. of the hydroxide.

TABLE II.—NaOH AS DRYING AGENT.

Number of experiment.	Temperature.	Con- ditions of experiment.	Liters per hour.	Liters of air. (0°; 760 mm.)	Mg. of water.	Cc. of water vapor. (0°; 760 mm.)	Internal pressure of system. Mm.	Pressure of water vapor. Mm.

9		Moist	1.7	11.55	13.90	17.30	763	1.15
Average, 1.15								

The experimental values may be computed from the expression

$$\log v. p. = -4.041 - \frac{373.3}{(T - 414)}$$

Potassium hydroxide was next investigated in the same way. The potassium hydroxide was fused in a silver dish and while still warm was broken into small pieces and transferred to the drying tubes. Two experiments at 25°, and two more at 50°, each involving nearly twelve

<sup>1</sup> *Compt. rend.*, 110, 632 (1890); 112, 284 (1891); 113, 328 (1892); 116, 170 (1893).

liters of air, gave changes in the weight of the phosphorus pentoxide tube no greater than the error of weighing. Then two experiments at 50°, each extending over three days, were performed. Air was actually passing through the apparatus only during the day; at night all stop-cocks were closed.

TABLE III.—KOH AS DRYING AGENT.

Number of experiment.	Temperature.	Conditions of experiment.	Liters per hour.	Liters of air. (0°; 760 mm.)	Mg. of water.	Cc. of water vapor. (0°; 760 mm.)	Internal pressure of system. Mm.	Pressure of water vapor. Mm.
1	50°	Moist	2.0	39.9	0.28	0.35	759	0.007
2		Moist	2.3	45.6	0.34	0.42	759	0.007

Average, 0.007

As pointed out by Morley<sup>1</sup> there is a possibility, in these long experiments, that water diffused through the rubber connections, or was formed by oxidation of the rubber.<sup>2</sup> In view of this possibility the results are to be considered as maxima. No weighable amount of moisture could have passed the pentoxide, since Morley<sup>3</sup> found that phosphorus pentoxide leaves not more than one milligram of water in 40,000 liters of air.

The noteworthy facts shown by the foregoing results are (1) the very considerable temperature coefficients in the case of calcium chloride and sodium hydroxide,<sup>4</sup> and (2) the remarkable efficiency of potassium hydroxide even at 50°. Judging from the temperature coefficients of the other two salts, potassium hydroxide at 25° is fully as efficient as sulfuric acid.

To summarize the results of this research, the aqueous vapor pressures of the lowest hydrates of the salts examined have the following maximum values:

	0°. Mm.	25°. Mm.	50°. Mm.
CaCl <sub>2</sub> .....	0.07	0.34	1.34
NaOH.....	0.04	0.15	1.15
KOH.....	..	..	0.007

The weights of residual water in one liter of a gas dried at 25° by these compounds, calcium bromide, zinc chloride, zinc bromide and sulfuric acid are:

Substance.....	CaCl <sub>2</sub>	CaBr <sub>2</sub>	ZnBr <sub>2</sub>	ZnCl <sub>2</sub>	NaOH	KOH (50°)	KOH <sup>5</sup>	H <sub>2</sub> SO <sub>4</sub>
Milligrams.....	0.36	0.2	1.1	0.8	0.16	0.007	0.002	0.003

CAMBRIDGE, MASS.

<sup>1</sup> *Am. J. Sci.*, 30, 441 (1885).

<sup>2</sup> Only one very short rubber connection was used in our apparatus before the air reached the phosphorus pentoxide tube.

<sup>3</sup> *Am. J. Sci.*, 34, 199 (1887); *THIS JOURNAL*, 26, 1171 (1904).

<sup>4</sup> Baxter and Warren found similar increments with rising temperature with the salts examined.

<sup>5</sup> Estimated from the temperature coefficient of the other salts.

## NOTES.

**The Electrolytic Preparation of Hydroxylamine Hydrochloride.**—The extensive use of hydroxylamine hydrochloride in the electroanalytical determination of metals according to the methods devised in this laboratory (see Schoch and Brown, *THIS JOURNAL*, **38**, 1660 (1916)), and the utter absence of this substance in the market at present rendered it necessary for us to prepare hydroxylamine hydrochloride in lots of several hundred grams. After trying various other methods, we found its preparation by electrolytic reduction from nitric acid according to the method of Julius Tafel<sup>1</sup> to be very convenient. Since, under the present circumstances, others may desire to make this material, we thought they might wish to learn how the method works, and to benefit by the changes in procedure which we have made.

The apparatus shown in the accompanying sketch is identical with that used by Tafel except that the anode (*f*) is a lead rod or pipe, about one inch in diameter; this was used in place of the graphite anode employed by Tafel because we found it necessary to use dilute sulfuric acid in the

Apparatus for electrolytic preparation of  $\text{NH}_2\text{OH}$ ,  $\text{HCl}$ .

anode compartment. The lead cup or cathode (*c*) has a diameter of 10 cm. and a height of 18 cm. Its inner surface was well amalgamated. When used continuously, it had to be re-amalgamated once a week. The porous cup (*d*) has an internal diameter of 6.5 cm. and a height of 19 cm.

<sup>1</sup> *Z. anorg. Chem.*, **31**, 289.

The space between these (the cathode compartment) holds about 400 cc., and is filled with a mixture of three volumes of water to one volume of hydrochloric acid (sp. gr. 1.20). Although the cathode liquid is kept cool by surrounding the lead cup with a freezing mixture (in the pail *a*), yet the anode liquid has to be cooled also; this is accomplished by connecting (*j*) to a suction pump and drawing the anode liquid through the glass tube (*s*) into the glass "adapter" (*g*). The latter is closed at the bottom by a two-holed rubber stopper; a  $1\frac{1}{2}$  in. lead pipe ( $\frac{1}{4}$  in. bore), 10 ft. long, has one end thrust through one of these holes at the bottom of (*g*) and is bent into a coil placed in the freezing mixture as shown. The anode liquid flows, by gravity, from (*g*) through the lead pipe, and then, through a glass tube extension to the bottom of the porous cup. A glass stirrer serves to stir the cathode liquid; its upper end is shown at (*e*). Its lower end is bent into circular form so as to fit between the lead cup and the porous cup. The stirrer is raised and lowered by the mechanical arrangement shown. The nitric acid is dropped in through the dropping funnel (*h*).

To operate the apparatus, the anode compartment is filled with dilute sulfuric acid, the cathode compartment with hydrochloric acid of the required concentration, and the pail with a freezing mixture. When the liquids in the cell has attained a temperature of  $15^{\circ}$  or less, a current of 50 amperes is turned on (pressure, 25 volts!), and then a mixture of nitric acid (sp. gr. 1.40) with one volume of water is allowed to drop into the cathode compartment through (*h*) at such a rate that  $2\frac{1}{2}$  hrs. are required to add 75 cc. of the nitric acid mixture. After this amount of nitric acid had been added, the current is allowed to continue to flow for 30 minutes longer, or a total of three hours. The current density in the above procedure is 8 amps. per 100 sq. cm.

After the end of three hours of electrolysis, the cathode liquid is removed by syphoning, and concentrated *in vacuo*, by heating it on top of a water bath; the flask should not be touched by the water in the water bath. The common practice of drawing air through the distilling flask must naturally not be employed. When the liquid has been concentrated to such an extent that crystals are formed in the drops spattered on the sides of the flask, it is removed and cooled in a freezing mixture without stirring (to avoid possible decomposition of the hydroxylamine by the oxygen of the air). The crystals are gathered on a filter paper, and the mother liquor is concentrated further to secure a second crop of crystals, and again a third crop; with the third crop the liquid may be evaporated almost completely.

To free the hydroxylamine hydrochloride from the accompanying ammonium chloride, the crude material is treated with separate small portions of cold absolute alcohol until a test shows that the residue is free

from hydroxylamine hydrochloride. In explanation of this procedure, it should be mentioned that one liter of alcohol at 15° dissolves 44.3 grams of hydroxylamine hydrochloride, and only 6.2 grams of ammonium chloride.

The hydroxylamine hydrochloride is obtained from the alcoholic solution by the same procedure as that employed for its crystallization from the cathode liquid above. In one case—which is typical—we obtained 45.7 grams of this “purified” material from 37.5 cc. of nitric acid (sp. gr. 1.40). If we deduct from this the maximum weight of ammonium chloride possibly mixed with it, we find that the yield of pure hydroxylamine hydrochloride is about 80% of the theoretical amount possible.

This work was done by Mr. R. H. Pritchett of this laboratory.

**Inclusions in the Silver Voltameter.**—In a very interesting and important paper on the inclusions of mother liquor in the crystals deposited in the silver coulometer<sup>1</sup>, Vinal and Bovard have determined the weight of mother liquor thus held, under the most satisfactory conditions which have been worked out with much care by the Bureau of Standards. They find it to be on the average 0.004 %—an amount only about one-quarter of our average value, but identical with the lowest which we found under our conditions. This is a contribution of great importance, for it gives positive information on the only important point previously in doubt about this work of the Bureau as regards the electrochemical equivalent of silver. It seems, indeed, by thus completing the investigation, to place this work of the Bureau, carried out under Professor E. B. Rosa, on a higher plane than any other which has ever been published concerning this important constant.

The small amount of inclusion thus found by the Bureau of Standards justifies the great care taken there to maintain adequate purity of the electrolyte. In this connection we wish to point out again<sup>2</sup> that these investigators were the first to investigate the precise effects of organic impurities on the weight of the deposit. A previous statement of ours<sup>3</sup> was not intended to claim priority of any such detailed knowledge; it was intended only to express the fact that the desirability of purity of electrolyte had been recognized in early work on general grounds. In all of the 56 “standard” electrolytes made at Harvard in 1901<sup>4</sup> with the porous cap coulometer, organic matter of all kinds was scrupulously ex-

<sup>1</sup> *Bull. Bur. Standards*, Reprint 271 (1916); *THIS JOURNAL*, 38, 496 (1916).

<sup>2</sup> Richards and Anderegg, *THIS JOURNAL*, 37, 692 (1915).

<sup>3</sup> *Ibid.*, 37, 8 (1915).

<sup>4</sup> Richards and Heimrod, *Proc. Am. Acad.*, 37, 415 (1902).

cluded from the electrolyte, both in preparation and during the electrolysis; but no effort was made to discover the part played by filter paper in affecting the weight of the deposit (recognized as too great) in the filter-paper coulometer. The excess of weight was then ascribed primarily to another cause, namely, the possible existence of a complex ion formed at the anode. The investigators at the Bureau of Standards have shown that the effect of filter paper is considerable, and believe indeed that its presence is the only cause of the excess.

Another important feature of the interesting paper of Vinal and Bovard was the discovery of a hitherto unsuspected source of error in the silver coulometer—namely, the effect of platinum black (remaining from a previous determination) upon the weight of silver deposited and upon the inclusion. Although recognizing the presence of traces of platinum black after the gently ignited silver had been dissolved, we did not suspect that this substance could affect a subsequent trial, because we thought that we were able to remove it wholly by scrubbing. But Vinal and Bovard have shown that even minute traces of platinum black, imperceptible to the eye, may have an appreciable effect upon the new deposit. Our oversight was in omitting to ignite the cathode at a high temperature between each trial<sup>1</sup>—a precaution which we can now see to be essential. On account of this error in experimentation, it is clear that our more subtle conclusions, especially that concerning the “volume effect” and the comparison of the Kohlrausch coulometer with the porous cup form, may have been invalidated. The amount of residual platinum black in our cathodes cannot be decided without further trial (now in progress) under precisely similar conditions; it must have been very small. The uncertainty introduced into our results is perhaps less than one part in ten thousand in the weight of the ignited silver;<sup>2</sup> but, nevertheless, small as the effect is in relation to the weight of silver, it is important in relation to the small divergencies upon which some of our conclusions were based.

Other less important minor points in connection with the irregularities of the coulometer are receiving further experimental attention, here and elsewhere. Discussion of all these points had better await the results. So far as we can see, none of the still unsettled questions affects appreciably the main outcome of the work of the Bureau of Standards, as regards the magnitude of the electrochemical equivalent of silver. This is now established by this recent paper of Vinal and Bovard, in an unusually impregnable position.

In brief, this note is intended to express our satisfaction that the ad-

<sup>1</sup> In our experiments the crucible was merely heated at 160° until constant in weight between each trial.

<sup>2</sup> This conclusion is based upon preliminary experiments carried out here by N. F. Hall.

mirable work of the Bureau of Standards has been completed by the determination of the actual amount of inclusion in their deposits; to emphasize the fact that in view of the newly discovered effect of invisible traces of platinum black, we overrated the significance and certainty of some of our recent conclusions, reasonable although they seemed at the time; and to state that further experiments are in progress.

## MOLECULAR REARRANGEMENTS OF $\beta$ -TRIPHENYLMETHYL- $\beta$ -METHYL HYDROXYLAMINES AND THE THEORY OF MOLECULAR REARRANGEMENTS.<sup>1</sup>

BY JULIUS STIEGLITZ AND BERT ALLEN STAGNER.<sup>2</sup>

Received August 1, 1916.

The earliest observations of molecular rearrangements of hydroxylamine derivatives were those of Lossen<sup>3</sup> in the case of hydroxamic acids,  $\text{RCO} \cdot \text{NHOH}$ , and of dihydroxamic acids,  $\text{RCO} \cdot \text{NHOCOR}_1$ .<sup>4</sup> In explanation of these and similar rearrangements, the one of us proposed the theory<sup>5</sup> that they take place through the intermediate formation of univalent nitrogen derivatives under the influence of the reagent used to effect the rearrangement. Thus, a hydroxamic acid could form such a univalent nitrogen derivative by the loss of water in the presence of dehydrating agents.

Dihydroxamic acids would yield the same products with the loss of a molecule of acid under the influence of bases or heat.

The free or latent valences of the unsaturated nitrogen atom were considered to have the power to take the radical R from the carbon atom. Of the many facts brought out in support of this theory by the one of us and by a number of independent investigators,<sup>6</sup> only the most important need be summarized here: (1) The ready application of the theory

<sup>1</sup> A brief preliminary report appeared in *Proc. Nat. Acad. Sciences*, **1**, 205 (1915). For literature references to previous papers, see Stieglitz and Leech, *THIS JOURNAL*, **36**, 272 (1914).

<sup>2</sup> The material presented here is used by Stagner in his dissertation in part fulfillment of the requirements for the Ph.D. degree of the University of Chicago.

<sup>6</sup> Schroeter, *Ber.*, **42**, 2340 (1909); **44**, 1207 (1911); Stoermer, *Ibid.*, **42**, 3133; Wieland, *Ibid.*, **42**, 4207; L. W. Jones, *Am. Chem. J.*, **48**, 1 (1912); **50**, 440 (1913).

without any further assumptions, to Hofmann's rearrangement of acyl halogenamides, to the Curtius rearrangement of acyl azides, to the rearrangement of triphenylmethyl hydroxylamines, halogen amines and azides, as investigated by the one of us and his collaborators. (2) The *non-occurrence* of rearrangements of compounds  $\text{RCO.N}(\text{CH}_3)\text{OH}$ ,<sup>1</sup>  $\text{RCO.N}(\text{CH}_3)\text{Cl}$ ,  $\text{RC}(:\text{NCl})\text{OCH}_3$ ,<sup>2</sup> which appear to have everything in common with the rearranging substances except the possibility of readily forming univalent nitrogen derivatives. (3) The close relation the reagents used to effect each rearrangement bear to the facilitating of a dissociation leading to univalent nitrogen derivatives (see Equations 1 and 2).

No other theory of the rearrangements, that has been proposed, could give as complete an explanation of any one of these sets of facts, we believe, not to speak of all three of them.

In recent years the initial force leading to the rearrangements has been more sharply defined, on the basis of the electron theory of valence, as *residing in the instability of the charges on the radicals held by the nitrogen* in the various classes of rearranging compounds and to the great tendency of these radicals to go over into their common stable forms.<sup>3</sup> This tendency has been compared with the electrolytic solution tension of elements.<sup>4</sup> Thus, in the hydroxylamine derivatives  $\text{RCO.NH}^+ + \text{OH}^-$ ,<sup>5</sup> we have to deal with the tendency of the positive OH radical to go over into its common negative form; in the chloroamines,  $\text{RCO.NH}^+ + \text{Cl}^-$ ,<sup>6</sup> we have positive chlorine with its enormous tendency to form its stable negative atom or ion. In satisfying these tendencies by the absorption of electrons from neighboring atoms, these radicals ( $^+\text{OH}$ ,  $^+\text{Cl}$ ,  $^+\text{Br}$ , and also<sup>7</sup>  $^+\text{N}$ , etc.) disturb the valence electrons of the neighboring atoms in the compounds under discussion and rearrangement is inevitable. Whatever view of the mechanism of the rearrangements may finally obtain, this, it

<sup>1</sup> This question is being re-investigated by Miss Quaesita Drake, as a result of the work described in this paper.

<sup>2</sup> Destruction distillation effects a rearrangement and the loss of methylchloride (Stieglitz, Earle and W. J. Hale, unpublished work).

<sup>3</sup> The electron interpretation of the rearrangements was presented independently and practically simultaneously (see *THIS JOURNAL*, 36, 287 (1914)) by L. W. Jones (*Am. Chem. J.*, 50, 448, published at the end of January, 1914) and by one of us (February number of *THIS JOURNAL* (1914)). The interpretations differ in some important respects, but they agree as to the fundamental relations. Preliminary suggestions were made by Stieglitz, *Ber.*, 43, 782 (1910); *Am. Chem. J.*, 46, 327 (1911); *Ber.*, 46, 2149 (1913), and by Jones, *Am. Chem. J.*, 48, 1 (1912). The same idea, expressed in the older terms then current, was clearly recognized in the earlier papers on the rearrangement of acyl halogen amides (Hoogawerff and van Dorp, *Rec. trav. chim.*, 8, 173 (1889); Lengfeld and Stieglitz, *Am. Chem. J.*, 15, 215, 504 (1893)).

<sup>4</sup> Stieglitz, *THIS JOURNAL*, 36, 276, 280 (1914).

<sup>5</sup> *Ibid.*

<sup>6</sup> *Ibid.*, and *Ber.*, 43, 782 (1910); 46, 2149 (1913).

<sup>7</sup> In hydrazine derivatives, including probably the azides, we have the unstable radical  $^+\text{N}^-$  (Stieglitz and Curme, *Ber.*, 46, 911 (1913)).

seems to us, is the most vital consideration<sup>1</sup> and should form the common ground on which all theories of the rearrangements must meet.

The one arrangement for which, from the outset, any further special assumptions had to be made in the univalent nitrogen theory has been the Beckmann rearrangement of oximes. For this rearrangement, under the influence of acid dehydrating agents, the one of us assumed, provisionally,<sup>2</sup> that the rearrangement is preceded by the absorption of acid and the subsequent loss of water (or its equivalent) as indicated in the equation

This interpretation seemed to be borne out by the proof that triaryl-methylhydroxylamines,  $R_3C.NHOH$ , of exactly the same structure as the assumed intermediate product,  $R_2CX.NHOH$ , rearrange in exactly the same way and under the same conditions.<sup>3</sup> But the assumption met difficulties<sup>4</sup> in explaining the observed differences in the migration of the radicals  $R$  and  $R'$  of stereoisomeric oximes  $RR'C : NOH$ . In this one case the conception of a direct exchange of radicals, *e. g.*:

as postulated by Beckmann,<sup>5</sup> seemed to agree with the facts rather better than the univalent nitrogen theory. In view of this fact, attempts have been included in all the investigations planned by the one of us, to effect this type of rearrangement with compounds which could not be expected to form a univalent nitrogen derivative without an easily recognized destructive change in the product. Compounds of the type  $RCO.N(Alkyl)-OH$ ,  $RCO.N(Alkyl)Cl$ , had been used for this purpose. All efforts to rearrange such compounds had given negative results, but the attempts were repeated with every new class of compounds investigated. A first clue to such a rearrangement was finally discovered last year, when the one of us, together with Leech,<sup>6</sup> examined the effect of phosphorus pentachloride on  $\beta$ -triphenylmethyl- $\beta$ -methylhydroxylamine,  $(C_6H_5)_3C.NCH_3.OH$ . The product of the action seemed to give methylaniline on hydrolysis and this could only be formed as the result of a rearrangement.

<sup>4</sup> Stieglitz, *Am. Chem. J.*, 18, 754 (1896); Montague, *Ber.*, 43, 2014 (1910); L. W. Jones, *Am. Chem. J.*, 48, 28 (1912).

<sup>5</sup> *Ber.*, 19, 988 (1886); 27, 300 (1894). Other prominent adherents of this view, in one form or another, have been Hoogewerff and van Dorp, *Rec. trav. chim.*, 8, 173 (1889); Hantzsch, *Ber.*, 24, 3516 (1891); Kuhara, *Mem. Coll. Sci. Eng. Kyoto*, 1, 254 (1903-1908); 2, 367 (1909-1910); 6, 1 (1913); *Mem. Coll. Sci. Kyoto*, 1, 25 (1914).

<sup>6</sup> *THIS JOURNAL*, *loc. cit.*

The yield of methylaniline was so small, however, that the evidence of its formation was limited to the characteristic chloride of lime color test, discovered by Leech,<sup>1</sup> and of the melting-point tests of the acetyl derivative. It was not beyond the range of possibility that the substance resulted from an alkylation of aniline rather than as a primary product of rearrangement. Under the circumstances, an exhaustive investigation of the reaction was undertaken by us. The results of this work and the conclusions drawn from it are presented in this paper.

It should be said at once that the observations of Stieglitz and Leech have been confirmed in every respect and conclusive evidence brought that methylaniline is formed in quantity by the hydrolysis of the product of the rearrangement of  $\beta$ -triphenylmethyl- $\beta$ -methylhydroxylamine.<sup>2</sup> The methylaniline was identified by the analysis of its chloroplatinate, by the examination of its hydrochloride, as well as, again, by its characteristic reaction with chloride of lime. It was not considered necessary to repeat the identification as acetylmethylaniline.

Furthermore, *benzophenone* has been isolated and identified by us as the compound formed, with methylaniline, in the hydrolysis of the product of rearrangement.

The demonstrated rearrangement of  $\beta$ -triphenylmethyl- $\beta$ -methylhydroxylamine must be considered to open up the whole problem of the theory of the molecular rearrangements outlined above: *the formation of a simple univalent nitrogen derivative,  $R_3C.N$ , is impossible* in this case. Of the various theories which suggested themselves<sup>3</sup> when the first indication of this rearrangement was obtained, an important one is excluded by the identification of benzophenone just mentioned: the possibility of a primary dissociation of triphenylmethymethylhydroxylamine into a *bivalent* nitrogen derivative,<sup>4</sup> corresponding to the dissociation of the related triphenylmethylperoxide into a univalent oxygen derivative, with a subsequent rearrangement, as discovered by Wieland,<sup>5</sup> is excluded<sup>6</sup> by the formation of benzophenone. A rearrangement proceeding along these lines should yield tetraphenylbenz pinacone by hydrolysis of the product.<sup>7</sup> Not the slightest indication of the presence of the pinacone was observed, although a careful search for it was made. The pinacone is known to be decomposed by heat into benzophenone and benzhydrol,

<sup>1</sup> THIS JOURNAL, 35, 1042 (1913).

<sup>2</sup> The behavior of acyl- $\beta$ -hydroxylamines,  $RCON(CH_3)OH$  and similar compounds is being re-investigated by Miss Quaesita Drake as a result of this work.

<sup>3</sup> Stieglitz and Leech, *loc. cit.*, p. 284.

<sup>4</sup> *Loc. cit.*, p. 286.

<sup>5</sup> *Ber.*, 44, 2550 (1911).

<sup>6</sup> A modification of this theory is discussed further on.

<sup>7</sup> This is readily apparent from a consideration of the product given in Equation

17, THIS JOURNAL, 36, 286 (1914).

but no such decomposition takes place under the conditions obtaining in the reaction studied by us: this was confirmed by parallel experiments carried out with a preparation of the pinacone.

This leaves only two important theories that we need take into account:<sup>1</sup> first, the theory of Beckmann that the rearrangements involve simply direct exchanges of radicals (see Equation 4), the reagents used acting "catalytically." For the rearrangement of  $\beta$ -triphenyl- $\beta$ -methylhydroxylamine we would have

A variation of this view, which finds its chief modern support in the important work of Kuhara,<sup>2</sup> is that in the rearrangement of hydroxylamine derivatives under the influence of acetyl chloride, acetic anhydride, sulfuric acid, etc., it is not the OH radical that migrates but an acyl derivative of it,  $\text{RCO.O-}$ . This view is practically identical with Beckmann's first interpretation<sup>3</sup> of the reaction that bears his name. From this point of view, as understood now, phosphorus pentachloride presumably reacts first on a hydroxylamine derivative like triphenylmethyl-methylhydroxylamine to form the product  $\text{R}_3\text{C.N}(\text{CH}_3)\text{OPCl}_4$ ,<sup>4</sup> which then rearranges according to

In the second place, we have the theory of the intermediate formation of univalent (or other unsaturated) nitrogen derivatives in these and re-

<sup>1</sup> All other theories that have been proposed are quite untenable in view of the facts now known; the formation of ring derivatives in which the nitrogen is connected with the migrating alkyl or aryl radical (Nef, *Ann.*, **298**, 308 (1897); **318**, 39, 227 (1901)), is incompatible with the position the nitrogen invariably takes in the migrating alkyl or aryl (cf. Stieglitz, *Am. Chem. J.*, **29**, 58 (1903)). The formation of

unstable triatomic rings,  $\begin{array}{c} \text{O} \\ \diagup \quad \diagdown \\ \text{C} \quad | \\ \quad \text{NH} \end{array}$ , proposed by v. Baeyer as a result of his observa-

tions of rearrangements of peroxides  $\begin{array}{c} \text{O} \\ \diagup \quad \diagdown \\ \text{C} \quad | \\ \text{O} \quad \text{O} \end{array}$  (*Ber.*, **32**, 3627 (1900)) is quite impossible

in view of the fact that triphenylmethyl derivatives, such as  $(\text{C}_6\text{H}_5)_3\text{C.NHCl}$  behave exactly as do the acyl derivatives; they cannot possibly form the rings demanded by Baeyer's theory. (See below, p. 2060, and see also, Stieglitz, *Am. Chem. J.*, **29**, 49 (1903), and Wieland, *Ber.*, **42**, 4207 (1909)).

<sup>2</sup> *Loc. cit.* See also Sluiter, *Rec. trav. chim.*, **24**, 372 (1905).

<sup>3</sup> *Ber.*, **19**, 988 (1886).

<sup>4</sup> Werner, *Ber.*, **25**, 40 (1892); Stieglitz and Leech, *THIS JOURNAL*, **36**, 279 (1914). The assumption of this intermediate product would be in far better agreement with the facts than the assumption of the intermediate formation of N-Cl derivatives, as made by Beckmann and others.

lated rearrangements. The observation that phosphorus pentoxide effects the rearrangement of triphenylmethyl hydroxylamine *hydrochloride*<sup>1</sup> suggested to the one of us the possibility that *salts* of hydroxylamines, by being deprived of water or its equivalent, could form *salts* of univalent nitrogen compounds, which could rearrange in exactly the same way as the univalent nitrogen compounds R<sub>3</sub>C.N. We would have<sup>2</sup>

These two theories,<sup>3</sup> it seems to us, are worthy of critical consideration on the basis of the new facts discovered,<sup>4</sup> and we shall indicate here, as briefly as possible, the facts, as at present known, which appear to favor the one theory or the other. We shall then attempt to show the common ground, on which both theories rest.

I. The following facts at present seem to us to weigh in favor of Beckmann's theory of a direct exchange of radicals (see Equations 4, 5 and 5a): 1. We have the fact, now established by us, that triphenylmethyl-β-methylhydroxylamine is rearranged in the same way and under the same conditions as triphenylmethylhydroxylamine itself. For the rearrangement to proceed by way of the hydrochloride of a univalent nitrogen derivative (Equation 6), it would be necessary to assume the temporary

existence of a compound, which we will call Compound A,  $\text{R}_3\text{C}^+ \begin{array}{c} +\text{CH}_3 \\ | \\ \text{N} \begin{array}{l} \nearrow \\ \searrow \end{array} \\ + \\ | \\ -\text{Cl} \end{array}$

and which would be an *electromer* of a compound B, triphenylmethyl-

chloromethylamine,  $\text{R}_3\text{C}^+ \begin{array}{c} +\text{CH}_3 \\ | \\ \text{N} \\ | \\ +\text{Cl} \end{array}$ ; the latter compound has been pre-

pared in this laboratory by the late Isabella Vosburgh<sup>5</sup> and found *not* to undergo rearrangement. Now, the possibility of the existence of *electromers* was recognized by J. J. Thomson<sup>6</sup> as a consequence of the ap-

<sup>1</sup> Stieglitz and Leech, *loc. cit.*

<sup>2</sup> The electronic interpretation is given in detail, p. 285, *loc. cit.*

<sup>3</sup> Our theory will be taken in its broadest sense, as including the intermediate formation of univalent or bivalent nitrogen and univalent oxygen derivatives, etc.

<sup>4</sup> These will include the more recent and especially important observations of Kuhara, *loc. cit.*

<sup>5</sup> THIS JOURNAL, 38, 2081 (1916).

<sup>6</sup> Cf. "Corpuscular Theory of Matter," 1907, p. 131.

plication of the electron theory to chemical valence and structure, and a number of other writers<sup>1</sup> have applied his ideas to specific cases and found definite *indications* of the existence of electromers in equilibrium. As to the separate existence of electromers, W. A. Noyes,<sup>2</sup> in an important investigation of electromerism in the case of nitrogen chlorides, has found experimental indications, but no final proof, of such a relation. Convincing evidence of the separate existence of electromers has been uncovered by L. W. Jones<sup>3</sup> in a brilliant critical review of the chemistry of hydroxylamine derivatives. For the critical consideration of the consequences which would follow from the postulated relation between the electromers A and B and especially of the question whether they necessarily must be convertible into each other, it will be best to discuss in a few words the fundamental relations that must exist between electronic isomers.

Theoretically considered,<sup>4</sup> when one electromer is changed into another, a transfer of electrons between atoms contained in the same molecule occurs—that is, we have a case of intramolecular oxidation and reduction of atoms. This, if reversible, should be subject to the same laws that hold for reversible intermolecular oxidations and reductions, notably to the law of equilibrium. As is well known, such a condition of equilibrium may be almost, although not quite, one-sided (as in  $2\text{Fe}^{++} + \text{Cl}_2 \rightleftharpoons 2\text{Fe}^{+++} + 2\text{Cl}^-$ ) or it may involve a reaction that is to a distinct extent reversible (as in  $2\text{Fe}^{++} + \text{I}_2 \rightleftharpoons 2\text{Fe}^{+++} + 2\text{I}^-$ ).<sup>5</sup> Similarly, we must expect cases of electromerism, in which one electromer would be extraordinarily stable and the other capable of existence only in traces; in other instances, we should have electromers, for which “the oxidation-reduction constants”<sup>6</sup> of the differently charged elements make possible the existence, in some quantity, of the two electromers side by side. In view of the tremendous mobility of electrons, the equilibria should establish themselves, as a rule, with enormous speed whenever the atoms, whose charges cause the electromerism, are directly linked with each other. When atoms, which cause electromerism, are not directly linked together, tolerably permanent separate existence of electromers seems to be possible, as is shown by the fact that the only electromers whose separate existence has been convincingly

established are the hydroxylamines<sup>1</sup> of the general type,  $R_3N^+ \begin{smallmatrix} -OR \\ +OH \end{smallmatrix}$  and  $R_3N^+ \begin{smallmatrix} -OH \\ +OR \end{smallmatrix}$ , which belong to the second class. Indeed, their separate existence and comparative stability is apparently due to the very fact that the different distribution of charges, which causes the electromerism, relates to two radicals OH and OR (more exactly, to their oxygen atoms), *which are not directly linked together*. Further, the following vital fact which has hitherto been too readily ignored, must be taken into account with the first class of electromers, whose differently charged atoms are directly linked and which must be considered to be reversibly convertible into each other. We will represent this type briefly as  $X^+ -Y$ ,  $X^- +Y$ . The reversible reaction  $X^+ -Y \rightleftharpoons X^- +Y$  involves the transfer of *two* electrons and, if we use the ordinary conceptions of electronic valence (the older or original Thomson conceptions), this should lead through the migration, first, of a single electron, to an intermediate stage, where neither X nor Y would be charged with excess of positive or negative electricity; in other words, the usual valence force between the two atoms would be lacking and, consequently, *dissociation into X and Y should take place*. The only alternative to this conclusion, which has apparently been entirely overlooked in the assumptions of electromeric relations before this, is that in the intermediate product  $X \ Y$ , *nonpolar valences*, of the type suggested by Bray and Branch,<sup>2</sup> G. N. Lewis,<sup>3</sup> Thomson,<sup>4</sup> and A. L. Parsons,<sup>5</sup> unite X and Y.<sup>6</sup> Indeed, the evident absence of such dissociation in indicated cases of electromerism would, if electromerism and nondissociation were proved beyond a doubt, be excellent chemical evidence in favor of the existence of some form of nonpolar valences. The well-known specific and generally one-sided actions of absorption, metathesis, etc., which are obviously *directed* by the nature of the specific *polar* charges on atoms both in inorganic and organic compounds, would find their explanation in the fact that *the chemically active molecules are those whose reacting atoms have polar charges*.<sup>7</sup>

On the basis of these general considerations concerning the relations

of electromers, Compound A,  $R_3C + \begin{array}{c} +CH_3 \\ | \\ \text{---}N\text{---} \\ | \\ + \\ | \\ -Cl \end{array}$ , which, according to the

univalent nitrogen theory would be the rearranging univalent nitrogen salt in the rearrangement of triphenylmethyl- $\beta$ -methylhydroxylamine,  $(C_6H_5)_3C.N(CH_3)OH$ , by phosphorus pentachloride, and Compound B,

$R_3C + \begin{array}{c} +CH_3 \\ | \\ \text{---}N\text{---} \\ | \\ -Cl \end{array}$ , which Miss Vosburgh found to be nonrearranging, would,

as far as composition is concerned, seem to be electromers of the first (XY) class. If this is their relation, one should expect them to be convertible into each other: then, either B should undergo the molecular rearrangement as a result of going over first into A, or A should be transformed, in part at least, into the stable electromer B—or both actions should take place. No indications of any such results have been observed.<sup>1</sup> It still remains possible—or, indeed, probable—that the *fifth* (positive<sup>2</sup>) valence of nitrogen which enables ammonium radicals to combine with anions and form salts, and which also holds the chlorine in compound A in the *salt* form, is of a different character, in regard to its position in the atom or some other relation, from the remaining four valences, and not capable of going over electromerically into one of these other (negative) valences. In that event, the two electromers would really belong to the second group of electrômeric substances, of which the hydroxylamine derivatives, discovered by Jones and discussed above, are the best known representatives, and they would not necessarily be convertible into each other. The hydroxylamine electromers are themselves ammonium compounds, in which the valence in question is concerned.

On the whole, however, interpretations of the rearrangement that can do without assumptions concerning electromeric substances, must, for the present, be considered the more conservative. For this reason, the proved rearrangement of triphenylmethyl- $\beta$ -methylhydroxylamine should at the present moment be judged as weighty, although not conclusive, evidence in favor of Beckmann's view, that these rearrangements take place by a direct exchange of radicals.

2. The relation of stereoisomeric ketoximes to the products of their rearrangement (see Equation 4) still remains as indicated in the earliest report by one of us on his own theory,<sup>3</sup> an important, although not conclusive, fact, weighing in favor of Beckmann's view. It *may* find its ex-

<sup>1</sup> Further work is suggested by these considerations.

<sup>2</sup> This valence is indicated by heavy type as  $\text{+}$  in the above formula for A.

<sup>3</sup> Stieglitz, *Am. Chem. J.*, 18, 754 (1896); *THIS JOURNAL*, 36, 277 (1914).

planation in the theory of a univalent nitrogen salt derivative, undergoing rearrangement, as discussed in detail in a previous paper by the one of us.<sup>1</sup> But such an interpretation is open to the same objections as raised by us in the previous paragraph against the salt theory, and, consequently, at present the relation of stereoisomerism to the rearrangement still remains important evidence in favor of a rearrangement by direct exchange of radicals.

3. A number of observations made by Kuhara<sup>2</sup> in a series of admirable investigations seem, at the first glance, to weigh heavily in the scales in favor of Beckmann's views. Among these facts we have as a most notable one, that syn-acetylethylbenzhydroxamic ester,  $C_6H_5C.OC_2H_5$ , is re-

arranged when it is heated for some time above its melting point.<sup>3</sup> The anti-derivative is not rearranged.<sup>4</sup> Kuhara formulates the rearrangement of the syn-derivative essentially in the way Beckmann would (Equation 4), but he also emphasizes the effect of the strength of the acid of the acyl radical attached to the oxygen of the oxime group on the ease with which the rearrangement takes place—a most important contribution to the subject. Further, it is characteristic, as Kuhara found, that the rearrangement of syn-acetylethylbenzhydroxamic ester, as well as that of the analogous acetyl derivative of benzophenone oxime,  $(C_6H_5)_2C:NO(\text{Acyl})$ , is *accelerated* by the presence of hydrogen chloride as a "catalytic agent," the velocities of rearrangement being found proportional to the concentration of acid present. Since acids act as "catalyzers" most commonly by salt formation, it is altogether likely that the rearranging substances, in the experiments with solutions, are the salts<sup>5</sup> of the acyl esters, rather than the esters themselves.<sup>6</sup> It is not at all impossible that, similarly, salts formed by the presence of traces of free acid should also be the active components even in the rearrangement by fusion. As a matter of fact, Kuhara found it impossible to rearrange the acetyl ester of benzophenoneoxime "by itself, even by the rise of temperature." It is always necessary to use hydrogen chloride as a catalytic agent. He ascribes this to the "weak negative character<sup>7</sup> of the acetic acid residue." In support of this view, he brings the important observation that the

<sup>5</sup> The question of the ionization of these salts is not considered here.

<sup>6</sup> Kuhara proposed this view for the rearrangement of acetylbenzophenoneoxime by hydrogen chloride [*Mem. Coll. Sci. Kyoto*, 1, 25 (1914)].

<sup>7</sup> *Loc. cit.* As a matter of fact, in these hydroxylamine derivatives we really have the unstable positive radical  $CH_3CO.O^+$  (see below).

benzenesulfonyl ester of benzophenone oxime, "owing to the presence of the strong negative acid residue," undergoes the rearrangement apparently spontaneously, without the need of a catalyzing acid, slowly in the cold, very rapidly when it is heated above its melting point of  $62^{\circ}$ . This whole evidence is open to quite another interpretation: it would seem as if the acetyl derivatives might not rearrange spontaneously on account of the fact that any traces of acetic acid, formed by the action of moisture on the ester, might be too weak to form a salt in sufficient quantity with the oxime ester, and in the absence of the salts, there would be no rearrangement; but any traces of benzene sulfonic acid, so liberated, could act autocatalytically, since the acid would be strong enough to form a salt with the ester. It would be important to determine whether the spontaneous rearrangement of the sulfonyl ester would not be *accelerated* by the presence of hydrogen chloride.<sup>1</sup> Beyond suggesting that the hydrochloric acid helps out the weak acetic acid residue in its tendency to exchange positions with the phenyl radical, Kuhara does not explain how the formation of the hydrochlorides of the acetyl derivatives should facilitate the rearrangement. Two explanations suggest themselves: one, obviously, is that *the apparent necessity for the formation of a rearranging salt* would be in excellent agreement with the view that a salt of a univalent nitrogen derivative is the *real rearranging component in these reactions*<sup>2</sup> and that the rearrangement does not proceed until salt formation gives the molecule its only opportunity to form any univalent nitrogen derivative. Kuhara's view that the "weak negative character of the acetic acid residue" is responsible for the nonrearrangement of acetyl benzophenoneoxime without the aid of hydrochloric acid seems to be contradicted by the peculiar fact that all attempts to rearrange chloroimido-benzophenone,  $(\text{C}_6\text{H}_5)_2\text{C}:\text{NCl}$ , have failed to indicate the least trace of a rearrangement;<sup>3</sup> the hydride corresponding to the radical Cl is hydrogen chloride itself,<sup>4</sup> an acid fully as strong as, or stronger than, benzene-

<sup>1</sup> Since this was written, Mr. Sidney Cadwell has investigated this question for me and found that added acid (hydrogen chloride, benzene sulfonic acid) does decidedly *accelerate* the rearrangement of the benzene sulfonic acid ester of benzophenone oxime, but he has also found that there is a slow, spontaneous rearrangement of the ester itself even at  $0^{\circ}$  and even in the presence of a weak base like pyridine (cf. Kuhara). This result will be published later in detail.—J. S.

<sup>2</sup> The equation representing the rearrangement from this point of view is given by Stieglitz and Leech, *loc. cit.*, p. 281.

<sup>3</sup> Heat, bases, chlorine, phosphorus pentachloride have been tried. Kuhara's work suggests a further trial with *acids* and this will be undertaken. (Since this was written, Henry R. Curme has studied the action of concentrated sulfuric acid on the chloroimide: no trace of a rearrangement product could be found, under exactly the same conditions of work as led to a rearrangement of benzophenoneoxime.)

<sup>4</sup> Kuhara takes no account of the positive charges on the radicals  $\text{CH}_3\text{CO}\cdot\text{O}^+$  and  $\text{C}_6\text{H}_5\text{SO}_3\cdot\text{O}^+$  in the oxime esters (Stieglitz and Leech, *loc. cit.*) and contrasts the

sulfonic acid. Acid decomposes the chloroimide and hence salts, when formed, decompose in another way than by rearrangement, and it is certainly significant that just in this case we cannot secure a rearrangement of the free chloroimide itself. It seems possible, therefore, that Kuhara's interesting results, from which we can recognize the importance of salt formation with acids for the rearrangements of oximes and their esters, may really signify that the easiest path for these rearrangements is over univalent nitrogen compounds, *including their salts*, and that a direct exchange of radicals is a much more difficult process.

We wish to point out, however, that the major role played by salt formation in the rearrangement of the oxime esters may consist not simply in making possible or facilitating the formation of a univalent nitrogen compound, but may well be a further instance of what seems to be a broad and fundamental principle, namely that *acids are found to facilitate changes and migrations of unstable positive atoms or radicals*,<sup>1</sup> *which in their migration or change go over into their stable negative forms*. Besides the cases just discussed, we find this principle applying to the various forms of rearrangement of hydrazines with the unstable atom  $+N^{\cdot}$ ,<sup>2</sup> such as  $C_6H_5HN^{\cdot} + NHC_6H_5$  (e. g., the rearrangement into benzidine with the stable atoms  $-N^{\cdot}$ ), applying to the rearrangement of phenylhydroxylamine,<sup>3</sup>  $C_6H_5HN^{\cdot} + OH^{\cdot}$ , with the unstable atom  $+O^{\cdot}$ , into amino phenols<sup>4</sup>  $HO^{\cdot} + C_6H_4.NH_2$ , with the stable atom  $-O^{\cdot}$ , of acylhalogenanilides<sup>5</sup>  $RCO.N(Cl^+)C_6H_5$ , with the unstable atom  $Cl^+$ , to acylchloroanilides  $RCO.NHC_6H_4Cl^{\cdot}$ , with the stable atom  $Cl^{\cdot}$ , which are all accomplished or accelerated with the aid of acids: *all involve the change* strength of the hydrides of the radicals, namely, acetic and benzenesulfonic acids. This is why HCl and not HOCl is used in the text for purposes of comparison. As a matter of fact, the real acids, of which the compounds may be said to be derivatives for the purposes of comparison, are the per-acids  $CH_3CO_2^{\cdot}O^+OH$ ,  $C_6H_5SO_3^{\cdot}O^+OH$ , and hypochlorous acid  $Cl^+OH$ .

<sup>1</sup> The result of the migration is always a stronger and more stable base and the effect of the acid is, therefore, in agreement with the energy relations that must be involved. Probably potential relations of the unstable positive forms of the elements, akin (*mutatis mutandis*) to solution tensions, are favorable to their transformation in acid media into the stable negative forms of the elements. Investigations from this point of view are greatly to be desired.

of unstable positive, to stable negative, atoms.<sup>1</sup> Underlying all of these rearrangements is the tendency of these unstable atoms to absorb electrons: and they thus disturb, *eo ipso*, the valence relations in a molecule and the rearrangements are necessary sequels.<sup>2</sup>

II. We will turn now to the consideration of the most important facts which appear to favor the view that unsaturated (primarily univalent, possibly also bivalent<sup>3</sup>) nitrogen derivatives are intermediate products in the rearrangements of the various classes of compounds which suffer this typical rearrangement, such as the hydroxylamines, the halogenamines, the azides.

1. By losing nitrogen, the azides,  $\text{RCO.N}_3$ ,  $\text{R}_3\text{C.N}_3$ , rearrange and give exactly the same products as do the other classes of compounds discussed. Recently, in this laboratory, Senior<sup>2</sup> found that  $(\text{ClC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.N}_3$ , even gives the same proportion of aniline and chloroaniline in the rearrangement as does  $(\text{ClC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.NHOH}$ . A "direct exchange" of nitrogen with the radical R,  $(\text{C}_6\text{H}_5)$  or  $(\text{ClC}_6\text{H}_4)$  seems out of the question.

2. When univalent nitrogen derivatives can be formed readily, we have smooth reactions, proceeding at low temperatures, in marked contrast with those cases where univalent nitrogen cannot be obtained readily and, at best, only indirectly: (a) Dry salts of acylchloroamides rearrange explosively when warmed gently,<sup>4</sup> and in solution the salts rearrange rapidly at low temperatures.

In contrast with this behavior we find that alkyl derivatives,  $\text{RCO.NCl}(\text{CH}_3)$ , do not rearrange<sup>5</sup> and none of the chloroimidoesters,  $\text{RC}(\text{:NCl})\text{OCH}_3$ , which have been obtained in syn and antistereoisomeric forms corresponding to those of the hydroxamic esters, is rearranged, until destructive distillation is resorted to, in which the methyl group is lost.<sup>6</sup> According to the univalent nitrogen theory of the one of us, these results are to be expected, but they cannot be explained without further specific assumptions on the basis of the Beckmann theory of direct exchanges, since there is no apparent reason why there should not be an equally ready direct exchange of the radical R and the (positive) chlorine atom in these cases and in the non-alkylated compounds. (b) The dry

<sup>1</sup> Miss De Sale is investigating the question to what extent acids accelerate the rearrangement of azides. The rearrangement of peroxides by acids will also be studied from this point of view.

<sup>6</sup> Unpublished work with Earle and W. J. Hale.

metals salts of dihydroxamic acids<sup>1</sup> also rearrange spontaneously and explosively at room temperatures, forming isocyanates (see Equation 2). The corresponding esters,  $\text{RC}(\text{OC}_2\text{H}_5) : \text{NO} \cdot \text{COCH}_3$ , rearrange very slowly, if at all, and then only at elevated temperatures. Their salts with acids rearrange much faster and may even be present in all of their rearrangements (see I, 3 above) and these salts may produce univalent nitrogen derivatives. (c) Triphenylmethyldichloroamine,  $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{NCl}_2$ , is readily rearranged by heat<sup>2</sup> with loss of chlorine; triphenylmethylbromoamine,  $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{NBr}$ , is likewise readily rearranged when heated with alkali with a loss of hydrogen bromide; but triphenylmethylchloromethylamine,  $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{NClCH}_3$ , is not rearranged by heat, by alkali, or, even by destructive distillation.<sup>3</sup> Chloroimidobenzophenone,  $(\text{C}_6\text{H}_5)_2\text{C} : \text{NCl}$ , has resisted every effort to effect its rearrangement and the same is true of the stereoisomeric chloroimides,<sup>4</sup>  $(\text{C}_6\text{H}_5)(\text{XC}_6\text{H}_4)\text{C} : \text{NCl}$ . If the theory of direct exchange were correct, these substances, above all others, should show a spontaneous exchange of the aryl and halogen radicals. It is true, however, that it is still possible that the favorable medium has not yet been discovered for effecting the rearrangement of these compounds.

3. As has often been pointed out by the one of us, the reagents used to effect the different varieties of rearrangement are the very ones which we would select in attempting to obtain univalent nitrogen derivatives as intermediate products: Bases for the acyl halogenamides,  $\text{RCO} \cdot \text{NH}(\text{Hal})$ , for dibenzhydroxamic acids,  $\text{RCO} \cdot \text{NH}(\text{OCOR})$ , for triphenylmethyl-halogen amines,  $\text{R}_3\text{C} \cdot \text{NH}(\text{Hal})$ , for benzoyltriphenylmethylhydroxylamine,<sup>5</sup>  $\text{R}_3\text{C} \cdot \text{NH}(\text{OCOC}_6\text{H}_5)$ ; acid dehydrating agents for oximes,  $\text{R}_2\text{C} : \text{NOH}$ , for hydroxylamines,  $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{NHOH}$  and  $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{N}(\text{CH}_3)\text{OH}$ , phosphorus pentoxide for the hydrochloride,  $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{NHOH} \cdot \text{HCl}$ ; heat for acylazides,  $\text{RCO} \cdot \text{N} \cdot \text{N}_2$  (with loss of nitrogen), for triphenylmethylazides,<sup>6</sup>  $\text{R}_3\text{C} \cdot \text{N} \cdot \text{N}_2$ , for triphenylmethyldichloroamine,  $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{NCl}_2$  (chlorine being lost). To these cases may now be added the apparent necessity of using a catalyzing acid for the rearrangement of the acetyl ester of benzophenone oxime<sup>7</sup> (see I, 3 above), the very agent required to make a univalent nitrogen derivative possible.

<sup>1</sup> L. W. Jones, *Am. Chem. J.*, **48**, 1 (1912).

<sup>5</sup> In the article by Stieglitz and Leech doubt was expressed about the position of the benzoyl group on account of the inability of the benzoate to form a salt (*loc. cit.*, p. 292). Difficulty in salt formation has now been found to be common in the triphenylmethyl derivatives we are studying. The absence of the ferric chloride test for an OH group makes the above structure probable.

<sup>6</sup> J. K. Senior and Stieglitz, *Proc. Nat. Acad. Sci.*, **1**, 207 (1915).

<sup>7</sup> Kuhara, *loc. cit.*

rangements produced by the action of an electric current on the salts of organic acids. The fundamental analogy of the resulting changes to the rearrangements of the nitrogen derivatives under discussion has already been pointed out by the one of us.<sup>1</sup>

III. If one considers the evidence in I and II, one must be impressed by the fact that certain facts are more simply interpreted on the basis of Beckmann's theory of a direct exchange of radicals, that still other facts are quite incompatible at present with Beckmann's views and in striking agreement with the intermediate product theory of the one of us. Common to both views and *the most important fact in any theory of the rearrangements, is that the latter originate from the presence of unstable positive atoms,  $Cl^+$ ,  $-O^+$ ,  $\equiv N^+$ , in the molecules of the compounds in question, and these atoms, by satisfying their tendencies to absorb electrons and form the common, stable, negatively charged atoms, disturb the valences which hold all atoms in the structure of the molecules and start the rearrangement into stable molecules.*<sup>2</sup> From this point of view, it must be evident that *both* forms of rearrangement might well be possible, one by a direct exchange, the other by way of a dissociation into unsaturated radicles. The question of the mechanism of the rearrangements resolves itself then largely into a question of the path followed by the migrating electrons. For these reasons it seems desirable to analyze, as briefly as possible, the electronic interpretations of the rearrangements from the different points of view: they bring out their relations more precisely than do the structural considerations alone and they point the direction for further experimentation.

A. The electronic interpretation of Beckmann's assumption of a direct exchange of radicles has never been presented, we believe. In illustration of it, we have for the rearrangement of β-triphenylmethyl-β-methyl hydroxylamine,<sup>3</sup>

The shifting charges are indicated by heavy type.

Characteristic of this theory, evidently, is that the unstable positive radical  $+OH$  secures its electrons *directly* from the carbon atom of the triphenylmethane nucleus, an exchange of radicals (the new negative  $-OH$  and the positive phenyl radical) occurring practically simultaneously with this shifting of electrons. This mode of expression brings out in the most striking fashion some of the most important objections to Beck-

<sup>1</sup> Stieglitz and Leech, *loc. cit.*, p. 281.

<sup>2</sup> Stieglitz, *Proc. Nat. Acad. Sci.*, 1, 207 (1915). See also L. W. Jones, *loc. cit.* and Stieglitz and Leech, *Ibid.*

<sup>3</sup> In place of  $+OH$  we may put its acyl derivatives,  $RCO.O^+$ .

mann's theory: it fails utterly to explain why we have no rearrangements of compounds strictly analogous to the above, such as

In these nonrearranging compounds the tendency for the exchange of electrons should be even greater than in the preceding rearranging compound, if we judge by comparing the activity of (positive) chlorine in chloroamines and hypochlorites with that of (positive) oxygen in such a substance as hydrogen peroxide.

B. According to the univalent nitrogen theory of the rearrangements, we should have, for instance, for triphenylmethylhydroxylamine:

The characteristic feature of this theory is that the unstable positive element secures its electrons from the nitrogen to which it is attached, by capturing two of its valence electrons. One of these two available electrons attached to the nitrogen in the original molecule is the one holding the positive radical itself (here  $^+\text{OH}$ ), the other is taken from the nitrogen only if it holds hydrogen, a metal (either may be ionized or non-ionized) or some other easily displaced atom, *but it is not available when it holds an alkyl group or its equivalent*.<sup>2</sup>

*In turn*, the unsaturated nitrogen, comparable with an element like fluorine,<sup>3</sup> secures from the carbon atom, to which it is attached, two electrons again, the rearrangement following as a result. This view explains the very facts which the Beckmann theory fails utterly to explain: thus, in  $(\text{C}_6\text{H}_5^+)_3 \text{—} \text{C}^+ \text{—} \text{N}^- (\text{Cl}^+) (\text{CH}_3)^+$ , the nitrogen has only one readily

<sup>1</sup> It was originally considered (Stieglitz and Leech, *loc. cit.* and Jones, *Ibid.*) that in the univalent nitrogen derivative the nitrogen might have the structure  $\text{—} \text{N}^+ \text{—}$  in place of  $\text{—} \text{N} \text{—}$ . The latter was given the preference by the one of us. Below, under C, additional reasons for distinguishing sharply between the two closely related forms will be brought.

<sup>2</sup> Similarly, in  $(\text{H}^+)_2 \text{—} \text{S}^-$ , the  $\text{—} \text{S}^-$  is very easily deprived by oxidizing agents of both its electrons, but in  $(\text{CH}_3^+) \text{—} \text{S}^- \text{—} \text{H}$  it is deprived only of the electron holding the hydrogen atom. This is most likely due to the fact that the ions,  $\text{HS}^-$ ,  $\text{S} = \text{CH}_3 \text{S}^-$ , with exposed electrons, are the components, which are most easily deprived of these electrons (cf. Stieglitz, "Qualitative Analysis," Vol. I, Chapters XIV and XV). Possibly, too, the union with  $\text{CH}_3$  is of the nonpolar type.

<sup>3</sup> Stieglitz and Leech, *loc. cit.*

available<sup>1</sup> electron, not the two necessary for the formation of a univalent nitrogen derivative and no rearrangement occurs. On the other hand, the present view does not explain, without further assumptions (see p. 2051) the rearrangement of  $\beta$ -triphenylmethyl- $\beta$ -methyl hydroxylamine.

Now, the *force* with which electrons would be drawn by the unstable positive atom from another atom in the same molecule must depend on at least two factors, namely a tension factor measuring the intensity of the selective tendency with which each element holds or seeks to absorb electrons—comparable with the solution tension of the free elements—and secondly, on the distance separating the atoms between which a transfer of electrons may occur. As to the tension factors in all of these rearrangements, the final products prove beyond question that these factors must favor the gain of electrons by the unstable positive element at the expense of the *carbon* atom holding the nitrogen. In other words, the carbon must lose two electrons, as far as tension is concerned, more readily than the nitrogen; otherwise the univalent nitrogen derivative would be tolerably stable. Consequently, unless the direct migration of electrons from the carbon to the unstable positive element is obstructed by virtue of the important factor of distance and intervening atoms, as far as the tension factor is concerned, *the direct migration would be the natural path for the transfer of electrons*. Instances of such direct migration under favorable conditions might therefore not be unexpected (see A).

But, further, the important factor of distance unquestionably must favor the absorption of electrons first from the nitrogen by the unstable positive element, which is in direct union with it; the nitrogen can then recover its electrons from the carbon with which it is in direct union. This probably is the reason why *the path of least resistance* to the rearrangements<sup>2</sup> seems to be over the univalent nitrogen products and why certain compounds, which have the necessary instability of charges, do not rearrange, when the path over the univalent nitrogen is blocked. This mechanism has the advantage therefore of having *both* factors, which control the movement of electrons, leading to the final readjustment.

It seems especially important, from these considerations, to subject the nonrearranging compounds to a still more searching experimental investigation, in order to determine whether the path toward a rearrangement really is altogether blocked.

C. There is a third electronic interpretation<sup>3</sup> of the rearrangements, which contains in it elements of both of the preceding interpretations; we may have a dissociation, preceding the exchange of radicals.

<sup>1</sup> The union with  $\text{CH}_3$  may even be of the nonpolar type, if such valences should be found to exist.

<sup>2</sup> Stieglitz and Vosburgh, *Ber.*, **46**, 2149 (1913).

<sup>3</sup> Cf. Stieglitz and Leech, *loc. cit.*, and L. W. Jones, *Ibid.*

This interpretation would labor under the same difficulties as the theory of Beckmann (see A) in accounting for the nonoccurrence of rearrangements of certain halogen derivatives (see A) and would have the added difficulty that the factor of proximity would be no obstruction to a similar rearrangement in this case. It should be borne in mind for those rearrangements which seem to take place without the intermediate formation of a univalent nitrogen derivative.<sup>2</sup>

Our conclusions may be summarized as follows:

1. Unless conclusive evidence is brought that *salts* leading to the intermediate formation of salts of univalent nitrogen derivatives, are involved in their rearrangement, the rearrangement of  $\beta$ -triphenylmethyl- $\beta$ -methylhydroxylamine, established in this paper, the relation of stereoisomerism of oximes to their rearrangement products, established by Beckmann, Werner and Kuhara, and also the spontaneous rearrangement of the sulfonic ester of benzophenone-oxime, observed by Kuhara, would be inconsistent with the theory of the intermediate formation of univalent nitrogen derivatives in the rearrangement of hydroxylamines and at present these facts agree better with Beckmann's theory of a direct exchange of radicals or with a modification of this theory (see C, above). Intermediate salt formation, if established, would harmonize these facts with the univalent nitrogen theory.

2. Other facts, such as the rearrangements of azides and especially also the nonrearrangement of chloroimidobenzophenones, of chloroimidoesters, and of  $\beta$ -triphenylmethyl- $\beta$ -methylchloroamine, are inconsistent, without further specific assumptions, with Beckmann's theory of a direct exchange of radicals, but are in striking agreement with Stieglitz's theory of the intermediate formation of unsaturated nitrogen derivatives in the rearrangements of chloroamines, hydroxylamines, and azides.

3. Unless further experimentation should modify these facts or their bearing, one should consider that both types of rearrangement may take place.

4. Common to both theories and the most important feature in their modern forms is that the rearrangements originate from the tendency of unstable positive atoms,  $\text{Cl}^+$ ,  $\text{O}^+$ ,  $\text{N}^+$ , etc., to go over into their

<sup>1</sup> Or some equivalent ion, such as  $\text{Cl}^-$ ,  $\text{C}_6\text{H}_5\text{SO}_3^-$ , etc.

<sup>2</sup> Other variations of this fundamental idea are possible.

stable negative forms,  $\text{Cl}^-$ ,  $\text{O}^-$ ,  $\text{N}^-$ , by a capture of electrons from other atoms in the same molecule a change which is effected in the rearrangements in question. It is quite consistent with this fundamental relation that the rearrangement should go over one or the other path, the one over the unsaturated nitrogen derivatives forming probably the path of least resistance.

5. The same fundamental cause, the charge on unstable atoms, with consequent shifting of electrons, underlies the rearrangement of peroxides, of hydrazines, of acylhalogenanilides, of aryl hydroxylamines, and similar compounds.

### Experimental Part.<sup>1</sup>

**The Rearrangement of Triphenylmethyl- $\beta$ -methylhydroxylamine,**  $(\text{C}_6\text{H}_5)_3\text{C}.\text{N}(\text{CH}_3)\text{OH}$ .—The method of Stieglitz and Leech<sup>2</sup> for preparing triphenylmethylmethylhydroxylamine hydrochloride was followed, but it was found better to purify this salt by washing it thoroughly with ligroin (b. p. 70–80°) than to crystallize it from a chloroform-ether solution. By the latter process there is always some dissociation into triphenylmethylchloride and methylhydroxylamine hydrochloride. The free base may also be extracted with ligroin instead of ether, as the base is quite soluble in it, and then the hydrochloride precipitated from the solution by the introduction of the dry acid gas.

The purity of the salt was determined by its melting point and by the analysis for the content of hydrogen chloride. The free base was prepared from it by treatment with alkali solution and extraction of the base with ether. The ether solution was dried with fused calcium chloride and the solvent evaporated. The base remaining was a very mobile, almost colorless liquid, which, without further purification, solidified, at once, when stirred with a glass rod. The solid melted at 106° and when it was once recrystallized from ligroin, it melted at 111°. Leech found 113° as the constant melting point, after prolonged recrystallization. The yield is good—5.5 g. were obtained from 9 g. of triphenylmethylchloride.

To rearrange the base, 3 g. of it were dissolved in 30–40 cc. of ether and 5 g. of phosphorus pentachloride added to the solution. The mixture stood at room temperature for 24 hours, during which time a slightly yellow coloration appeared. The coloration increased when the mixture was heated on an electric bath for four hours. After the heating, a strong ether solution (3 cc.) of hydrogen chloride was added to the mixture to insure the presence of an excess of the acid. The supernatant liquid was decanted through a filter and the residue washed well with ether.

<sup>1</sup> I take pleasure in giving expression to my grateful appreciation of the painstaking and skilful work of Mr. Stagner, who carried out the experimental work under my direction.—J. S.

<sup>2</sup> *Loc. cit.*

Water (20 cc.), containing hydrochloric acid, was now added to the residue and any trace of residue on the filter was washed into the flask with the larger residue. Some of this residue was insoluble in the dilute acid. The mixture was warmed an hour on the water bath. The insoluble residue melted but did not dissolve. The mixture was cooled and ether added to it. This dissolved the residue which was not soluble in the aqueous solution. The ether solution was separated and the water solution extracted twice again with ether. The ether extracts, containing benzophenone, was examined as described later on. The aqueous solution remaining was made alkaline, saturated with sodium chloride, and the free methyl aniline twice extracted with ether. The base was next twice extracted from the ether solution with 20 cc. of very dilute hydrochloric acid (0.5 *N*). The acid solution was filtered into a weighed beaker and the solution evaporated nearly to dryness on a steam bath and the last traces of moisture removed *in vacuo*. The residue (methyl-aniline hydrochloride) weighed 0.535 g.

A second rearrangement was similarly made in which a gram of the free base gave 0.151 g. of methylaniline hydrochloride. The theoretical yield is 0.496 g. methylaniline hydrochloride per gram of triarylmethyl-methylhydroxylamine.

**Identification of Methylaniline.**—The following tests proved the salt to be methylaniline hydrochloride:

1. A small quantity of the residue was dissolved in water and the solution made alkaline. Bleaching powder solution was added and gave the characteristic deep blue color, discovered by Leech as a test for methylaniline.<sup>1</sup>

2. A small quantity of the residue, when twice crystallized from dry chloroform by the addition of ether, melted at 119–122°. When these crystals were mixed with synthetic methylaniline hydrochloride they melted at the same temperature, 119–122°. Methylaniline hydrochloride, obtained from a redistilled Kahlbaum preparation, melted at 119–121°.

3. 0.1392 g. of the residue, which had been twice recrystallized from chloroform and ether, required 9.76 cc. of 0.1 *N* AgNO<sub>3</sub>, when analyzed by the Volhard method. Theoretical quantity for C<sub>7</sub>H<sub>10</sub>NCl, 9.70 cc.

4. A quantitative analysis of the chloroplatinate was made. The older literature<sup>2</sup> states that methylaniline chloroplatinate is unstable and darkens quickly, with decomposition. But this is erroneous. The chloroplatinate prepared from synthetic methylaniline hydrochloride forms a nice looking yellow precipitate which does not darken at all and which contains the theoretical quantity of platinum. After this fact

<sup>1</sup> THIS JOURNAL, 35, 1042 (1913).

<sup>2</sup> Graham-Otto-Kolbe, IIIa, 178 (1878).

had been determined, the methylaniline salt obtained from the rearrangement products was analyzed. About 0.22 g. of the hydrochloride, that had been once crystallized from chloroform and ether, was dissolved in 10-15 drops absolute alcohol. This solution was added to 0.4 g. of chloroplatinic acid dissolved in 15-20 drops of alcohol. The yellow precipitate of methylaniline chloroplatinate formed at once. The precipitate was transferred to a filter, washed first with 10-20 drops of alcohol, and then slowly with 30 cc. of a half and half mixture of absolute ether and alcohol. The solid was brought to constant weight *in vacuo* in an hour or two.

Subst. 0.3493 g. gave 0.1097 g. Pt.

Calc. for  $C_{14}H_{20}N_2PtCl_6$ : Pt, 31.27%. Found: Pt, 31.40%.

**Identification of Benzophenone.**—The ether solution of the benzophenone, which was extracted from the acid solution of the hydrolyzed products of the rearrangement, was freed from the ether by evaporation in a current of air. A red tinted very mobile liquid remained which weighed 0.611 g. This substance remained liquid for several days. Finally, when it was touched by a minute trace of pure benzophenone clinging to the rounded end of a melting point tube, it solidified at once. Some of it was twice crystallized from ligroin and melted at 46-47° and when it was mixed with pure benzophenone, it melted at 46.5-48°. Pure benzophenone melted at 47-48.5°.

**Triphenylcarbinol.**—The triphenylmethylmethylhydroxylamine did not rearrange quantitatively. This was shown by the fact that approximately 1.5 g. of triphenylcarbinol was obtained in addition to the aniline and benzophenone already described. A part of the base appeared to dissociate into triphenylmethylchloride and hydroxylamine, as observed by Stieglitz and Leech. The ether solution which had been decanted from the insoluble rearranged products was freed from ether by evaporation and the gummy residue remaining was hydrolyzed with alkali solution. The carbinol thereby produced was crystallized from ligroin and identified by its melting point.

**Rearrangement of  $\beta$ , $p$ -bromophenyldiphenylmethyl- $\beta$ -methylhydroxylamine,  $(BrC_6H_4)(C_6H_5)_2C.NCH_3OH$ .**— $p$ -Bromotriphenylmethylchloride was condensed with methyl hydroxylamine. The concentrations of solutions were the same as those used in the preparation of triphenylmethylmethylhydroxylamine. The solvents were evaporated and the gummy residue was extracted with ligroin,<sup>1</sup> (b. p. 70-80°). From this solution the hydrochloride of the base was precipitated by dry hydrogen chloride.

<sup>1</sup> Attempts were made to precipitate the hydrochloride from an ether solution but the salt is very soluble in ether and solidification cannot be obtained if ether is present. A few drops of ether added to the salt purified from ligroin softens it into a gum—probably due to the base being very weak and the salt being decomposed by the oxonium valences of the ether.

The salt separates out very white. It is quite insoluble in the ligroin but is soluble in chloroform, alcohol, and ether. It reduces boiling Fehling's solution, softens at  $70^{\circ}$ , but has no true melting point. The yield of the salt is good; 8 g. of it was obtained from 12 g. bromotriphenylmethylchloride. From its behavior it seems to be an unstable salt, easily losing its acid.

For analysis, it was placed in a flat crystallization dish and stirred in an atmosphere of dry hydrogen chloride and then placed in a desiccator over potassium hydroxide and left in an ice chest for five days. Analysis for the content of the hydrochloric acid was then made by titration with 0.1 *N* KOH. The salt was dissolved in 25 cc. of absolute alcohol and ten drops of phenolphthalein indicator used. It required 0.06 cc. of alkali to correct for  $\text{CO}_2$  in the alcohol.

Subst. 0.2437, 0.1950; cc. 0.1 *N* KOH, 6.12, 4.88.

Calc. for  $(\text{BrC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{CNCH}_2\text{OH}\cdot\text{HCl}$ : HCl, 9.01. Found: 9.16, 9.12.

The salt was next left *in vacuo* at room temperature over sticks of potassium hydroxide for three days. It then showed 92% of the calculated amount of hydrogen chloride. The salt evidently is not stable and dissociates slowly at room temperature into the free base and free hydrogen chloride.

**Rearrangement of *p*-Bromophenyldiphenylmethyl- $\beta$ -methylhydroxylamine.**—The base,  $(\text{BrC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{CNCH}_2\text{OH}$ , was obtained from its hydrochloride by treatment of the latter with alkali solution and extraction with ether. The ether solution was freed from moisture by means of fused calcium chloride. The solvent was then evaporated, leaving a liquid substance. Some of this liquid (2.25 g.) was dissolved in 30–40 cc. of ether and phosphorus pentachloride (4 g.) was added to the solution. The mixture was heated on an electric bath for four hours. After the heating, 3 cc. of ether containing hydrogen chloride was added, and the supernatant liquid poured from the insoluble yellow colored compounds. The insoluble substance was washed twice with 15 cc. of ether. The residue was hydrolyzed and the ketones (benzophenone and bromobenzophenone) and the aniline salts (the hydrochlorides of methylaniline and methyl bromoaniline) were isolated exactly as they were in the case of the rearrangement of triphenylmethylmethylhydroxylamine.

The base (2.25 g.) yielded 0.172 g. of mixed aniline hydrochlorides and 0.301 g. of the two ketones, benzophenone and bromobenzophenone. A second rearrangement of 1.6 g. of base gave 0.111 g. of the mixed aniline salts.

A trace of the hydrochlorides, when made alkaline and treated with bleaching powder solution, gave a navy blue color, the test for methyl aniline (methylbromoaniline does not give this color test). Another small quantity of the aniline salts was freed from the hydrochloric acid and precipitated from ether solution by means of oxalic acid. This oxalate showed the presence of halogen when tested with copper oxide in Bunsen flame.

## THE MOLECULAR REARRANGEMENT OF TRIARYLMETHYL-HYDROXYLAMINES.

BY BERT ALLEN STAGNER.<sup>1</sup>

Received August 1, 1916.

That the hydroxylamine derivatives of triphenylmethane undergo a rearrangement entirely analogous to the Lossen rearrangement of hydroxamic acids and the Beckmann rearrangement of oximes and under exactly similar conditions, was shown by the work of Stieglitz, Reddick and Leech.<sup>2</sup> The rearrangement is effected by the action of phosphorus pentachloride on the hydroxylamine derivative or by the action of phosphorus pentoxide on the hydrochloride of the base.<sup>3</sup> The product of the rearrangement is a phenylimidobenzophenone. According to the theory of Stieglitz<sup>4</sup> the action is formulated as follows:

When a substituting group replaces hydrogen in one or more of the phenyl groups, as in  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.NHOH}$ , the rearrangement leads to the formation of two substituted phenylimidobenzophenones, part of the substance yielding the phenylimide of the substituted benzophenone, for instance  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)\text{C} : \text{NC}_6\text{H}_5$ , part forming a substituted phenylimido derivative of benzophenone itself, namely,  $(\text{C}_6\text{H}_5)_2\text{C} : \text{NC}_6\text{H}_4\text{X}$ .

A study of the proportions in which the groups migrate in a series of such derivatives promises to shed light on a number of interesting questions. In the first place, exactly the same rearrangements have been observed by Stieglitz and Vosburgh<sup>5</sup> in the study of triarylmethylhalogenamines, and, recently, by Stieglitz and Senior<sup>6</sup> in the case of the triarylmethyl azides. In all three series the assumption of the formation of intermediate univalent nitrogen derivatives as the actually rearranging substances gives us, according to Stieglitz, the best explanation of the rearrangements. Then, corresponding compounds in the three series, such as  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.NHOH}$ ,  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.NH}(\text{Hal})$ ,  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.N}(\text{N}_2)$  could well yield the identical rearranging compound  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.N}$ . The conditions for the rearrangement in each of these series vary as to the temperature and other environment factors,

<sup>1</sup> The material presented here forms part of a dissertation in fulfilment of the requirements for the Ph.D. degree (1914).

<sup>5</sup> 8th Intern. Congr. Appl. Chem., **25**, 444 (1912) and dissertation work of Isabella Vosburgh, University of Chicago, completed in 1913.

<sup>6</sup> Dissertation work of James K. Senior, University of Chicago, completed in 1914.

but the rearrangement of the univalent nitrogen derivative, being intramolecular, might very well be largely independent of environment. The determinations of the proportions in which the various radicals  $C_6H_5$ ,  $XC_6H_4$ , migrate in the rearrangement of corresponding compounds in each of the three series would give us, therefore, the necessary data for quantitative comparisons of the reactions in the three series.

In the second place, such quantitative determinations would show what differences, if any, are shown in the migration of aryl groups  $XC_6H_4$  with various negative or positive substitution groups in them ( $X = H, Cl, Br, NO_2, CH_3$ , etc.), thus giving a definite answer to the question whether certain groups are more easily lost by carbon and drawn to nitrogen than others. In previous studies of this problem, conclusions have been based, either on the behavior of the groups in question in related but different substances (*e. g.*,  $C_6H_5CONHBr$  and  $NO_2C_6H_4CONHBr$ <sup>1</sup>) or on the behavior of ketoximes, in which stereoisomerism is supposed to play the major role in determining the migration of a given radical. For the triphenylmethane derivatives this complication is eliminated and we have, furthermore, all the groups in question in exactly the same rearranging molecule, *e. g.*,  $(C_6H_5)(XC_6H_4)(YC_6H_4)C.N$  and, therefore, under strictly comparable conditions. The problem is thus reduced to its simplest terms.<sup>2</sup>

Stieglitz and Leech having examined only *p*-chlorophenyldiphenylmethylhydroxylamine in regard to the proportion in which the phenyl and the chlorophenyl groups migrate to the nitrogen, I took up, at the suggestion and under the direction of Professor Stieglitz, the further investigation of this problem at this point. For this purpose the rearrangement of *p*-bromophenyl-diphenylmethylhydroxylamine, of di-*p*-chlorophenyl-phenylmethylhydroxylamine and finally of *p*-chlorophenyl-*p*-bromophenyl-phenylmethylhydroxylamine was studied by me.

The interesting result was obtained that whereas bromophenyl-diphenylmethylhydroxylamine,  $(BrC_6H_4)(C_6H_5)_2CNHOH$ , exactly as the corresponding chloro derivative studied by Leech, rearranges so that, roughly, in two-thirds of the rearranging molecules a phenyl group and in the remaining third the bromophenyl group migrates, the ratio is reversed when one subjects dichlorophenyl-phenylmethylhydroxylamine,  $(ClC_6H_4)_2(C_6H_5)CNHOH$ , to the rearrangement. In this case for two-thirds of the rearranging molecules it is the chlorophenyl group that migrates and in the remaining third the phenyl group. Furthermore,

<sup>1</sup> Hoogewerff and van Dorp, *Rec. trav. chim.*, 6, 373 (1887), etc.

<sup>2</sup> A further question which is being studied is that of the effect of the positions of the substituting groups (ortho, meta and para) on the migration. It is expected to produce experimental evidence concerning the nature of the charges on the carbon atoms holding the aryl groups to the methyl carbon atoms and thus to secure evidence on certain of Fry's assumptions concerning the charges in the benzene derivatives.—J. S.

in the case of chlorophenyl-bromophenyl-phenylmethylhydroxylamine,  $(\text{ClC}_6\text{H}_4)(\text{BrC}_6\text{H}_4)(\text{C}_6\text{H}_5)\text{CNHOH}$ , roughly one-third of the rearranging molecules show a migration of the chlorophenyl group, the bromophenyl group and the phenyl group, respectively. This result certainly would indicate that there is no marked effect of the halogens on the tendency of the aryl group to migrate to the nitrogen.<sup>1</sup>

### Experimental Part.

*p* - Bromophenyldiphenylmethylhydroxylamine,  $(\text{BrC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{CNHOH}$ .—This was prepared according to Gomberg<sup>2</sup> from benzophenone-dichloride and bromobenzene by the Friedel and Craft reaction. The chloride was treated with hydroxylamine by a modification of the methods of Mothwurf<sup>3</sup> and of Stieglitz and Leech.<sup>4</sup> Many futile preliminary attempts by these methods showed that it is necessary to have the hydroxylamine solution very concentrated, for otherwise the principal reaction takes place between the triarylmethylchloride and the alcohol, forming the ether  $(\text{C}_6\text{H}_5)_2(\text{BrC}_6\text{H}_4)\text{COCH}_3$ . Even with this precaution some of the ether was always formed.

A saturated solution of 3.2 g. of hydroxylamine hydrochloride in warm methyl alcohol was added to a solution of sodium methylate (1 g. of sodium dissolved in the least quantity of methyl alcohol). It is desirable not to have any excess of the sodium methylate present and this was carefully determined by evaporation of a drop of the solution on a crucible lid and gentle ignition of any residue. If any alkaline substance remained, more hydroxylamine hydrochloride was added to the methylate solution until the test gave a negative result. The sodium chloride formed in the reaction was removed by filtration and the filtrate evaporated at 20 mm. pressure and 40° to a volume of 10 cc. This treatment gave a very concentrated hydroxylamine solution and but little of the hydroxylamine escaped.<sup>5</sup> The approximate strength of the solution was determined by titration of 0.5 cc. of it with 0.1 *N* hydrochloric acid, methyl orange being used as the indicator.<sup>6</sup>

Three grams of *p*-bromophenyl-diphenylmethyl chloride, dissolved in 30 cc. of anhydrous benzene, were added to the 10 cc. of the alcohol solution of hydroxylamine. After the mixture had stood a few hours the small quantity of hydroxylamine hydrochloride which had separated was removed by filtration and the filtrate evaporated at 20 mm. pressure

<sup>1</sup> The discussion of minor differences in the migration of these radicals and the comparison of the results obtained with corresponding hydroxylamines, chloroamines and azides will be presented in another paper by Professor Stieglitz.

<sup>6</sup> Lobry de Bruyn, *loc. cit.*

and 50°. A yellow, gummy residue, consisting chiefly of the bromophenyl-diphenylmethylhydroxylamine, was left. This base was extracted with dry ether and the extract treated with an excess of dry hydrogen chloride. The salt,  $(\text{BrC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{CNH}_2\text{OHCl}$ , separated at once as a white solid. The salt becomes slightly soluble in ether after a large excess of the acid is introduced. It was collected on a filter, washed several times with ether, and once quickly with cold dilute (about 3 molar) hydrochloric acid to remove hydroxylamine hydrochloride.<sup>1</sup>

From 3 g. of bromophenyl-diphenylmethylchloride, 1.8 g. of the purified salt was obtained. This was analyzed by titration of the hydrochloric acid with silver nitrate solution by the Volhard method.

Subst. 0.1711, 0.1730; cc. 0.1  $N$   $\text{AgNO}_3$ , 4.34, 4.37.

Calc. for  $(\text{BrC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{CNH}_2\text{OHCl}$ :  $\text{HCl}$ , 9.33. Found: 9.25, 9.19.

The salt reduces Fehling's solution when boiled, but not in the cold, melts at 144–5° with decomposition, is soluble in alcohol, but not in ligroin and but slightly soluble in ether.

**Rearrangement of *p*-Bromophenyl-diphenylmethylhydroxylamine.**—The free base,  $(\text{BrC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{CNHOH}$ , was obtained from the hydrochloride just described by treatment of the latter with 20% sodium hydroxide solution and extraction of the base with ether. The ether solution was dried with potassium carbonate and the solvent evaporated in a current of dry air. The base thus obtained was a pale yellow viscous liquid or gum. Some of it (1.35 g.) was dissolved in 30 cc. of anhydrous ether and powdered phosphorus pentachloride (2.5 g.) was added to it. When the mixture was allowed to stand at room temperature for a few hours a trace of a yellow deposit collected on the phosphorus chloride. The mixture was then heated on an electric bath for two hours and a greater amount of the yellow deposit collected. The molecular rearrangement was expected to yield the two phenylimidobenzophenones, *p*-bromophenylimidobenzophenone,  $(\text{C}_6\text{H}_5)_2\text{C} : \text{NHC}_6\text{H}_4\text{Br}$  and phenylimidobromobenzophenone,  $(\text{BrC}_6\text{H}_4)(\text{C}_6\text{H}_5)\text{C} : \text{NH.C}_6\text{H}_5$ . To insure that these bases should be present in the form of their salts, some ether (2 cc.) saturated with hydrogen chloride was added to the reaction product. The supernatant liquid was then decanted through a filter from the main residue and the residue was washed with ether containing some hydrogen chloride. Since partial hydrolysis of some of the imidoketones by traces of moisture would form anilines and since aniline hydrochlorides are somewhat soluble in ether containing an excess of hydrogen chloride, it was always possible that some of the aniline, if any were present here, might be dissolved by this treatment. For the recovery of any such substance, the ether filtrate was evaporated almost to dryness, a small amount of

<sup>1</sup> The presence of this salt was indicated by the hydrogen chloride content of the product when it was not purified in this way.

water added to the residue, and this warmed to decompose the phosphorus oxychloride. This aqueous solution and the trace of solid on the filter were then added to the main residue. This was then warmed with alcohol (10 cc.) and dilute hydrochloric acid (5 cc.) for an hour on a steam bath to completely hydrolyze the imidoketones.

The alcohol was removed by evaporation of the solution almost to dryness, followed by a second evaporation after some acidulated water had been added to the residue. Now, water (15 cc.) was added to the product and the solution twice extracted with 15 cc. of ether to remove the ketones. These ketones were identified as described further on. The aqueous solution contained the aniline and bromoaniline hydrochlorides. It was made alkaline, saturated with sodium chloride and the free anilines extracted with two portions of 25 cc. each of ether. The extract was filtered into a weighed beaker and 2 to 3 cc. of ether saturated with hydrogen chloride were added to this filtrate to convert the anilines into hydrochlorides. Because of the partial solubility of these salts in such an acid-ether solution, the ether and the water held in solution by it were evaporated in a current of dry air and the salts remaining were dried *in vacuo*. The dried salts were washed once with 10-15 cc. of absolute ether, dried again, and weighed. The *p*-bromophenyl-diphenylmethylhydroxylamine (1.35 g.) used in the rearrangement yielded 0.2075 g. of aniline hydrochloride and bromoaniline hydrochloride.

Two other quantitative rearrangements of the base were made by this method. In the first a yield of 0.2145 g. of aniline salts was obtained from 1.08 g. of the base and in the second the yield of the salts was 0.2865 g. when 1.17 g. of the base was used. Theoretically 1 g. of the base could yield either 0.36 g. of aniline hydrochloride or 0.58 g. bromoaniline hydrochloride.

These mixtures of aniline and bromoaniline hydrochlorides were analyzed to ascertain the molar ratios of the aniline and bromoaniline. The bromination method of Curme<sup>1</sup> was used.

Subst. 0.0589, 0.0569, 0.0659; cc. 0.1 *N* KBrO<sub>3</sub>, 21.65, 21.31, 24.63. Found: aniline hydrochloride, 74.73, 76.81, 76.58; bromoaniline hydrochloride, 25.27, 23.19, 23.42.

**Identification of Aniline and Bromoaniline.**—The method of separating aniline and chloroaniline used by Stieglitz and Leech<sup>2</sup> proved satisfactory for separating and identifying the aniline and bromoaniline of this re-

<sup>1</sup> THIS JOURNAL, 35, 1162 (1913).

<sup>2</sup> *Loc. cit.*

arrangement. The hydrochlorides were converted into the oxalates and the greater solubility of the aniline oxalate in hot water permitted its separation from the bromoaniline oxalate. The former, in water solution and made alkaline, gave the violet color with bleaching powder solution; and the latter, freed from the acid, gave crystals from ether solution, which melted at  $62^{\circ}$ . These when mixed with pure *p*-bromoaniline,<sup>1</sup> melted at  $62-63^{\circ}$ .

**Identification of Benzophenone and Bromobenzophenone.**—The ether containing the ketones in solution was evaporated. The residue was quickly washed with a small amount of ligroin and then about seven-eighths of the residue was dissolved in warm ligroin (b. p.  $70-80^{\circ}$ ). The small quantity of residue remaining melted at  $81^{\circ}$  (pure *p*-bromobenzophenone melts at  $82.5^{\circ}$ ). The ligroin solution was evaporated to dryness and two-thirds of the residue dissolved. This treatment was repeated until about one-eighth of the original residue was in solution. A few crystals obtained from this solution melted at  $46-47^{\circ}$  and when they were mixed with pure benzophenone they melted at  $47-48^{\circ}$  (pure benzophenone melts at  $48.5^{\circ}$ ).

**Rearrangement of *p*-Bromophenyl-diphenylmethylhydroxylamine Hydrochloride by Means of Phosphorus Pentoxide.**—Bromophenyl-diphenylmethylhydroxylamine hydrochloride (0.8 g.) and phosphorus pentoxide (0.9 g.) were placed together in a test tube and gradually warmed in a metal bath. At  $107^{\circ}$  a rapid reaction took place and the mixture expanded to about three times its original volume into a brown gummy mass. The mass was kept at this temperature for 20 minutes and then cooled.<sup>2</sup> The subsequent treatment was similar to that described above for the product of the rearrangement of the free base. Approximately 0.1 g. of the hydrochlorides of aniline and bromoaniline was obtained. The aniline gave the characteristic test with bleaching powder solution. No further attempts at effecting rearrangements by means of phosphorus oxide were made as the pentachloride seemed to give more satisfactory yields.

**Di-*p*-chlorophenyl-phenylmethylhydroxylamine,  $(\text{ClC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{-CNHOH}$ .**—This was made by Gomberg's method<sup>3</sup> from dichlorobenzophenone by the Grignard reaction. The reagent was used according to the proportions given by Houben,<sup>4</sup> *i. e.*, 2.36 g. of special magnesium, 17.5 g. of bromobenzene, and 120 cc. of ether. After a few hours, when the reaction between the magnesium and the bromobenzene was com-

<sup>1</sup> Kahlbaum's pure bromoaniline, melting at  $63-64^{\circ}$ .

<sup>2</sup> The reaction seems to take place slowly even when the mixture is heated only slightly, as shown by the fact that the yellow tint of the mixture grew deeper in color when it was pressed hard against the sides of the test tube with a glass rod.

<sup>3</sup> *Ber.*, 39, 3279 (1906).

<sup>4</sup> *Ibid.*, 36, 3087 (1903).

plete, 9 g. of the solid di-*p*-chlorobenzophenone were added. This ketone is only moderately soluble in ether but it dissolved at once in the Grignard reagent. The solution must be kept free from moisture. It was warmed for three hours on a water bath and the magnesium compound was then decomposed with water. The excess of bromobenzene used in making the Grignard reagent and the benzene formed from it later were removed by steam distillation and the light colored insoluble gum remaining in the water was washed free from magnesium hydroxide with dilute hydrochloric acid. The gum was dissolved in ligroin and dried with fused calcium chloride. The solution was filtered and the solvent evaporated spontaneously in a desiccator over paraffin shavings. In three hours crystals of the carbinol began to form and 8.6 g. of the carbinol had separated out overnight. The carbinol melted at  $85^{\circ}$  without recrystallization. Gomberg did not succeed in obtaining this carbinol crystallized until he had taken it through a long troublesome method of purification. The preparation was twice repeated and the crystallization similarly obtained. The carbinol was converted into the chloride,  $(\text{ClC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{CCl}$ , in the usual manner by dry hydrogen chloride passed into a carbon disulfide solution of the carbinol. The chloride thus formed was a gum at first and assayed 94% of the calculated amount of chlorine when it was hydrolyzed in alcohol solution with excess of alkali. This gum was used for the preparation of the hydroxylamine, but about 5 g. of it were left in a desiccator over solid potassium hydroxide and in a month's time crystals had formed on the sides of the beaker. These were pushed down into the gum and in several days the whole had become solid. This impure solid melted at  $43\text{--}50^{\circ}$ .

Subst. 0.4333 g.; cc. 0.1 *N* KOH 11.58. Calc. for  $(\text{ClC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{CCl}$ : Cl, 10.21. Found: 9.50.

Gomberg was not successful in getting this gum to solidify. The solidification is slow and time did not permit further efforts at the purification of the product. The chloride, as a gum, was allowed to act on a strong solution of hydroxylamine, in the way described above for bromophenyl-diphenylmethylchloride. The free base remaining after the alcohol and benzene were removed, was extracted with ether and hydrogen chloride added to the ether extract. The hydrochloride,  $(\text{ClC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{CNH}_2\text{OHCl}$ , separated at once as a white solid. The salt was removed by filtration and washed well with ether and once quickly washed with cold dilute hydrochloric acid. It is slightly soluble in ether, soluble in alcohol, but insoluble in ligroin and benzene. It reduces boiling Fehling's solution, and melts at  $129\text{--}30^{\circ}$  into a pale yellow liquid which soon reddens when left at that temperature.

Subst. 0.2287, 0.2869; cc. 0.1 *N*  $\text{AgNO}_3$ , 5.85, 7.29.  
Calc. for  $(\text{ClC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{CNH}_2\text{OHCl}$ : HCl, 9.58. Found: 9.32, 9.26.

**Rearrangement of Di-*p*-chlorophenyl-phenylmethylhydroxylamine.**—

The free base was obtained from the hydrochloride described above by treatment of the salt with 20% alkali solution and extraction with ether. The ether solution was dried over potassium carbonate and the ether evaporated. The base was left as a pale yellow, syrupy liquid or gum which is soluble in ether, alcohol, ligroin, and benzene. The substance (1.47 g.) was dissolved in ether (30-40 cc.) and phosphorus pentachloride (2.5 g.) was added to the solution. The subsequent treatment was similar to that of the bromophenyl-diphenylmethylhydroxylamine as given above.

A yield of 0.4229 g. of mixed aniline hydrochlorides was obtained from 1.47 g. of the base. A second rearrangement of 1.21 g. of the base gave 0.354 g. of the aniline salts.

A complete rearrangement would yield at most 0.37 g. of aniline hydrochloride, or 0.47 g. of chloroaniline hydrochloride per gram of substance.

A quantitative analysis of the aniline salts obtained from each of the rearrangements was made by the bromination method for their molar ratios.

Subst. 0.0794, 0.0767; cc. 0.1 *N* KBrO<sub>3</sub>, 25.13, 23.93.

Found: aniline hydrochloride, 38.41, 36.30; chloroaniline hydrochloride, 61.56, 63.70.

**Identification of the Anilines.**—A qualitative separation of the two anilines was made by the method of Stieglitz and Leech.<sup>1</sup> When separated, the aniline gave the violet color test with bleaching powder and the chloroaniline gave crystals which melted at 68-69°, and when they were mixed with pure chloroaniline they melted at 68-69° (pure chloroaniline melts at 69°).

**Identification of Chlorobenzophenone and Dichlorobenzophenone.**—

The ether was evaporated from the *p*-chlorobenzophenone and di-*p*-chlorobenzophenone solution, leaving a large bulk of flaky crystals. Preliminary tests with a mixture of known mono- and di-chlorobenzophenones showed that the latter is the less soluble in ligroin and that the two could be separated by virtue of this difference. The ketones obtained from the rearrangement were dissolved in a small quantity of warm ligroin. When a few crystals had separated from the solution, as it cooled, they were collected in a filter. They melted at 139° and when they were mixed with pure *p*-dichlorobenzophenone they melted at 141-142° (pure *p*-dichlorobenzophenone melts at 143°). The filtrate still containing the greater portion of the ketones, was evaporated to dryness and three-quarters of the residue again dissolved in ligroin. This process was repeated until the last extraction contained about one-eighth of the original ketone residue. About one-half of this was crystallized from the solution and the melting point of these crystals determined. They melted at 79-

<sup>1</sup> *Loc. cit.*, p. 296.

80°, and when they were mixed with pure *p*-chlorobenzophenone<sup>1</sup> they melted at 78–80°.

**Di-*p*-bromophenyl-phenylmethylhydroxylamine Hydrochloride**,  $(\text{BrC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{C.NH}_2\text{OH.Cl}$ . — Di-*p*-bromophenyl-phenylmethylchloride was prepared by Gomberg's method.<sup>2</sup> The corresponding carbinol,  $(\text{BrC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{COH}$ , which was first obtained, melted at 113.5° when recrystallized from ligroin. It melted at the same temperature when twice recrystallized. Gomberg gives the melting point as 110°. The chloride,  $(\text{BrC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{CCl}$ , was dissolved in benzene and added to a solution of hydroxylamine in alcohol. The molecular proportions of substances, and the method of procedure used in the previous preparations were repeated here. The alcohol and benzene were removed by distillation under diminished pressure and without the temperature rising above 60°. A gummy residue remained and consisted principally of the free base dibromophenyl-phenylmethylhydroxylamine. This base was extracted with ether and hydrogen chloride introduced into the solution. A small quantity of white precipitate separated out at first but it redissolved as the solution became more strongly acid. The acid and ether were now evaporated and a mobile liquid was left. Low boiling ligroin (b. p. 40–60°) was added to it and the mixture stirred. The liquid, which was but little soluble in the ligroin, began to solidify immediately. The di-*p*-bromophenyl-phenylmethylhydroxylamine hydrochloride thus formed is as soluble in methyl and ethyl alcohol and ether as is the dibromophenyl-phenylmethylchloride itself, but it is not soluble in ligroin, while the latter is. The salt was washed well with ligroin (b. p. 70–80°) and once with cold dilute hydrochloric acid. It reduces boiling Fehling's solution and softens at about 75°.

Subst. 0.2850, 0.3113; cc. 0.1 *N* AgNO<sub>3</sub>, 5.73, 6.31.

Calc. for  $(\text{BrC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{CNH}_2\text{OHCl} \cdot \text{HCl}$ , 7.73. Found: 7.34, 7.40.

**Rearrangement of Di-*p*-bromophenyl-phenylmethylhydroxylamine.** — The free base,  $(\text{BrC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{CNHOH}$ , was prepared from the hydrochloride in the usual way. It was obtained as a yellow viscous liquid. Some of the base (1.6 g.) was dissolved in 30 cc. of ether and 3 g. of phosphorus pentachloride added to the solution. The mixture was warmed at the boiling point of the ether for two hours. The imido-benzophenones appeared in that time as indicated by the yellow color of the mixture. The mixture was then subjected to hydrolysis and to the isolation of the ketones and the aniline hydrochlorides. The yield of the mixed aniline and bromoaniline hydrochlorides from the base (1.6 g.) was 0.4785 g. A second rearrangement of 1.11 g. base gave 0.3104 g. of mixed aniline salts. Theoretically one gram of base could give 0.30 g. aniline hydro-

<sup>1</sup> Kahlbaum's *p*-chlorobenzophenone melted at 77–78°.

<sup>2</sup> *Ber.*, 39, 3280 (1906).

chloride or 0.48 g. of bromoaniline hydrochloride. Each quantity of the mixed aniline hydrochloride was analyzed for the molar ratios of the anilines by the bromination method.

Subst. 0.0513, 0.0439; cc. 0.1 *N* KBrO<sub>3</sub>, 12.80, 11.04.

Found: aniline hydrochloride, 30.25, 31.05; bromoaniline hydrochloride, 69.76, 68.95.

**Identification of Aniline and Bromoaniline.**—The aniline and bromoaniline were separated exactly as were the bases from the rearranged *p*-bromophenyl-diphenylmethylhydroxylamine. The aniline oxalate, after separation from the bromoaniline salt, was made alkaline and tested with bleaching powder solution. The violet color confirmed the identity of the aniline. The less soluble bromoaniline oxalate was freed from the oxalic acid and crystallized from ether. The crystals melted at 62–63°, and, when they were mixed with pure bromoaniline, they melted at 63–64° (pure bromoaniline melts at 64°).

**Identification of Bromobenzophenone and Dibromobenzophenone.**—The ether solution of the ketones was evaporated to dryness in a current of air. Of the *p*-bromobenzophenone and *p*-dibromobenzophenone, the latter is the less soluble in ligroin (b. p. 70–80°) and by fractional crystallization from that solvent some of it was isolated. It melted at 167° and when it was mixed with synthetic dibromobenzophenone it melted at 167–168° (pure dibromobenzophenone melts at 172–173°). The ligroin solution containing the more soluble portion of the ketones was evaporated to dryness and the process for separating monochlorobenzophenone from dichlorobenzophenone was followed. The crystals thus isolated melted at 78–80° (pure *p*-bromobenzophenone melts at 82.5°).

***p*-Chlorophenyl-*p*-bromophenyl-phenylcarbinol**, (ClC<sub>6</sub>H<sub>4</sub>)(BrC<sub>6</sub>H<sub>4</sub>)-(C<sub>6</sub>H<sub>5</sub>)COH.—This carbinol and the corresponding chloride required for the next experiment are not described in the literature and probably have not been made. For the preparation of the carbinol, *p*-chlorobenzophenone was first obtained from benzoylchloride and chlorobenzene with the aid of the Friedel and Crafts reaction.<sup>1</sup> The chlorobenzophenone was converted into the dichloride by treatment with phosphorus pentachloride by the method used by Kekulé and Franchmont in converting benzophenone into benzophenone dichloride.<sup>2</sup> The dichloride was fractionally distilled.<sup>3</sup> Then, one molar proportion of the *p*-chlorobenzophenonedichloride and two to three of bromobenzene were placed on a steam bath in a round bottom flask with a reflux condenser attached, and to this solution 1.4 molar proportions of aluminum chloride were gradually added in portions of 5 to 10 g. After

<sup>1</sup> Gomberg, *B. r.*, 39, 3278 (1906).

<sup>2</sup> Mackenzie, *J. Chem. Soc.*, 69, 987 (1896).

<sup>3</sup> Overton, *Ber.*, 26, 28 (1893); Peterson, *Am. Chem. J.*, 46, 332 (1911).

all of the aluminum chloride had been added the mixture was heated two hours longer. It was then cooled and poured on ice and water to decompose the aluminum compound. The excess of bromobenzene was removed by steam distillation and the residue, a dark gum insoluble in water, was well washed with dilute hydrochloric acid to remove the aluminum hydroxide. The gummy residue was extracted with carbon disulfide, the carbon disulfide solution filtered, the filtrate dried over fused calcium chloride, and the solvent evaporated. The dark colored gum remaining was dissolved in warm ligroin (b. p. 70–80°) and the solution left in a cold place overnight. The carbinol separated out in light colored crystals. Recrystallization was twice repeated and the carbinol then melted at 91–93°.

0.2161 g. of the carbinol gave 0.4850 g. CO<sub>2</sub> and 0.0760 g. H<sub>2</sub>O.

Calc. for C<sub>19</sub>H<sub>14</sub>OCIBr: C, 61.03%; H, 3.77%. Found: C, 61.22%; H, 3.93%.

***p*-Chlorophenyl - *p*-bromophenyl - phenylmethylchloride**, (ClC<sub>6</sub>H<sub>4</sub>)-(BrC<sub>6</sub>H<sub>4</sub>)(C<sub>6</sub>H<sub>5</sub>)CCl.—The carbinol was converted into the chloride, (ClC<sub>6</sub>H<sub>4</sub>)(BrC<sub>6</sub>H<sub>4</sub>)(C<sub>6</sub>H<sub>5</sub>)CCl, by a stream of hydrogen chloride passed into a carbon disulfide solution of the carbinol. After the acid was added, the disulfide solution was dried over fused calcium chloride and filtered and the excess of acid and the carbon disulfide evaporated *in vacuo*. The chloride was left as a very viscous liquid. When it was hydrolyzed with excess of 0.1 *N* KOH and the excess of alkali was titrated with 0.1 *N* HCl, it showed 93% of the calculated amount of chlorine. Attempts to crystallize the chloride were, at first, unsuccessful and for this reason the liquid chloride was used in making the hydroxylamine preparation. Later, however, the chloride crystallized from low boiling ligroin. The solid was twice recrystallized from higher boiling ligroin by inoculation of the solution with the crystals first obtained. It now melted at 69–72°.

Subst. 0.2229; cc. 0.1 *N* KOH, 5.44. Calc. for (C<sub>19</sub>H<sub>13</sub>ClBr)Cl: 9.05% Cl (hydrolyzable). Found: 8.67%.

***p*-Chlorophenyl-*p*-bromophenyl-phenylmethylhydroxylamine Hydrochloride**, (ClC<sub>6</sub>H<sub>4</sub>)(BrC<sub>6</sub>H<sub>4</sub>)(C<sub>6</sub>H<sub>5</sub>)CNH<sub>2</sub>OHCl.—The chlorophenyl-bromophenyl-phenylmethylchloride (7 g.) was dissolved in benzene (200 g.) and condensed with a saturated alcoholic solution of hydroxylamine. The solvents were removed by evaporation. The gummy residue remaining was extracted with ether and the ether solution made strongly acid with hydrogen chloride. The hydrogen chloride salt of the hydroxylamine derivation does not precipitate out from the ether solution. After the ether and excess acid were evaporated the triarylmethylhydroxylamine hydrochloride remained as a syrupy liquid; it was treated with low boiling ligroin and the mixture stirred with a glass rod. The salt began to solidify immediately. It is insoluble in ligroin and was purified by being washed well with that solvent. It cannot be washed with dilute

hydrochloric acid as it forms a soft, sticky mass as soon as brought into contact with the water. It is soluble in alcohol, ether, and chloroform. It reduces boiling Fehling's solution and softens at  $45^{\circ}$ , but has no true melting point.

Subst. 0.4155; cc. 0.1 *N* AgNO<sub>3</sub>, 9.41. Calc. for (C<sub>19</sub>H<sub>16</sub>NOCIBr)HCl: Cl, 8.58%. Found: 8.27.

A yield of 5 g. of this salt was obtained from the chloride (7 g.) used.

**Rearrangement of *p*-Chlorophenyl-*p*-bromophenyl-phenylmethylhydroxylamine.** The free base of the salt just described was obtained as a yellow syrupy substance, which under low pressure began to expand as a kind of foam and to spread throughout the beaker as a viscous gum. This behavior is characteristic of all these bases.

Some of the base (2.37 g.) was dissolved in 30-40 cc. of ether and phosphorus pentachloride (4 g.) added to the solution. In twelve hours a slight change in color to yellow indicated a slow formation of the imido ketones at room temperature. The mixture was then heated for two hours at the temperature of boiling ether to complete the rearrangement. The mixture was next subjected to hydrolysis of the imido ketones,<sup>1</sup> and the isolation of the benzophenones and the anilines carried out in the manner described for the previous rearrangements.

The yield of the mixed aniline, chloroaniline and bromoaniline hydrochlorides from the 2.37 g. of base was 0.626 g. In a second rearrangement of 1 g. of base 0.1595 g. of the aniline salts was obtained. A complete rearrangement would give 0.33 g. of aniline hydrochloride, or 0.42 g. of chloroaniline hydrochloride or 0.54 g. of bromoaniline hydrochloride per gram of substance.

A trace of the aniline mixture was made alkaline and treated with bleaching powder solution. A violet color was produced, proving the presence of the unsubstituted aniline. Another part of the aniline mixture was freed from hydrogen chloride and precipitated from ether solution with oxalic acid. The precipitate showed the presence of halogen when heated in a bunsen flame with copper oxide and also when fused with sodium and tested with silver nitrate solution.

The mixed aniline hydrochlorides obtained from each of the rearrangements were analyzed volumetrically for the determination of the molar ratios of the three salts: the hydrochlorides of aniline, chloroaniline and bromoaniline. The bromination and the Volhard methods were used jointly to give sufficient data for the calculations.<sup>2</sup>

<sup>1</sup> Three imido ketones were present, (ClC<sub>6</sub>H<sub>4</sub>)(BrC<sub>6</sub>H<sub>4</sub>)C = N(C<sub>6</sub>H<sub>5</sub>), (ClC<sub>6</sub>H<sub>4</sub>)(C<sub>6</sub>H<sub>5</sub>)C = NC<sub>6</sub>H<sub>4</sub>Br, and (BrC<sub>6</sub>H<sub>4</sub>)(C<sub>6</sub>H<sub>5</sub>)C = NC<sub>6</sub>H<sub>4</sub>Cl.

<sup>2</sup> The reliability of this method of analysis was determined with a known mixture of the three hydrochlorides. For the Volhard method a larger quantity of the mixed salts was used than for the bromination method, as the data show. The method is reliable only to within 5%.

0.0754 g. of the mixed hydrochlorides required 21.68 cc. of 0.1 *N* KBrO<sub>3</sub>; and 0.2128 g. required 12.85 cc. 0.1 *N* AgNO<sub>3</sub>. Found: aniline hydrochloride, 38.0; chloroaniline hydrochloride, 28.8; and bromoaniline hydrochloride, 33.2.

0.0318 g. of the mixed hydrochlorides required 9.24 cc. of 0.1 *N* KBrO<sub>3</sub>, and 0.1276 g. of the same mixture required 7.85 cc. of 0.1 *N* AgNO<sub>3</sub>. Found: aniline hydrochloride, 36.2; chloroaniline hydrochloride, 38.9; and bromoaniline hydrochloride, 24.9.

I wish to express my indebtedness to Professor Stieglitz, not only for the constant interest that he has shown in this investigation and the many helpful suggestions, but also for the encouragement and his kindness toward me personally.

CHICAGO, ILL.

## THE MOLECULAR REARRANGEMENT OF TRIPHENYLMETHYLHALOGENAMINES.<sup>1</sup>

BY ISABELLA VOSBURGH.<sup>2</sup>

Received August 1, 1916.

The characteristic Hofmann rearrangement<sup>3</sup> of acid halogen amides, RCONH(Hal), to derivatives of amines RNH<sub>2</sub> forms the basis of the well-known general method of preparation of amines.<sup>1</sup> The rearrangement<sup>5</sup> is analogous in many important respects to the "Beckmann" rearrangement of oximes.<sup>6</sup> When it was found in this laboratory by Stieglitz and Reddick<sup>7</sup> that triphenylmethylhydroxylamine undergoes a rearrangement quite as smoothly as any oxime, Professor Stieglitz proposed to me that I undertake under his direction a parallel investigation on the possibility of effecting rearrangements of the triphenylmethylhalogenamines, Ar<sub>3</sub>CNH(Hal). The investigation of these particularly simple halogen amine derivatives promised to shed light on a number of questions connected with the rearrangements: of those taken up in this in-

<sup>1</sup> See a preliminary report (abstract) by Stieglitz and Vosburgh, *8th Intern. Congr. Appl. Chem.*, **25**, 445 (1912); *Ber.*, **46**, 2151 (1913).

<sup>2</sup> The work reported on in this paper formed the basis of a dissertation submitted to the University of Chicago in part fulfillment of the requirements for the Ph.D. degree. Before Miss Vosburgh could come up for her final examinations, she was the victim of a fatal automobile accident, Dec. 4, 1914, near Mt. Holyoke, Mass. The present posthumous report, except for editing, is in the form in which it was written by Miss Vosburgh.—J. STIEGLITZ.

<sup>3</sup> A. W. Hofmann, *Ber.*, **14**, 2725 (1882); **15**, 408 (1883), etc.

<sup>4</sup> Hofmann, *loc. cit.*; Hoogewerff and van Dorp, *Rec. trav. chim.*, **6**, 373 (1887); **8**, 173 (1889), etc.; Lengfeld and Stieglitz, *Am. Chem. J.*, **15**, 215, 504 (1893); Elizabeth Jeffreys, *Ber.*, **30**, 898 (1897); *Am. Chem. J.*, **22**, 14 (1899).

<sup>5</sup> The analogy was pointed out by Hoogewerff and van Dorp, *loc. cit.*; and by Stieglitz, *Am. Chem. J.*, **18**, 751 (1896).

<sup>6</sup> Beckmann, *Ber.*, **19**, 988 (1886), etc.

<sup>7</sup> See Stieglitz, Reddick and Leech, *8th Intern. Congr. Appl. Chem.*, **25**, 444 (1912).

vestigation, we have, first, that it promised to lend itself to a further study of the extent to which Stieglitz's theory<sup>1</sup> of the related "Hofmann-Beckmann-Lossen<sup>2</sup>-Curtius<sup>3</sup> rearrangements would hold in the new group of rearrangements, if such should indeed be found to occur. In the second place, it would contribute to a knowledge of the nature of the metal salts that are the active components in the Hofmann rearrangement of acid halogen amides, in which the question of the nature of the salts involved is complicated by the formation of tautomeric salts.

The results obtained have brought definite information concerning both of the questions outlined. The Stieglitz theory<sup>4</sup> of these rearrangements ascribes the rearrangements to the intermediate formation of univalent nitrogen derivatives (*e. g.*,  $\text{RCO.N}$  from  $\text{RCO.NH(Hal)}$ ) which are considered to be the real rearranging substances.<sup>5</sup> The alkyl or aryl group  $\text{R}$  is subsequently torn from the carbon atom by virtue of the powerful unsaturated affinities of the univalent nitrogen atom. We have, for instance,  $\text{RCO.N} \longrightarrow \text{CO} : \text{NR}$ .

The reagents selected to effect the rearrangement of the various classes of compounds are just those which one would anticipate would be necessary to facilitate the formation of the univalent nitrogen derivative from the original material.

In agreement with these considerations we have found that triphenylmethylhalogenamines readily undergo the same kind of rearrangement under the influence of *bases*.

It is of interest to note how, once again, the relation of the reagent to the compound that is to be rearranged is shown and to compare this action with the rearrangement of triphenylmethylhydroxylamine under the influence of phosphorus pentachloride,<sup>6</sup>

It has been found, further, that triarylmethyldichloroamines, like the acid azides  $\text{RCO.N(N}_2\text{)}$ , require simply heat to undergo the rearrange-

<sup>1</sup> *Am. Chem. J.*, **18**, 751 (1896); **29**, 49 (1901).

<sup>2</sup> *Ann.*, **161**, 359 (1872), etc.; L. W. Jones, *Am. Chem. J.*, **48**, 1 (1912).

<sup>3</sup> *Ber.*, **27**, 778 (1895); *J. prakt. Chem.*, **50**, 289 (1894), etc.

<sup>4</sup> The theory is given in detail in *Am. Chem. J.*, **29**, 49 (1901), and only one or two of its most salient features need be considered here.

<sup>5</sup> The theoretical possibility of a direct exchange of  $\text{R}$  for the halogen atom in certain cases is not excluded by the theory, which emphasizes simply that the path over the univalent nitrogen derivatives seems to be the easiest and the ordinary one and possibly in the majority of cases the only path. See Stieglitz and Leech, *Ber.*, **46**, 2147 (1913) and Stieglitz and Leech, *THIS JOURNAL*, **36**, 272 (1914).

<sup>6</sup> Stieglitz, Reddick and Leech, *loc. cit.*

ment, chlorine being given off and the rearrangement taking place with explosive violence at 120–130°.

Again, we have found that alkylated triarylchloroamines, *e. g.*,  $R_3CN(CH_3)Cl$ , in which the formation of univalent nitrogen would be very greatly obstructed, or altogether prevented, do not undergo the rearrangement<sup>1</sup> when treated exactly in the same way as the halogen amines,  $R_3CNH(Hal)$  or as the dihalogen amines,  $R_3CNCl_2$ .

All of these results, therefore, show that the above theory of the rearrangements is borne out by the behavior of triarylmethylhalogenamines, as thus far observed.

Closely related to these questions is the following: all attempts to effect a rearrangement of chloroimidobenzophenone,  $(C_6H_5)_2C : NCl$ , by the action of heat, or of alkalis, under various conditions have proved unsuccessful,<sup>2</sup> although this is the very compound which one should expect to be readily rearranged, if the rearrangements involve simply direct exchanges of radicals, as is assumed by Beckmann and some other prominent chemists.<sup>3</sup>

This is in interesting contrast to the ready rearrangement of the closely related triphenylmethylbromoamine,  $(C_6H_5)_3CNHBr$ , the essential difference between the two compounds being that the latter by the loss of hydrogen bromide can give a univalent nitrogen derivative, the former cannot; the chloroimide corresponds in that respect essentially to  $(C_6H_5)_3CN(CH_3)Cl$ , which also does not rearrange, as has been stated above. Now, the behavior of triphenylmethyldichloroamine,  $(C_6H_5)_3CNCl_2$ , in rearranging under the influence of heat suggested<sup>4</sup> that the action of chlorine on the chloroimide might lead to the formation of an intermediate addition product which would correspond in structure to triphenylmethyldichloroamine and which might lose chlorine from the nitrogen and then rearrange.

<sup>1</sup> Stieglitz and Leech (THIS JOURNAL, 36, 272 (1914)) have recently made the important observation that the analogous  $(C_6H_5)_3CN(CH_3)OH$  is rearranged to a methylaniline derivative.

<sup>4</sup> Stieglitz and Leech, *Ber.*, 46, 2147 (1913).

Under the conditions tried by us, namely, the action of chlorine at  $120^{\circ}$  to  $150^{\circ}$ , no rearrangement of this nature was, however, observed. Possibly at that high temperature no measurable absorption of chlorine by the  $\text{—C:N—}$  group takes place.

Concerning the second question raised in connection with this investigation (see above), the relations, briefly are as follows: the rearrangement of acid halogen amides is effected by bases, (alkalies,<sup>1</sup> calcium oxide,<sup>1</sup> silver carbonate,<sup>1</sup> alkali alcoholates,<sup>2</sup> etc.) and there is no doubt that the active substances leading presumably primarily to the formation of acylimides,  $\text{RCO.N}$ , as just now discussed, are the metal salts of the acid halogen amides. Now, these salts may have either of two structures—they may be nitrogen salts,  $\text{RCO.NMe(Hal)}$  or oxygen salts,  $\text{RC(OMe)N.Hal}$ . The first structure was assumed for them by their discoverer, Hofmann,<sup>3</sup> by Hoogewerff and van Dorp,<sup>3</sup> Lengfeld and Stieglitz<sup>3</sup> and others of the early workers in this field. The second structure was suggested for them by Hantzsch<sup>4</sup> as the result of his study of acid chloroamides as tautomeric compounds, and by Stieglitz, in some later work, on the basis of the formation of oxygen ethers by the methylation of the acylchloroamides with diazomethane.<sup>5</sup> As a result of the investigations of Ley,<sup>6</sup> Hantzsch,<sup>7</sup> Baly, Marsden and Stewart,<sup>8</sup> and Acree<sup>9</sup> on tautomeric salts, it seems now reasonably certain that we have both salts present together in solution in a condition of equilibrium. It is, therefore, uncertain which form of salt, nitrogen salt,<sup>10</sup> or oxygen salt, is directly involved in the rearrangement. In our present investigation the rearrangement of triarylmethylhalogenamines is also effected by bases and there is again no question as to the action being due to the formation of salts, which favor the subsequent reactions that lead to the rearrangements more than do the hydrogen derivatives. In the present instance, these salts can only have the structure  $\text{R}_3\text{CNMe(Hal)}$ , that is, they must be nitrogen salts. This result makes it quite probable that the active components in the rearrangement of the salts of acid halogen amides is also the nitrogen salt,  $\text{RCO.NMe(Hal)}$ , in spite of the fact that it is most likely present in considerably smaller proportions than the oxygen salt, the equilibrium favoring the oxygen salt, according to the work of Hantzsch.

### Experimental Part.

**Triphenylmethylbromoamine**,  $(C_6H_5)_3CNHBr$ .—The first halogen derivative of a triarylmethylamine prepared was triphenylmethylbromoamine. Hemilian and Silberstein<sup>1</sup> had previously studied the effect of halogens upon triphenylmethylenamines and had concluded that compounds containing from two to seven atoms of the halogen resulted. They gave the formula  $(C_6H_5)_3CNH_2Br_2$  to the bromine derivative. For the present investigation triphenylmethylchloride, obtained by the Friedel and Crafts<sup>2</sup> method, was converted into the amine hydrochloride by the Elbs method, with the modification that ammonia was passed repeatedly into the benzene solution of the chloride in order to obtain a satisfactory yield. The free base was obtained from the hydrochloride by precipitation by ammonium hydroxide in aqueous solution, and was brominated by treatment with bromine and aqueous sodium hydroxide,

The preparation is not an easy one and the observation of the following details will be found useful: Bromine (1.39 g.), weighed in a small bulb with capillary, was added to the dry amine (2.1 g.). The mixture, placed in an ice and salt preparation, was treated with a few drops of chloroform and a 10% solution of sodium hydroxide (3.25 cc.). The mixture was shaken for fifteen minutes, then more chloroform was added to it, and the two layers separated by means of a separatory funnel. The chloroform solution was dried a few minutes with calcium chloride and the chloroform then immediately evaporated in a blast of air. A yellow gum remained, part of which dissolved on the addition of ligroin (b. p. 70–80°). The evaporation of the ligroin in the cold gave a yellowish substance, which is likely to remain semi-solid. In one case, however, a few large crystals were obtained, and, thereafter, inoculation made the preparation of a crystalline product comparatively simple. By repeated recrystallizations from ligroin, a compound melting at 63° was obtained. The triphenylmethylbromoamine thus prepared, was analyzed by titration of the iodine liberated according to the equation

Subst., 0.0746; cc. 0.1 N  $Na_2S_2O_3$ , 4.39.

Calc. for  $C_{19}H_{15}NBr$ : Br, 23.64%. Found: 23.57.

The structure of triphenylmethylbromoamine was confirmed as follows:<sup>3</sup> Treatment of the bromoamine with dry hydrogen chloride gas in ether solution precipitated triphenylmethylamine hydrochloride. This was identified by its melting point (244°), and by its conversion into the

<sup>1</sup> *Ber.*, 17, 748 (1884).

<sup>2</sup> *Ibid.*, 33, 3147 (1900).

<sup>3</sup> See Stieglitz and Earle, *Am. Chem. J.*, 30, 399, 412 (1903); Hilpert, *Ibid.*, 40, 155 (1908); Peterson, *Ibid.*, 46, 325 (1911).

free base, which melted at  $102^{\circ}$ , when heated by itself or mixed with synthetic triphenylmethylamine, we have:

**The Rearrangement of Triphenylmethylbromoamine.**—*1. By Treatment with Soda-lime.* Preliminary experiments showed that when the bromoamine is heated with soda-lime over a flame, a sudden action occurs with the evolution of brown fumes and the formation of a bright yellow substance. From this mass the yellow substance phenylimidobenzophenone may be extracted and identified by hydrolysis, the aniline formed being readily recognized by the chloride of lime test. Occasionally, however, this method gave negative results, probably because the mixture of bromoamine and soda-lime had not been heated sufficiently high.

The following method gives uniformly good results: Half a gram of the bromoamine is mixed with a gram of finely powdered soda-lime and the mixture is heated in a hard glass test tube by immersion in a metal-bath kept at  $110$ – $120^{\circ}$ . As soon as the intense yellow product is formed, a small part of the mixture is tested by being boiled with an excess of hydrochloric acid, the resulting solution being neutralized and tested with calcium hypochlorite. If a strong aniline reaction is shown, the remainder of the mass is extracted with benzene. The evaporation of the solvent leaves crude phenylimido-benzophenone, melting at  $89^{\circ}$ . Recrystallized from absolute alcohol, it formed yellow crystals which softened a little at  $106^{\circ}$  but melted at  $110^{\circ}$ . A synthetic preparation,<sup>1</sup> obtained from aniline and benzophenonedichloride, gave a melting point of  $111$ – $112^{\circ}$ . A mixture of this preparation with the product obtained by the rearrangement of the bromoamine melted at  $111^{\circ}$ . Their identity is thus established.

In confirmation of the structure of the rearrangement product, 0.32 g. of it was warmed with alcohol and dilute hydrochloric acid for half an hour, water was then added to the mixture and the precipitate which formed was collected and identified as benzophenone by its melting point,  $46$ – $48^{\circ}$ , which was not changed by the addition of synthetic benzophenone to the product. The filtrate from the benzophenone yielded aniline hydrochloride, which was converted into the chloroplatinate for analysis.

Subst., 0.1247, Pt 0.0404. Calc. for  $\text{C}_{12}\text{H}_9\text{N}_2\text{PtCl}_6$ : Pt, 32.78%. Found: 32.41.

The formation of phenylimidobenzophenone by the action of soda-lime on triphenylmethylbromoamine has thus been established beyond question

*2. By Treatment with Calcium Oxide.*—Some of the bromoamine (0.8 g.) was mixed with pulverized calcium oxide (0.8 g.) and the mixture gently heated in a hard glass test tube. The benzene extract was dried and evaporated *in vacuo*. Some of the yellow-brown substance obtained was

<sup>1</sup> Pauly, *Ann.*, 187, 198 (1877).

treated without further purification with hot dilute acid. The neutralized solution was tested with some calcium hypochlorite solution for aniline and the characteristic color reaction for aniline was shown intensely.

3. *By Treatment with Sodium Methylate.*<sup>1</sup>—Owing to the reducing power of sodium alcoholates and the sensitiveness of bromoamines to reducing agents, the rearrangement of triphenylmethylbromoamine by this reagent was expected to be accompanied by a partial reduction of the compound to triphenylmethylamine. Such a reduction does take place to a certain extent, but no difficulty was encountered in showing that a large part of the substance is rearranged when it is treated with a methyl alcohol solution of sodium methylate.

Two grams of bromoamine were added to a hot solution of sodium methylate, prepared from 1 g. sodium and 40 g. of methyl alcohol. The bromoamine melted, forming an oil which soon went into solution. In fifteen minutes a little of the solution gave the test for aniline, when treated as described above. The whole solution was then cooled and diluted with twice its volume of water. A yellow oil was formed which, on standing overnight, gave yellow crystals of phenylimidobenzophenone and a little of a white powder (benzophenone). The solids were treated with hot dilute acid and a small amount of recovered triphenylmethylamine hydrochloride was removed by filtration. Alkali was added to the solution and the aniline was distilled over with steam. Benzoyl chloride was added to the distillate and a white substance resulted, which on recrystallization gave 0.7 g. of benzanilide, melting at 158–160°. A mixture of the substance with synthetic benzanilide gave the same melting point.

The rearrangement also takes place if the bromoamine is added to a cold sodium methylate solution, but it is necessary to heat the mixture on the water bath for one-half hour instead of fifteen minutes, and the yield of benzanilide is not as good.

**Benzotriphenylmethylanide**,  $C_6H_5CO.NHC(C_6H_5)_3$ .—In order to become familiar with the properties of the benzoyl derivative of triphenylmethylamine itself, which might have been met with in the preceding experiment, it seemed best to prepare the compound. For this purpose, the amine (3 g.) was dissolved in 30 cc. of absolute ether and treated with a gram of benzoyl chloride. The mixture was shaken and allowed to stand for forty-eight hours. Since the odor of benzoyl chloride was still perceptible, the mixture was heated in a water bath with reflux for fifteen minutes. The ether was then filtered off and the precipitate dried. Two substances could be discerned: the hydrochloride of the amine and the benzoylated amine. Hot water removed the hydrochloride. Yellow crystals remained, a further portion of which was obtained by evaporation

<sup>1</sup> Cf. Lengfeld and Stieglitz, *loc. cit.*

of the ether solution. Recrystallization of the product from alcohol gave white crystals melting at 160–162°.

Subst., 0.2619, cc. moist N, 23°, 752.7 mm.: 8.99. Calc. for  $C_{20}H_{21}NO$ : N, 3.86%. Found: 3.84.

**Triphenylmethyldichloroamine**,  $(C_6H_5)_3CNCl_2$ .—Hemilian and Silberstein<sup>1</sup> found that the passing of dry chlorine into a benzene solution of triphenylmethylamine gave ammonium chloride and triphenylmethylcarbinol. I obtained quite different results when the amine was treated with hypochlorous acid in an attempt to prepare the chloroamine corresponding to the bromoamine just described. It was found that a dichloroamine could readily be isolated. This compound apparently is more stable than the monochloroamine. Some monochloroamine is probably formed but it could not be isolated and identified despite many efforts to do so (see below). Berg<sup>2</sup> observed similar relations for chloroamines and dichloroamines of amines of the aliphatic series.

We have:

Hypochlorous acid was prepared according to Graebe's<sup>3</sup> method: the chlorine obtained from 13 cc. of concentrated hydrochloric acid and potassium permanganate (2 g.) was passed into an ice-cold solution of anhydrous sodium carbonate (3 g.) in 40 cc. of water. To this cold hypochlorous acid solution was added a solution of triphenylmethylamine (1 g.) in 5 cc. of alcohol and 10 cc. of water. This mixture was shaken for ten minutes in the freezing bath. Chloroform was then added to dissolve the white cheesy substance which had separated out, the chloroform solution was drawn off and the solvent evaporated in a blast of air. The addition of a little ligroin to the residue, and the continued scratching of the substance in the cold gave a white substance melting at 128°. This was analyzed iodometrically.

Subst., 0.0397 g. Cl, 0.00825. Calc. for  $C_{19}H_{18}NHCl$ : Cl, 12.09%;  $C_{19}H_{18}NCl_2$ : Cl, 21.64%. Found: 20.79.

Various attempts were made to prepare the monochloroamine by the mixing of theoretical amounts of the dichloroamine and the free base. Analysis and melting point determinations lead to the conclusion that if the monoderivative is formed at all, it is unstable, reverting to the amine and the dichloroamine.

**Rearrangements of Triphenylmethyldichloroamine.**—*I. By Heat.* Triphenylmethyldichloroamine (0.2 g.) was heated in a hard glass test tube to 132° in a metal bath. There was a slight explosion, and the odors of chlorine and hydrogen chloride and a penetrating odor, similar to that

<sup>1</sup> *Ber.*, 17, 757 (1884).

<sup>2</sup> *Ann. chim. phys.*, [7] 3, 289 (1894).

<sup>3</sup> *Ber.*, 35, 2754 (1902).

of isonitriles,<sup>1</sup> were detected. The contents of the tube were dissolved in alcohol, water and acid added and the solution heated on a water bath with reflux for one hour. A small amount of a dark brown oil separated. The solution was poured off from it, and the oil extracted with ether. On evaporation of the solvent the characteristic crystals of benzophenone were obtained, melting at 46°, alone, and when the crystals were mixed with synthetic benzophenone.

The acid solution was made alkaline, and again extracted with ether. Anhydrous oxalic acid was added to the dried extract and the oxalates of aniline and chloroaniline were precipitated. The mixture of oxalates was treated with cold water, the chloroaniline oxalate remaining undissolved. The oxalate solution when treated with alkali and chloride of lime solution gave a splendid aniline test. From the insoluble oxalate, treatment with alkali and ether gave *p*-chloroaniline melting, alone, at 67°, and at 69° when mixed with synthetic *p*-chloroaniline (m. p. 69°). With chloride of lime solution it produced a yellow color analogous to that obtained with *p*-chloroaniline. The formation of *p*-chloroaniline was evidently due to the chlorination of the phenyl group previous to, after, or during, its passage from the carbon to the nitrogen atom. The amount formed was very small.

2. *By Treatment with Soda-lime.*—The dichloride (0.2 g.) was intimately mixed with dry soda-lime (3 g.) and the mixture heated in a metal bath. At 132° a white smoke was given off, in which the odor of chlorine could be discerned. The benzene extraction of the residue was brown and on evaporation gave yellow-brown crystals. Recrystallization from hot absolute alcohol gave yellow crystals of phenylimidobenzophenone, melting at 109° alone, or at 110°, when mixed with the synthetic product. The soda-lime prevented any appreciable chlorination of a phenyl group, and no chloroaniline was obtained.

**Triphenylmethylchloromethylamine**,  $(C_6H_5)_3CNCl(CH_3)$ .—Triphenylmethylchloromethylamine was the next object of investigation with the view of determining whether the introduction of an alkyl radical into the amine group would prevent the rearrangement of a chloro- or bromoamine by interfering with the formation of a univalent nitrogen derivative.

Considerable difficulty was experienced in preparing methyltriphenylmethylamine from which the chloroamine has to be made. It was first made according to the method of Hemilian and Silberstein<sup>2</sup> by passing dry methylamine gas into a hot benzene solution of triphenylmethylchloride or bromide. The methylamine salt was removed by filtration and

<sup>1</sup> It will be recalled that a similar odor of isonitrile is observed when phenylhydroxylamine is heated. (Bamberger, *Ber.*, 32, 62; 33, 3605.) In both of these cases the odor may be due to a free univalent nitrogen derivative  $C_6H_5N:$  and  $(C_6H_5)_3CN$ .

<sup>2</sup> *Ber.*, 17, 745 (1884).

the filtrate evaporated to dryness. Recrystallization of the residue from alcohol gave a small yield of the amine and some ethoxytriphenylmethane  $(C_6H_5)_3COC_2H_5$ . With other solvents the yield was better but at no time was it very good. It was decided to try the preparation with sodium methylate and methylamine hydrochloride, following the method used successfully by Mothmer<sup>1</sup> and by Stieglitz and Leech<sup>2</sup> in the preparation of triphenylmethylhydroxylamine. Methylamine hydrochloride (2.9 g.) was added to a concentrated solution of sodium methylate obtained from sodium (1 g.) and methyl alcohol (9 g.). After the precipitation of sodium chloride, triphenylmethylchloride (4.6 g.) dissolved in benzene was added and the mixture shaken for one-half hour. The precipitated methylamine hydrochloride was recovered by filtration and the filtrate taken to dryness in a vacuum desiccator. This must be done slowly and with only a slight reduction of pressure, as the solution shows a great tendency to spatter. The residue was treated with dry ether and dry hydrogen chloride gas. A fine powder, triphenylmethylmethylamine-hydrochloride,  $(C_6H_5)_3CN(CH_3)H_2Cl$  (m. p.  $216^\circ$ ), was obtained. It was converted into the free base with potassium hydroxide solution and the base extracted with ether. Evaporation of the solvent gave a substance which on recrystallization from ligroin melted at  $73^\circ$ .<sup>3</sup>

For the conversion of the amine into the chloroamine, the hydrochloride (2 g.) was dissolved in 10 cc. of 50% alcohol and the solution poured into a hypochlorous acid solution made from 4 g. of chlorine and 6 g. of anhydrous sodium carbonate, to which had been added 2 g. of potassium carbonate. The cheesy substance formed was dissolved in chloroform, the solution was separated and brought to dryness in a desiccator. The residue was slightly yellow, but was not recrystallized. It melted at  $102-104^\circ$ .

Subst., 0.2777, Cl 0.03136. Calc. for  $C_{20}H_{18}NCl$ : Cl, 11.52%. Found: 11.30.

When hydrogen chloride gas was passed into an ether solution of the chloroamine, chlorine was given off and triphenylmethylmethylamine-hydrochloride was precipitated quantitatively. This proves the structure of the compound to be  $(C_6H_5)_3CNCl(CH_3)$ .

**Attempts to Rearrange Methyltriphenylmethylchloroamine.**—1. *By Heat.* Some of the chloroamine (0.4 g.) was placed in a hard glass test tube and heated in a metal bath. The substance melted at  $102^\circ$ ; the temperature was raised to  $130-135^\circ$  and maintained there for four minutes. On cooling, the slightly colored gum hardened; it was dissolved in ligroin and the original white substance melting at  $102-104^\circ$  was obtained in practically a quantitative yield. There were no signs of chemical action.

<sup>1</sup> *Ber.*, 37, 3152 (1904).

<sup>2</sup> *THIS JOURNAL*, 36, 272 (1914).

<sup>3</sup> Hemilian and Silberstein, *loc. cit.*, give the melting point as  $73^\circ$ .

2. *By Treatment with Soda-lime.*—Some of the methyltriphenylmethylchloroamine (0.6 g.) was mixed with powdered soda-lime (0.6 g.). The mixture was placed in a hard glass test tube and heated at 140° for five minutes. The only visible sign of reaction was the darkening of the soda-lime. When cool, water was added to the mixture, a part of the extract was made neutral and tested with calcium hypochlorite solution. No trace either of the purple test for aniline or of the blue color due to methylaniline<sup>1</sup> was observed. Nor was there any color reaction when the rest of the aqueous extract was boiled with acid, the solution made neutral and then tested as above.

The residue left by the water was boiled with dilute hydrochloric acid; a brown substance resulted which was contaminated with calcium oxide and melted at 184–190°. It was purified by treatment with potassium hydroxide solution, and extraction with ether. Hydrogen chloride gas was run into the ether extract, and a substance resulted, which melted at 216° when heated by itself or when mixed with methyltriphenylmethylamine hydrochloride. This shows that the chloroamine was converted back into the amine either by the action of the soda-lime

or by the subsequent action of hydrochloric acid,

No product of a rearrangement could, therefore, be detected.

3. *With Calcium Oxide.*—The methylchloroamine (0.5 g.) was mixed with powdered calcium oxide (0.6 g.) and treated as with soda-lime, save that the temperature was maintained at 130–140° for forty-five minutes. The tests with chloride of lime solution were made as previously and failed to show the slightest trace either of aniline or methylaniline. From the residue, methyltriphenylmethylamine was recovered as before. Therefore, no traces of any molecular rearrangement could be observed.

4. *By Destructive Distillation.*—Some of the methylchloroamine (0.6 g.) was placed in a small retort and heated in a metal bath. The end of the tube extended into acidulated water. At 180° the melted substance began to fume, and as the temperature was raised to 250° a gas was given off which smelled like hydrogen chloride. A part of the water solution was made neutral and tested with hypochlorite solution, but no indications of the presence even of traces of aniline or methylaniline were observed. The rest of the solution was evaporated, and no residue remained, which proved that the distillate contained no hydrochloride of aniline, methylaniline or methylamine.

The residue in the retort was heated with acid and part of it tested in slightly alkaline solution with chloride of lime solution. There were

<sup>1</sup> P. N. Leech, *THIS JOURNAL*, 35, 1042 (1913).

no color reactions. The remainder of the acid solution was treated with alkali and extracted with ether. The ether solution was saturated with hydrogen chloride gas, but there was no precipitate. It is evident that the compound was destroyed by heat, but there were no evidences of a molecular rearrangement leading to the formation of an aniline or methyl-aniline derivative.

***p*-Chlorophenyldiphenylmethylamine**,  $(p\text{-ClC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{CNH}_2$ .—The behavior of chlorophenyldiphenylmethylchloroamine was next investigated as a first step toward studying the influence of substitution groups in the phenyl groups in determining which of the aryl groups would pass from the carbon to the nitrogen in this rearrangement.

For the preparation of *p*-chlorophenyldiphenylmethylamine, which is not described in the literature, the corresponding chloride was first prepared according to the method of Gomberg<sup>1</sup> from benzophenonedichloride, chlorobenzene, and aluminium chloride. It was recrystallized from ligroin and melted at 86–89°.

Some of the substance (5.0 g.) was dissolved in hot benzene and dry ammonia gas was run into the solution. The addition of a little absolute alcohol aided the precipitation of ammonium chloride. After the treatment with ammonia gas had been continued for at least one-half hour, the solution was filtered and heated slightly to remove excess of ammonia gas; then dry hydrogen chloride gas was run into it. Part of the amine hydrochloride was precipitated, and the rest was obtained by evaporation of the benzene solution. A better yield resulted when the benzene solution saturated with ammonia gas was filtered to remove the ammonium chloride, the filtrate taken to dryness, the residue extracted with ether and the solution saturated with hydrogen chloride gas. The *p*-chlorophenyldiphenylmethylamine hydrochloride was precipitated, in part, and recovered in part by evaporation of the ether solution.

Some of the hydrochloride was treated with alkali to liberate the base; the ether extract of the latter gave a gum, which all attempts failed to convert into a crystallized solid. An analysis was, therefore, made of the hydrochloride, which was purified by conversion into the free base, the oxalate, the free base again and finally the hydrochloride. The latter melted at 185–186°. It was used for the preparation of the chloroplatinate; the latter was found to contain one molecule of water of crystallization and to melt at 155°.

Subst., 0.1587 g., heated three times, for five minutes each to 100–120° gave a constant weight of 0.1555 g. Calc. for 1 molecule  $\text{H}_2\text{O}$ :  $\text{H}_2\text{O}$ , 1.77%. Found: 2.01.

(Anhydrous) 0.1528: Pt, 0.0296. Calc. for  $\text{C}_{18}\text{H}_{14}\text{N}_2\text{Cl}_2\text{Pt}$ : Pt, 19.57%. Found: 19.37.

***p*-Chlorophenyl-diphenylmethyldichloroamine**,  $(\text{ClC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{CNCl}_2$ .—One gram of the amine hydrochloride was added to a mixture of two

<sup>1</sup> Ber., 39, 3278 (1906).

grams of potassium carbonate and of hypochlorous acid, prepared from 8 g. of anhydrous sodium carbonate dissolved in 150 cc. of water and treated with 5 g. of chlorine. The solution became milky as the hydrochloride dissolved. After the mixture had been shaken ten minutes in the freezing bath, chloroform was added to it to dissolve the semisolid mass. The evaporation of the chloroform left a gum, part of which dissolved in ligroin (b. p. 40-60°). The extract was placed in a stoppered tube and left in the icebox for three days. A white crystalline substance melting at 110-112° resulted. This was used for seeding subsequent preparations, and also for analysis.

Subst. 0.1321, active<sup>1</sup> chlorine 0.02578. Calc. for  $C_{19}H_{14}Cl.NHCl$ : Cl, 10.84%;  $C_{19}H_{14}Cl.NCl_2$ : Cl, 19.56%. Found: Cl, 19.51.

**Rearrangement of *p*-Chlorophenyl-diphenylmethyldichloroamine.—**

1. *By Heat.* A little of the substance was heated to 150°, at which temperature there was a sudden evolution of yellow smoke. When the resulting product was tested in the usual way, after it had been heated with acid, the characteristic aniline test was observed. No further test was made of this product.

2. *By Soda-lime.*—The main experiments were performed with soda-lime in order to prevent the formation of any chloroaniline by chlorination. The reaction was carried out in the same way as described for triphenylmethyldichloroamine. The mixture was heated to 150°, the benzene extract saturated with hydrogen chloride and taken to dryness. It was then heated with alcohol and dilute hydrochloric acid for ten minutes, and shaken with ether to remove the benzophenone and chlorobenzophenone formed by the hydrolysis of the imido ketones. Potassium hydroxide solution was added to the water solution and the alkaline mixture extracted with ether. Anhydrous oxalic acid was added to the dried ether solution and the oxalates of aniline and chloroaniline obtained as a white precipitate. This was dissolved in the least amount of hot water and the solution then cooled to 40°. The precipitate of *p*-chloroaniline oxalate, which formed, was decomposed by alkali and chloroaniline extracted with ether. *p*-Chloroaniline resulted, melting at 67° alone and at 69° when mixed with the pure product (m. p. 69°). It gave a yellow-red-brown color with hypochlorite in the same way as pure *p*-chloroaniline does.

The dissolved aniline oxalate gave the characteristic aniline color reaction with hypochlorite.

**Determination of the Proportion of Aniline and Chloroaniline Formed.<sup>2</sup>**

—Two experiments were performed to determine the proportion of phenyl-

<sup>1</sup> Only two of the three chlorine atoms are determined, they being active toward the iodide which was used in the analysis.

<sup>2</sup> The method of analysis used was worked out by Stieglitz and Leech, *loc. cit.*, for the study of the rearrangement of the corresponding chlorophenyl-diphenylmethylhydroxylamine.

imidochlorobenzophenone and chlorophenylimidobenzophenone formed by the migration of the  $(C_6H_5)$  and  $(ClC_6H_4)$  radicals, respectively, from carbon to nitrogen in the molecular rearrangement of the chloroamine as induced by soda-lime. The reaction and subsequent treatment were carried out as described above, save that the two anilines were precipitated as hydrochlorides instead of as oxalates, the precautions given by Leech being observed. From 0.5 g. of the dichloroamine, 0.1 g. of mixed dry hydrochlorides was obtained. The proportion of aniline and chloroaniline was found by Curme's bromination method.<sup>1</sup>

Subst., 0.0689, 0.0528; cc. 0.1  $N$   $KBrO_3$  27.30, 20.97. Found: Aniline, 74.2, 76.6 molar per cent., chloroaniline 25.8, 25.4.

**An Attempt to Effect the Rearrangement of Benzophenonechloroimide,**  $(C_6H_5)_2C : NCl$ .<sup>2</sup>—It was hoped that chlorine might be absorbed by benzophenonechloroimide to form a substance,  $(C_6H_5)_3CCl.NCl_2$ , similar in structure to  $(C_6H_5)_3CNCl_2$ , which might rearrange at a high temperature, and produce benzchloroanilide,  $C_6H_5CCl : NC_6H_5$ , by a series of reactions discussed in the theoretical part of the paper. The chloroimide was prepared in the way described by P. P. Peterson<sup>3</sup> and melted at  $37^\circ$ .

Five attempts were made to rearrange this product but all were unsuccessful. For the sake of future workers in this field, the experiments will be described briefly to indicate the path followed. After each attempt the substance was tested in the following ways: (a) It was boiled with acid, the solution was made neutral and hypochlorite solution was added. A color reaction would have indicated the presence of aniline or chloroaniline.

(b) The substance was heated with soda-lime and then boiled with acid. The mixture was made neutral and tested with hypochlorite solution as above. The treatment with soda-lime was applied because benzochloroanilide on hydrolysis would give benzanilide which does not show the aniline test until it has been decomposed by soda-lime.

1. Dry chlorine gas was passed for one-half hour over the chloroimide (0.5 g.) maintained at a temperature of  $130$ – $140^\circ$  in a metal bath. When cooled, the product was the unchanged compound melting at  $37^\circ$ . It gave no test for the anilines.

2. The second and third experiments were similar and were as follows: The chloroimide (0.5 g.) was placed in a small tube and dry chlorine gas was run into the tube for fifteen minutes. The substance became yellow, and melted slightly. The tube was sealed, and heated for two hours in a furnace at  $150^\circ$ . When cool, some of the substance was removed and treated as described above. It gave no test for the anilines,

<sup>1</sup> THIS JOURNAL, 35, 1143 (1913).

<sup>2</sup> See p. 2083.

<sup>3</sup> Stieglitz and Peterson, *Ber.*, 43, 782 (1910); Peterson, *Am. Chem. J.*, 46, 325 (1911).

3. Chloroimide (0.5 g.) was dissolved in ether and phosphorus pentachloride (0.5 g.) was added to the mixture. This was heated with reflux for two hours. The precipitate was filtered off, and proved to be the imido-hydrochloride,  $(C_6H_5)_2C = NH_2Cl$ . When tested, no color reactions were observed.

4. The fifth attempt to effect the rearrangement of benzophenone-chloroimide was similar to the second and third attempts, except that the closed tube was heated to  $230^\circ$  for two hours. The substance was colored owing to decomposition, but no trace of aniline or chloroaniline could be observed.

Although this work was negative in regard to the formation of benzo-chloroanilide by rearrangement, the results are of interest, in that they emphasize the remarkable difference in behavior of  $(C_6H_5)_3CNHCl$  and  $(C_6H_5)_2C : NCl$  and that they bring additional evidence against the theory by some chemists that  $R_2C = NCl$  is an intermediate product in the rearrangement of  $R_2C = NOH$  to  $R.CCl(:NR)$  by means of phosphorus pentachloride.

## THE MOLECULAR REARRANGEMENT OF SOME TRIARYLMETHYLCHLOROAMINES.<sup>1</sup>

BY AGNES FAY MORGAN.

Received August 1, 1916.

Three series of triphenylmethane derivatives have been found, in this laboratory, to undergo molecular rearrangements akin to each other and quite analogous to the Lossen-Curtius-Hofmann-Beckmann rearrangements of acid and ketone derivatives.<sup>2</sup> Triphenylmethylhydroxylamines rearrange under the influence of phosphorus pentachloride,<sup>3</sup> triphenylmethylchloroamines rearrange under the influence of alkaline reagents,<sup>4</sup> and, according to recent work, triphenylmethyl azides also undergo rearrangement under the influence of heat.<sup>5</sup> In all three series the same products of rearrangement are obtained, a result which we may most easily interpret on the basis of Stieglitz's theory of the intermediate formation

<sup>1</sup> The work presented in this paper is used in a dissertation presented to the University of Chicago in part fulfillment of the requirements for the Ph.D. degree.

of a univalent nitrogen derivative. In the first series, this product is formed by the loss of water through the action of phosphorus pentachloride, in the second one through the loss of halogen acid by the action of the alkali used, and in the final series through the loss of nitrogen under the influence of heat. We have, thus:

When substituted triphenylmethane derivatives, such as  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.NHCl}$ , are employed, mixtures are obtained, containing some  $(\text{C}_6\text{H}_5)_2\text{C} : \text{NC}_6\text{H}_4\text{X}$  and some  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C} : \text{NC}_6\text{H}_5$ . It seemed an interesting question to determine in each of the series the ratios in which these products are formed, since such determinations might throw light on the mechanism of the rearrangements, especially on the question whether the same intermediate product  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.N}$ , yielding the same proportions of the above two derivatives, may be considered to be the real rearranging substance in all three cases. For this purpose it was necessary to follow, quantitatively, the rearrangement in a number of cases in which X is varied. For the chloroamines, Miss Vosburgh examined the monochlorine derivative. In continuation of her work, I have, at the suggestion and under the direction of Professor Stieglitz, studied the behavior of two further derivatives of this series, dichlorophenylphenylmethylchloroamine and chlorophenylbromophenylphenylmethylchloroamine. Mr. Stagner has determined the ratios of the products formed for the corresponding hydroxylamine derivatives.<sup>1</sup>

### Experimental Part.

**Di-*p*-chlorophenyl-phenylmethaniminehydrochloride**,  $(\text{ClC}_6\text{H}_4)_2(\text{C}_6\text{H}_5)\text{C.NH}_2\text{Cl}$ .—For the preparation of di-*p*-chlorophenyl-phenylmethylchloroamine it was necessary to obtain the amine itself from the corresponding triaryl methylchloride. For this purpose di-*p*-chlorobenzophenone was first prepared through the condensation of carbon tetrachloride and chlorobenzene with the aid of aluminium chloride at ordinary temperature, the reaction described by Norris and Twiege<sup>2</sup> being followed. The mixture of dichlorobenzophenones was recrystallized from hot dilute alcohol, and then from warm ligroin (40 to 60°). Di-*p*-chlorobenzophenone was obtained as a glistening flaky crystalline substance which melted at 144°. The ortho-ortho and ortho-para forms of the dichlorobenzophenone are very much more soluble in alcohol and in ligroin than the para-para compound, and the separation is thus made almost quantitatively.

<sup>1</sup> The results obtained in the different groups of triphenylmethyl derivatives will be compared with one another by Professor Stieglitz.

<sup>2</sup> *Am. Chem. J.*, **30**, 392 (1903).

The *di-p*-chlorobenzophenone thus obtained was next converted into *di-p*-chlorophenylphenyl carbinol by the method of Gomberg and Cone<sup>1</sup> by means of the Grignard reaction. The resulting yellow gum crystallized at once from cold ligroin (40 to 60°). On recrystallization several times from ligroin a product melting at 87° was obtained.<sup>2</sup>

From the carbinol the *p,p'*-dichlorophenylphenylmethylchloride was prepared in carbon disulfide solution by saturation with anhydrous hydrogen chloride. The chloride made in this way remained as a yellowish semisolid gum when the carbon disulfide was removed.<sup>3</sup> It was, however, quite pure, as shown by the hydrolysis of a weighed portion in alcohol with an excess of 0.1 *N* alkali and titration of the excess with 0.1 *N* hydrochloric acid.

Subst. 0.5035 g.; cc. of 0.1 *N* KOH, 14.39. Calc. for (C<sub>13</sub>H<sub>13</sub>Cl<sub>2</sub>)Cl: 10.20% hydrolyzable Cl. Found: 10.13%.

The chloride was converted into the amine by means of ammonia. The chloride (2 g.) was dissolved in hot benzene, and dry ammonia gas from a liquid ammonia tank passed into the solution, for at least half an hour. After the first twenty minutes a small quantity of absolute ethyl alcohol was added through the reflux condenser, to aid in the precipitation of ammonium chloride. The precipitated salt was at once filtered off and the clear benzene solution of the dichlorophenylphenylmethylamine evaporated on an electric plate. The gum remaining was dissolved in absolute ether and the solution saturated with dry hydrogen chloride. Most of the amine hydrochloride was at once precipitated, and the rest recovered by evaporation of the solution to dryness, the residue being washed with a little absolute ether. By this method 75% of the theoretical yield of the hydrochloride was obtained. The substance was purified by solution in chloroform and fractional precipitation with low-boiling ligroin. The purest product melted at 201°. For the analysis a weighed portion of the hydrochloride was dissolved in alcohol, an excess of 0.01 *N* NaOH was added, and the excess titrated with 0.01 *N* HCl, phenolphthalein being used as the indicator.<sup>4</sup>

Subst. 0.0381 g.; cc. of 0.01 *N* NaOH, 10.18. Calc. for (C<sub>13</sub>H<sub>13</sub>Cl<sub>2</sub>N)HCl: HCl 10.00%. Found: 9.74%.

***p*-Dichlorophenyl-phenylmethylchloroamine**, (ClC<sub>6</sub>H<sub>4</sub>)<sub>2</sub>(C<sub>6</sub>H<sub>5</sub>)CNHCl. —The dichlorophenyl-phenylmethylchloroamine was prepared from the amine hydrochloride by treatment with sodium hypochlorite. The

<sup>1</sup> *Ber.*, 39, 3280 (1906); cf. Stagner, *THIS JOURNAL*, 38, 2069 (1916).

<sup>2</sup> Gomberg and Cone found the same melting point for the purest dichlorophenylphenyl carbinol made by them.

<sup>3</sup> Stagner, *loc. cit.*, obtained the chloride in crystallized form by allowing the gum to stand a month.

<sup>4</sup> For this analysis special carbondioxide-free reagents and special apparatus were used, prepared by S. D. Wilson for measurements of velocities of saponification.

hypochlorite solution was prepared by Graebe's method by passing chlorine (from 5 g. of potassium permanganate and 40 cc. of concentrated hydrochloric acid) into an ice-cold solution of sodium carbonate (8 g.). The dichlorophenylphenylmethylamine hydrochloride (1 g.), dissolved in 2 or 3 cc. of chloroform, and potassium carbonate (2 g.) were added to the hypochlorite solution, and the mixture stirred with a Schultze stirrer at  $-2^{\circ}$  for ten minutes. The chloroform solution of the chloroamine was then separated from the aqueous mixture by means of a separating funnel, and dried with a little granular calcium chloride. The solvent was then removed in a blast of dry air, and the gum remaining extracted with low-boiling ligroin. Most of the ligroin was driven off by air also and the last traces removed by prolonged drying in a vacuum desiccator. The chloroamine formed at first a thick, viscous yellow gum which dried to a hard, varnish-like substance that could be pulverized. The solid melted at  $55^{\circ}$ . A weighed portion of the substance was dissolved in a little alcohol, small quantities of acetic acid and of a 5% solution of potassium iodide were added, and the iodine, released according to the equation

was titrated with 0.1 *N* thiosulfate solution. No starch was used, the yellow color of the iodine giving a perfectly satisfactory end point.

Subst. 0.2032 g.; 0.0649; cc. of 0.1 *N*  $\text{Na}_2\text{S}_2\text{O}_3$ , 11.02, 3.39. Calc. for  $(\text{C}_{13}\text{H}_{13}\text{Cl})\text{-NHCl}$ : active Cl, 9.78%. Found: 9.61, 9.26.

It was evident from the analysis that the monochloroamine was formed in this case. With chlorophenyldiphenylmethylamine, Miss Vosburgh<sup>1</sup> found that the formation of the dichloroamine was favored, and the monochloroamine could not be obtained by her.

**Rearrangement of *p,p'*-Dichlorophenyl-phenylmethylchloroamine.**—In order to effect the rearrangement of the chloroamine, soda lime (2 g.) was heated with the chloroamine (1 g.) for five minutes in a metal bath at 160 to 180°. As the chloroamine was obtained chiefly as a sticky solid gum, the mixture with soda lime was best prepared by allowing the ligroin solution of the gum to evaporate to dryness, after it had been mixed with soda lime in an Erlenmeyer flask. The mixture when heated turned yellow, the color of the phenylimidobenzophenones. The mass was extracted with several portions of benzene and the benzene solution filtered and evaporated to dryness. The resulting gum, consisting of a mixture of phenylimido-*p*-dichlorobenzophenone and *p*-chlorophenylimido-*p*-chlorobenzophenone, was hydrolyzed at once by solution in a little alcohol, and by being heated with a small amount of dilute hydrochloric acid for fifteen minutes. After evaporation of the alcohol, the ketones were extracted with ether and the aqueous solution examined for the hydrochlorides of aniline and *p*-chloroaniline.

<sup>1</sup> Isabella Vosburgh, *THIS JOURNAL*, 38, 2081 (1916).

**Identification of *p*-Chlorobenzophenone and *p,p'*-Dichlorobenzophenone.**—The ether extract of the hydrolyzed mixture described above was spontaneously evaporated, and the resulting flaky crystals recrystallized from alcohol. Enough alcohol was added to dissolve about three-fourths of the entire mass, the residue was collected and dissolved in a small amount of hot alcohol. The few crystals precipitated on cooling, were collected on a Hirsch filter and dried *in vacuo*. The melting point of this substance was  $141^{\circ}$ . *p,p'*-Dichlorobenzophenone melts at  $144^{\circ}$ , and a mixture of the product obtained with some synthetic substance melted at  $141^{\circ}$ , which proved the identity of the isolated ketone. The alcoholic filtrate was allowed to evaporate spontaneously, the residue taken up with a few drops of alcohol, the solution decanted through a cotton filter, the filtrate evaporated almost to dryness, and the remaining few drops of solution decanted from a small crystalline residue. When dried, this melted at  $77$  to  $78^{\circ}$ ; *p'*-chlorobenzophenone, according to different authors, melts at  $74$  to  $78^{\circ}$ , and a mixture of some synthetic substance (m. p.  $74^{\circ}$ ) with the product isolated as described, melted at  $74^{\circ}$ .

**Identification of Aniline and *p*-Chloroaniline.**—The aqueous solution recovered from the hydrolysis of the rearranged product was placed in a separatory funnel, strong sodium hydroxide solution and solid sodium chloride added to it, and the liberated aniline and *p*-chloroaniline extracted with two portions of ether. An ether solution of hydrogen chloride was used to form aniline hydrochloride and *p*-chloroaniline hydrochloride. As the hydrochlorides are somewhat soluble in ether containing hydrogen chloride, most of the ether was driven off on the electric oven, and the hydrochlorides finally dried over solid potassium hydroxide *in vacuo*. Part of the dry salts was dissolved in water and on the addition of a few drops of concentrated ammonium hydroxide, *p*-chloroaniline separated out in white crystals. The difference in solubility in water of aniline and *p*-chloroaniline was great enough to secure an almost perfect separation. The *p*-chloroaniline thus obtained melted at  $69.5^{\circ}$  and mixed with pure synthetic *p*-chloroaniline (m. p.  $70.5^{\circ}$ ) melted at  $70.5^{\circ}$ . The filtrate gave a strongly positive test for aniline when tested with bleaching powder solution in the usual way.

**Proportion of Aniline to *p*-Chloroaniline.**—From two grams of the rearranged substance 0.6 g. of the mixed aniline hydrochloride and *p*-chloroaniline hydrochloride was obtained as described above. A weighed portion was analyzed by the bromination method of Curme<sup>1</sup> for the determination of the proportion of aniline and chloroaniline present.

The calculation is made with the aid of the simultaneous equations  $0.1295x + 0.164y = a$  and  $60x + 40y = b$ , when  $x$  and  $y$  represent, respectively, the millimols of aniline hydrochloride and *p*-chloroaniline hydrochloride present,  $a$  the weight of the mixture of salts used, and  $b$  the number of cubic centimeters of 0.1 *N*  $\text{KBrO}_3$  used.

<sup>1</sup> THIS JOURNAL, 35, 1143 (1913).

Subst. 0.0382, 0.0556, 0.242; cc. of 0.1 *N* KBrO<sub>3</sub>, 11.54, 16.88, 7.41. Found, in molar %: C<sub>6</sub>H<sub>5</sub>NH<sub>2</sub>Cl, 31.4, 32.1, 33.2; ClC<sub>6</sub>H<sub>4</sub>NH<sub>2</sub>Cl, 68.6, 67.9, 66.8.

***p*-Chlorophenyl-*p*-bromophenyl-phenylmethylaniline Hydrochloride**, (ClC<sub>6</sub>H<sub>4</sub>)(BrC<sub>6</sub>H<sub>4</sub>)(C<sub>6</sub>H<sub>5</sub>)NH<sub>2</sub>Cl.—For the preparation of this compound a start was made from *p*-chlorobenzophenone, obtained from chlorobenzene and benzoyl chloride with the aid of aluminium chloride: the ketone first obtained was semisolid and was distilled at 220° at 35 mm. pressure, and recrystallized from hot alcohol. The ketone then melted at 74°. The yield was 80% of the theoretical amount. This *p*-chlorobenzophenone was converted into the ketone dichloride,<sup>1</sup> which was purified by distillation under reduced pressure, as directed by Overton.<sup>2</sup> The fraction of the oil used distilled at 190° at 10–12 mm. pressure and gave, by hydrolysis, 26.02% HCl (theory 26.12%). The yield of purified dichloride was 90% of the theoretical.

The dichloride was converted into *p*-chlorophenyl-*p*-bromophenyl-phenylcarbinol in the way described by Stagner.<sup>3</sup> The carbinol was found to be more difficult to crystallize than the corresponding dichloroderivative and recourse was had to the method described by Gomberg and Cone<sup>3</sup> for the crystallization of the latter compound. Anhydrous ferric chloride in ethyl acetate solution in molecular proportions was added to an ethyl acetate solution of the carbinol. The resulting ferric salt crystallized out in glistening greenish scales which yielded a yellowish oil on hydrolysis. This oil was easily converted into crystals by solution in warm ligroin (70 to 80°); after purification by recrystallization the compound melted at 92°. The chloride was obtained from this carbinol by saturation of a dry carbon disulfide solution of the latter with hydrogen chloride. Without further purification, this *p*-chlorophenyl-*p*-bromophenylphenylmethyl chloride was treated with ammonia in benzene solution as described for the dichloro compound and from the product the amine hydrochloride was precipitated from its solution in ether. The hydrochloride was purified by precipitation by ligroin out of chloroform solution, and was found to melt at 196°.

Subst. 0.1019; cc. of 0.01 *N* NaOH, 25.42. Calc. for (C<sub>15</sub>H<sub>13</sub>ClBrN)HCl: HCl, 8.91%. Found: 9.10%.

***p*-Bromophenyl-*p*-chlorophenyl-phenylmethylchloroamine**, (ClC<sub>6</sub>H<sub>4</sub>)(BrC<sub>6</sub>H<sub>4</sub>)(C<sub>6</sub>H<sub>5</sub>)CNHCl.—The amine hydrochloride, dissolved in chloroform, was stirred with an ice-cold solution of sodium hypochlorite and potassium carbonate exactly as described above for the dichloro substance. The chloroamine, purified by extraction with ligroin, remained in a semi-solid condition. It was dissolved in alcohol and analyzed iodometrically.

<sup>2</sup> *Ber.*, 26, 28 (1893).

<sup>3</sup> *Loc. cit.*

Subst. 0.1722, 0.0950; cc. of 0.1 *N* Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>, 7.80, 4.62. Calc. for (C<sub>18</sub>H<sub>13</sub>ClBr)-NHCl: active Cl, 8.71%. Found: 8.03, 8.62.

**Rearrangement of *p*-Bromophenyl-*p*-chlorophenyl-phenylmethyl-chloroamine.**—This substance was heated with soda-lime in a metal bath at 200 to 210° for five minutes in order to effect its rearrangement. The extraction with benzene was carried out as explained before and the hydrolysis of the resulting mixture of arylimidobenzophenones yielded a mixture of ketones (*p*-chlorobenzophenone, *p*-bromobenzophenone, and *p*-bromo-*p*-chlorobenzophenone) and an aqueous solution of the hydrochlorides of *p*-chloroaniline, *p*-bromoaniline, and aniline. This mixture of the aniline hydrochlorides was made alkaline and extracted with ether, and the hydrochlorides reprecipitated with a freshly made solution of hydrogen chloride in absolute ether. The resulting crystalline mass was further purified by precipitation by ether from absolute alcohol solution and the product and then carefully dried *in vacuo*.

The proportions of aniline, *p*-chloroaniline, and *p*-bromoaniline in the hydrolyzed product of the above rearrangement were found by determinations of the hydrochloric content of, and the bromine absorbed by, a definite weight of the mixed hydrochlorides.

We have then the three simultaneous equations,  $0.1295x + 0.164y + 0.208z = a$ ;  $60x + 40y + 40z = b$ ; and  $x + y + z = c$ . In these equations, *x*, *y* and *z* represent, respectively, the millimols of aniline hydrochloride, chloroaniline hydrochloride and bromoaniline hydrochloride present in a given weight *a* of the mixed salts, *b* is the number of cc. of 0.1 *N* KBrO<sub>3</sub> used to brominate the salts, and *c* represents the number of cc. of *N* NaOH (1/100 of the volume of 0.01 *N* solution actually used) required to neutralize the same weight of the mixed hydrochlorides. In carrying out the determinations, the titration with alkali is made first, phenolphthalein being the indicator, and the same solution is used for the bromination process. In view of the determinations representing an indirect method for three unknown components, the molecular weights of two of which are not very far apart, the method gives only approximate results.

## DIETHYLAMINO-*m*-HYDROXYBENZOYL TETRACHLOROBENZOIC ACID AND TRICHLORODIETHYLAMINOXANTHONE-CARBOXYLIC ACID AND SOME OF THEIR DERIVATIVES.

BY W. R. ORNDORFF AND C. C. ROSE.

Received August 3, 1916.

### Historical.

Diethylamino-*m*-hydroxybenzoylbenzoic acid is first mentioned by Graebe, Kohn and Huguenin.<sup>1</sup> They obtained it by fusing tetraethylrhod-

<sup>1</sup> *Archives des sciences physiques et naturelles de Genève*, 2, 91 (1893).

amine with soda, the decomposition of the rhodamine being analogous to that of fluorescein into dioxybenzoylbenzoic acid<sup>1</sup> (page 2115).

In 1896, a German patent was granted the Basler Chemical Company covering a method of preparing new condensation products from phthalic acid anhydride and the dialkylmetamino-phenols.<sup>2</sup> This method, as applied to the diethyl acid, is as follows: 15 kg. of phthalic acid anhydride are dissolved in 75 kg. of toluene and 16.5 kg. of diethyl-*m*-aminophenol added. The solution is boiled for several hours, until there is no further increase in the crystalline precipitate, which separates after some time. The product is purified by crystallization from alcohol. It behaves like an amino acid, since it forms salts with both bases and mineral acids. The melting point cannot be sharply determined. Above 180°, it decomposes forming a red liquid. From the method of formation and the properties of the compound, the following formula is given to it:

Later the Basler Chemical Company was granted another patent<sup>3</sup> covering a new method for the preparation of this compound as follows: 17 kg. of diethyl-*m*-aminophenol are melted at 100° and 15 kg. of phthalic acid anhydride added. The temperature is held at 100° until the mass completely solidifies. It is then extracted with a small quantity of alcohol and the residue purified by crystallization from alcohol.

Haller and Guyot<sup>4</sup> were the first to make a scientific investigation of this compound. They prepared it according to the patents of the Basler Chemical Company and describe it as being made up of small white needles which decompose at 203° and which are but slightly soluble in alcohol even on warming.

Haller and Umbgrove<sup>5</sup> describe later the preparation of *p*-diethyl-aminobenzoyltetrachloro-*o*-benzoic acid,

With acetic anhydride, this acid gave a mixed anhydride, to which they assign the formula

They state that the acid cannot be esterified by the ordinary method and they prepared the esters by heating the mixed anhydride with sodium alcoholate.

<sup>1</sup> Baeyer, *Ann.*, **183**, 23 (1876).

<sup>2</sup> D. R. P. 85931, *Frdl.*, **4**, 260.

<sup>3</sup> D. R. P. 87065, *Ibid.*, **4**, 262.

<sup>4</sup> *Compt. rend.*, **126**, 1248 (1898).

<sup>5</sup> *Bull. soc. chim.*, **25**, 598 (1901).

Later the same authors<sup>1</sup> prepare diethylamino-*m*-hydroxybenzoyltetrachlorobenzoic acid according to the German patent 87068. Diethyl-*m*-aminophenol is melted on the water bath and the calculated amount of tetrachlorophthalic acid anhydride added. At the end of three hours the reaction is complete. It is brought about more rapidly when the temperature of the mixture is raised to 150° and the mass is stirred. The product is extracted with a small quantity of alcohol to dissolve any tetrachlororhodamine formed, and the products not entering into the reaction. Crystallized from alcohol it melts at 198° to a red liquid. Analyses gave the following results:

Calc. for  $C_{18}H_{15}Cl_4NO_4$ : C, 47.89; H, 3.32; N, 3.10; Cl, 31.48. Found: C, 47.76; H, 3.53; N, 3.27; Cl, 31.30 (page 2106).

In 1901, a patent<sup>2</sup> was granted to the Farbwerke vormals Meister, Lucius und Brüning covering the preparation of phthalic acid dyes of the naphthalene series, in which is described the preparation of diethylaminohydroxybenzoyldichloro- and -tetrachlorobenzoic acids.

For the former, 108 parts of dichlorophthalic acid anhydride, 82.5 parts of diethyl-*m*-aminophenol and 650 parts of toluene are heated to boiling for about 10 hours. The product is freed from toluene, dissolved in soda solution (93 g.  $Na_2CO_3$  to one liter  $H_2O$ ) and the solution heated. On cooling, an oil separates consisting of the sodium salt of the new acid and the diethyl-*m*-aminophenol not entering into the reaction. It is purified by dissolving in water, precipitating with sodium carbonate, redissolving in water and extracting the diethyl-*m*-aminophenol with ether. The dichloro acid precipitated out of the solution of the sodium salt by acetic or hydrochloric acid is amorphous, insoluble in water, soluble in alcohol and chloroform, and, in the pure condition, in excess of sodium carbonate solution without the separation of the oily sodium salt.

The tetrachloro acid is prepared from tetrachlorophthalic acid anhydride and diethyl-*m*-aminophenol in the same way as the dichloro acid and is like the latter in nearly all respects, only it is far more difficultly soluble in chloroform. It forms a sodium salt that even in the pure condition separates as an oil on the addition of excess of sodium carbonate solution.

Bloch<sup>3</sup> in 1913 prepared *dimethylamino-m*-hydroxybenzoyltetrachlorobenzoic acid by heating equal molecules of *dimethylmetaminophenol* and tetrachlorophthalic acid anhydride in xylene. The solvent was distilled off, the material dissolved in sodium carbonate solution, precipitated by a dilute acid and purified by crystallization from acetic acid or dilute alcohol.

<sup>1</sup> *Bull. soc. chim.*, **25**, 747 (1901).

<sup>2</sup> D. R. P. 118077, *Frdl.*, **6**, 276.

<sup>3</sup> *Bull. de la Société Industrielle de Mulhouse*, **83**, 81 (1913).

He states that "besides the benzoylbenzoic acid, the presence of a yellow colored derivative was observed, insoluble in alkalis and which gave a colorless salt with hydrochloric acid. It crystallized from glacial acetic acid in yellow needles." He gives no analysis of this product, but thinks it may result from the esterification of dimethyl-*m*-aminophenol with tetrachlorophthalic acid anhydride (page 2113).

This investigation was undertaken for the purpose of determining the best conditions for preparing diethylamino-*m*-hydroxybenzoyltetrachlorobenzoic acid and to study its properties, chemical reactions and some of its derivatives. It seems probable that this acid is an intermediate product in the formation of tetrachlororhodamine and hence it was thought that its study would throw some light on this important class of dyes.

### Experimental.

In the following pages all chlorine determinations were made by the lime method.<sup>1</sup> The nitrogen determinations were made by the Kjeldahl method, with the added precaution that the digestion was extended over a period of about three hours after the solution had become colorless. This was to insure complete transformation of all the nitrogen to ammonia, as nitrogen which splits off from a compound as an amine (diethylamine in this case) is difficultly transformed into ammonia in the Kjeldahl reaction. The drying tube used to bring the substances to constant weight was the electrically heated one described by Chamot and Pratt,<sup>2</sup> and more in detail by Orndorff and Nichols.<sup>3</sup> As most of the compounds described have decomposition points instead of melting points, and these show a tendency to vary with the speed of heating, it might be well to say here that the temperatures of decomposition were determined in an electrically heated Thiele apparatus which was so regulated as to give a rise in temperature of about 1° in 3 seconds. All temperatures of decomposition and melting points given, are uncorrected.

The diethyl-*m*-aminophenol used was very kindly furnished by the Badische Anilin- und Soda-Fabrik. It was in dark colored lumps but quite pure. Just before using it was always purified by distillation in a vacuum, as described by Meyenburg.<sup>4</sup> When exposed to the air, it quickly reddens. In order to determine its purity it was distilled under reduced pressure, the receiver being changed after the temperature had

The sulfuric acid became colorless after digesting for one hour. The first determination was stopped at this point while the second was run for three hours longer.

The tetrachlorophthalic acid anhydride was prepared by heating pure tetrachlorophthalic acid to 105°. The purity of the anhydride was checked by molecular weight determinations, made by titrating a weighed sample with standard alkali.<sup>2</sup>

**Hydroxyphenyldiethylammoniumdiethylaminomethoxybenzoyl tetrachlorobenzoate.**—When diethyl-*m*-aminophenol and tetrachlorophthalic acid anhydride condense, under such conditions that tetrachlororhodamine formation does not take place, the product resulting is made up of two molecules of the diethyl-*m*-aminophenol to one of the tetrachlorophthalic acid anhydride and not one molecule to one molecule as Haller and Umbgrove state (page 2103). The condensation was brought about, both in toluene according to the German patent 118077 (page 2103), and by heating a mixture of the two components as described by Haller and Umbgrove (page 2103). The following are the detailed experiments:

(a) One molecule of diethyl-*m*-aminophenol to one molecule of tetrachlorophthalic acid anhydride in toluene solution.

Twelve grams of diethyl-*m*-aminophenol were dissolved in toluene and a solution of 20 g. of tetrachlorophthalic acid anhydride in toluene added. When the two nearly colorless solutions were mixed, a red color developed. The solution was heated to boiling and after several hours a white precipitate began to settle from the boiling toluene. When this precipitate no longer increased in amount (which required about 20 hours) the boiling was stopped. The product consisting of white needles was filtered off and washed with methyl alcohol. Yield 17.9 g. corresponding to 80% of the calculated amount (figured from the diethyl-*m*-aminophenol). The filtrate evaporated to dryness left a residue of between 5 and 6 g., which was found to be mostly tetrachlorophthalic acid anhydride.

(b) Two molecules of diethyl-*m*-aminophenol to one molecule of tetrachlorophthalic acid anhydride in toluene solution.

The procedure was exactly the same as in (a) except that 18 g. of diethyl-*m*-aminophenol and 18 g. of tetrachlorophthalic acid anhydride

<sup>1</sup> International atomic weights (1916) are used in this paper.

<sup>2</sup> *Am. Chem. J.*, 41, 399 (1909).

were used. This allows for a slight excess of the anhydride. Yield 29.3 g. corresponding to 87% of the calculated amount.

(c) Fusion: one molecule of diethyl-*m*-aminophenol to one molecule of tetrachlorophthalic acid anhydride.

Twelve grams of diethyl-*m*-aminophenol and 20 g. of tetrachlorophthalic acid anhydride were fused in an atmosphere of carbon dioxide at 120° and at the same time the fused mass was stirred. After the melted mass became solid, it was crystallized once from toluene to remove any of the unchanged components. Yield 15 g. corresponding to 67% of the calculated amount.

(d) Fusion: two molecules of diethyl-*m*-aminophenol to one molecule of tetrachlorophthalic acid anhydride.

Thirty-six grams of diethyl-*m*-aminophenol and 36 g. of tetrachlorophthalic acid anhydride were fused as in (c). The melted mass thickened appreciably in ten minutes and was solid in half an hour. At first the temperature of the fused mass was about 30° to 45° higher than the temperature of the bath, but at the end of about 20 minutes it began to drop. During the fusion the contents of the flask *lost no weight*. The product, which had a bluish violet color, was crystallized once from toluene. Yield 65 g. corresponding to 96% of the calculated amount.

The condensation product crystallizes from methyl alcohol in prisms, containing no solvent of crystallization, which grind to a powder having a very faint yellowish tinge. It decomposes at 198° to a red liquid. When dried at 130° to constant weight, all products gave the same results on analysis.

Subst., *a*, 0.1610; *b*, 0.2873; *c*, 0.2280; *d*, 0.2768; cc. 0.1 *N* AgNO<sub>3</sub>, *a*, 10.45; *b*, 18.64; *c*, 14.76; *d*, 17.95.

Subst., *b*, 0.7282; *d*, 0.3345; cc. 0.1 *N* HCl, *b*, 23.68; *d*, 10.51.

Calc. for C<sub>23</sub>H<sub>30</sub>N<sub>2</sub>O<sub>5</sub>Cl<sub>4</sub>: Cl, 23.02; N, 4.55. Found: Cl, *a*, 23.02; *b*, 23.01; *c*, 22.96; *d*, 22.99; N, *b*, 4.56; *d*, 4.42.

It is therefore the result of the condensation of two molecules of diethyl-*m*-aminophenol with one molecule of tetrachlorophthalic acid anhydride as shown in the following equations:

Hydroxyphenyldiethylammoniumdiethylamino-*m*-hydroxybenzoyltetra-

chlorobenzoate is slightly soluble in benzene, more so in toluene and xylene. It is soluble in methyl and ethyl alcohols, glacial acetic acid, and acetone; insoluble in water. It dissolves in solutions of caustic alkalis, alkali carbonates and ammonium hydroxide with a yellow color which gradually darkens. After some time a bright yellow precipitate forms which was found to be a salt of an acid containing but three atoms of chlorine. This trichloro acid will be taken up in detail later (page 2111). The removal of one atom of chlorine takes place very quickly when the alkaline solutions are heated to their boiling points which was proven in the following way: A weighed quantity of the tetrachloro product was dissolved in 2.5% aqueous potassium hydroxide and the solution heated until the potassium salt of the trichloro acid had entirely separated. The solution was made strongly acid, with concentrated nitric acid and filtered. An excess of standard silver nitrate solution was added to the filtrate and the silver chloride removed. The silver nitrate in the filtrate was titrated with standard ammonium thiocyanate. The weight of chlorine equivalent to the volume of standard silver nitrate solution used up, gave the weight of chlorine removed from the tetrachloro product.

Subst., I, 0.6250; II, 0.7867; cc. 0.1 *N* AgNO<sub>3</sub>, I, 9.62; II, 12.18.

Calc. for one atom Cl, grams, I, 0.03594; II, 0.04524. Found: Cl, grams, I, 0.03414; II, 0.04318.

On account of the darkening of the alkaline solutions of the tetrachloro product, it was concluded that the second molecule of the diethyl-*m*-aminophenol is present in the form of a substituted ammonium radical and that the darkening is due to the fact that this second molecule is split off by the alkali and then the case is simply one of the increased sensitiveness of the alkylaminophenol in alkaline solution to the action of the oxygen of the air. If this is so, then concentrated mineral acids, as well as alkalis, should split off this second molecule of diethyl-*m*-aminophenol, and give the tetrachloro acid. This actually takes place under the influence of an alkali or a mineral acid.

(a) 24.8 g. of the original tetrachloro condensation product were dissolved in cold 5% aqueous sodium hydroxide and *immediately* poured into dilute sulfuric acid. A yellow product separated which weighed 17.8 g., corresponding to 99% of the calculated amount. It crystallized from methyl alcohol in the form of light yellow prisms, which decomposed at 217° forming a red liquid.

(b) Some of the original tetrachloro condensation product was dissolved in cold concentrated sulfuric acid, and the solution poured into distilled water kept cold by a freezing mixture. Reddish flakes separated. By crystallization from alcohol, a yellow product was finally obtained which decomposed at 217° forming a red liquid.

When dried to constant weight at  $130^{\circ}$ , analyses of both products proved them to be the tetrachloro acid.

**Diethylamino-*m*-hydroxybenzoyltetrachlorobenzoic Acid.**—This acid crystallizes from methyl alcohol, ethyl alcohol, acetone and ether in pale yellow prisms containing no solvent of crystallization. It dissolves in solutions of the caustic alkalis, alkali carbonates and ammonium hydroxide with a yellow color *which does not darken on standing*. It is but slightly soluble in benzene and toluene; insoluble in water. That the tetrachloro acid loses an atom of chlorine when heated with caustic alkalis was proven in the same way as with the original condensation product (page 2107).

Subst., I, 0.6448; II, 0.7234; cc. 0.1  $N$   $AgNO_3$ , I, 13.91; II, 15.29.

Calc. for one atom Cl, grams, I, 0.05668; II, 0.05686. Found: Cl, grams, I, 0.04931; II, 0.05423.

In 10% solutions of the caustic alkalis there is no separation of the yellow colored salt of the trichloro acid until the solution is heated or diluted with water (page 2117).

**Action of Dry Ammonia Gas on the Tetrachloro Acid.**—A weighed quantity of the acid, dried at  $130^{\circ}$ , was treated with dry ammonia gas. It absorbed ammonia very rapidly at first, becoming slightly brighter yellow in color, and at the end of 24 hours had reached constant weight, showing an increase corresponding to two molecules of ammonia.

Subst., 0.6477; gain,  $NH_3$ , 0.0507.

Calc. for  $C_{18}H_{18}O_4NCl_4(NH_3)_2$ :  $NH_3$ , 7.02. Found:  $NH_3$ , 7.26.

When a current of dry air is passed over this diammonium salt it loses one molecule of its ammonia and becomes constant in weight. The mono-ammonium salt is hygroscopic.

**Silver Salt of the Tetrachloro Acid.**—Five grams of the tetrachloro acid were dissolved in absolute alcohol and 70 cc. of an alcoholic solution of silver nitrate (32 g. to the liter) added. After some time the silver salt precipitated in the form of yellow crystals. These were analyzed for silver as follows: A weighed amount was dissolved in concentrated nitric acid, poured into distilled water, the tetrachloro acid filtered off and the silver determined by titrating with standard ammonium thiocyanate solution.

Subst., I, 0.7612; II, 0.6391; cc. 0.1  $N$   $NH_4SCN$ , I, 13.66; II, 11.43.

Calc. for  $C_{18}H_{18}O_4NCl_4Ag$ : Ag, 19.34. Found: Ag, I, 19.36; II, 19.29.

**Methyl Ester of the Tetrachloro Acid.**—Fifteen grams of the tetrachloro acid were heated to boiling for 9 hours with 300 cc. of a 3% solu-

tion of dry hydrochloric acid gas in absolute methyl alcohol. On cooling, the solution was poured into its own volume of water. The ester separated as an amorphous body, which gradually became granular. It was purified by crystallization from ether. The ester has a very faint yellow color and melts at 146–148° to a clear yellow liquid. As the substance on being heated to even 100°, showed signs of decomposition, the analyses were made on the air-dried material.

Subst., I, 0.2267; II, 0.2142; cc. 0.1 *N* AgNO<sub>3</sub>, I, 19.56; II, 18.47.

Calc. for C<sub>18</sub>H<sub>14</sub>NO<sub>4</sub>Cl<sub>4</sub>CH<sub>3</sub>: Cl, 30.50. Found: Cl, I, 30.60; II, 30.57.

The methyl ester shows an extraordinary solubility, being soluble in methyl alcohol, ethyl alcohol, ether, benzene, toluene, chloroform, carbon tetrachloride, acetone and ethyl acetate.

**Ethyl Ester of the Tetrachloro Acid.**—The preparation was exactly analogous to that of the methyl ester, using a 3% solution of dry hydrochloric acid gas in ethyl alcohol. The ethyl ester was purified by crystallization from ether and is very like the methyl ester in its appearance and solubilities. It melts at 120° to a clear yellow liquid. Analyses of the air-dried material gave the following results:

Subst., I, 0.1992; II, 0.2125; cc. 0.1 *N* AgNO<sub>3</sub>, I, 16.66; II, 17.83.

Calc. for C<sub>18</sub>H<sub>14</sub>NO<sub>4</sub>Cl<sub>4</sub>C<sub>2</sub>H<sub>5</sub>: Cl, 29.61. Found: Cl, I, 29.65; II, 29.75.

**Acetylation Products of the Tetrachloro Acid.**—Ten grams of the tetrachloro acid were heated with 70 g. of acetic anhydride for 7 hours on a boiling water bath. Previous experiments had shown that two products were formed, one of which is changed by boiling with alcohols. With this in mind, part of the solution was poured into a well cooled mixture of equal parts of acetone and water and the whole vigorously shaken. The acetylation products separated as a yellowish brown precipitate. This was dissolved in acetone and precipitated by the addition of water. This procedure was repeated until the substance was obtained free from the odor of acetic anhydride. It was dissolved in ether, the solution boiled for 10 minutes with boneblack and filtered, giving a bright yellow solution. From this, after repeated fractional crystallization, there was obtained a small quantity of a white product melting at 230–231°, and which analyses showed to be a diacetate of the tetrachloro acid.

Subst., I, 0.1585; II, 0.1643; cc. 0.1 *N* AgNO<sub>3</sub>, I, 11.86; II, 12.26.

Calc. for C<sub>18</sub>H<sub>12</sub>NO<sub>4</sub>Cl<sub>4</sub>(COCH<sub>3</sub>)<sub>2</sub>: Cl, 26.51. Found: Cl, I, 26.53; II, 26.47.

There was also obtained a much larger amount of a pale yellow product, melting at 174–180° and which was also a diacetate of the tetrachloro acid.

Subst., I, 0.2143; II, 0.2780; cc. 0.1 *N* AgNO<sub>3</sub>, I, 16.03; II, 20.79.

Calc. for C<sub>18</sub>H<sub>12</sub>NO<sub>4</sub>Cl<sub>4</sub>(COCH<sub>3</sub>)<sub>2</sub>: Cl, 26.51. Found: Cl, I, 26.52; II, 26.52.

**Methyl and Ethyl Esters of the Monoacetate of the Tetrachloro Acid.**—

The remainder of the acetic anhydride solution was poured into absolute ethyl alcohol. Grayish white crystals separated on standing, which on

crystallization from ether, gave a pale yellow product which melted at  $174-180^{\circ}$  and was identical with the yellow diacetate. The filtrate was boiled to convert the acetic anhydride into ethyl acetate and from this solution, after repeated fractional crystallization, two substances were obtained, one, a white product in very small amount, melting at  $230-231^{\circ}$ , identical with the white diacetate; the other in larger amount, a yellow substance, melting at  $190-192^{\circ}$ , and which analyses showed to be the ethyl ester of the monoacetate of the tetrachloro acid.

Subst., I, 0.1999; II, 0.1872; cc. 0.1  $N$   $AgNO_3$ , I, 15.42; II, 14.41.

Calc. for  $C_{18}H_{13}NO_4Cl_4(COCH_3)(C_2H_5)$ : Cl, 27.22. Found: Cl, I, 27.35; II, 27.29. Two portions of the pale yellow product, melting at  $174-180^{\circ}$ , were boiled for 6 hours, one with ethyl alcohol and the other with methyl alcohol. From the ethyl alcohol solution, a yellow product was obtained melting at  $190-192^{\circ}$  and identical with the ethyl ester of the monoacetate. The methyl alcohol solution gave a yellow product melting at  $152-155^{\circ}$  and which analyses showed to be the methyl ester of the monoacetate of the tetrachloro acid.

Subst., I, 0.1888; II, 0.1940; cc. 0.1  $N$   $AgNO_3$ , I, 14.90; II, 15.32.

Calc. for  $C_{18}H_{13}NO_4Cl_4(COCH_3)(CH_3)$ : Cl, 27.98. Found: Cl, I, 27.98; II, 28.00.

The pale yellow product melting at  $174-180^{\circ}$  is therefore an acetate of a mixed anhydride similar to the one obtained by Haller and Umbgrove (page 2102). The white product melting at  $230-231^{\circ}$  undergoes no change when boiled with alcohols and is undoubtedly a true diacetate of the tetrachloro acid (page 2116).

Both the white and yellow acetylation products gradually dissolve in 2% aqueous potassium hydroxide solution. This shows that they are gradually saponified and go into solution as the yellow potassium salt of the tetrachloro acid. On longer standing, an atom of chlorine is removed, and the salt of the trichloro acid (page 2111) precipitates.

Both of the acetylation products are readily soluble in methyl alcohol, ethyl alcohol, benzene, chloroform, carbon tetrachloride, acetone, ethyl acetate and ether.

**Action of Dry Hydrochloric Acid Gas on the Tetrachloro Acid.**—A known weight of the dry tetrachloro acid was treated with dry hydrochloric acid gas. It rapidly increased in weight becoming constant at the end of 3 hours and absorbing an amount of hydrochloric acid corresponding to slightly more than one molecule when it was colorless.

Subst. 0.3308; gain, HCl, 0.0280.

Calc. for  $C_{18}H_{13}O_4NCl_4.HCl$ : HCl, 7.48. Found: HCl, 7.80.

When exposed to dry air it quickly loses most of its hydrochloric acid, finally returning to its original weight in about 20 hours. When the excess of hydrochloric acid over one molecule is lost, the substance changes to a light yellow.

**Action of Dry Hydrochloric Acid Gas on the Methyl Ester of the Tetrachloro Acid.**—When this compound is treated with dry hydrochloric acid gas, it rapidly takes up two molecules and the dihydrochloride formed is colorless.

Subst., 0.3458; gain, HCl, 0.0542.

Calc. for  $C_{19}H_{17}O_4NCl_4 \cdot 2HCl$ : HCl, 13.56. Found: HCl, 13.55.

When this is placed in dry air it quickly loses one molecule of hydrochloric acid and changes to a pale yellow. The second molecule of hydrochloric acid is lost very slowly, in fact at the end of 14 days the substance still retained nearly 3% of hydrochloric acid.

**Action of Dry Hydrochloric Acid Gas on the Methyl Ester of the Monoacetate of the Tetrachloro Acid.**—When this substance is placed in dry hydrochloric acid gas, it quickly takes up more than two molecules and becomes colorless.

Subst., 0.2802; gain, HCl, 0.0439.

Calc. for  $C_{21}H_{19}NO_3Cl_4 \cdot 2HCl$ : HCl, 12.27. Found: HCl, 13.54.

The dihydrochloride in dry air gradually loses weight and becomes constant, holding one molecule of hydrochloric acid at room temperature. The monohydrochloride is light yellow in color.

**Potassium Salt of the Trichloro Acid.**—This salt was prepared by dissolving the tetrachloro acid in aqueous 3% potassium hydroxide and heating the solution to boiling by passing in steam, when the yellow potassium salt of the trichloro acid separated. It crystallizes from methyl alcohol in bright yellow needles which melt at  $285^\circ$  to a pale red liquid. When crystallized from ethyl alcohol it had the same melting point. The crystals, from both methyl alcohol (I) and ethyl alcohol (II) contain two molecules of water of crystallization. This was shown by making potassium determinations on the air-dried product from the two solvents and also by determining the loss in weight on heating. A weighed quantity of the salt was dissolved in boiling water, an excess of standard hydrochloric acid added, the trichloro acid filtered off and the excess of hydrochloric acid titrated with standard sodium hydroxide solution.

As it has already been shown that one atom of chlorine is removed from

the tetrachloro acid by the potassium hydroxide (page 2108), the reaction is probably as follows (page 2118):

This potassium salt is soluble in methyl alcohol, ethyl alcohol, glacial acetic acid; slightly soluble in acetone, benzene and ether. It is quite soluble in hot water, from which it is precipitated by a solution of potassium hydroxide. This product loses weight when heated to 160° corresponding to three molecules of water of crystallization.

Subst., 0.9203; loss, H<sub>2</sub>O, 0.1017.

Calc. for C<sub>18</sub>H<sub>13</sub>NO<sub>4</sub>Cl<sub>3</sub>K·3H<sub>2</sub>O: H<sub>2</sub>O, 10.67. Found: H<sub>2</sub>O, 11.05.

**Trichlorodiethylaminioxanthonecarboxylic Acid.**—This compound was made by dissolving the potassium salt described above in boiling water, and adding hydrochloric acid to the solution. The trichloro acid separates as an amorphous mass. It crystallizes from methyl alcohol in bright yellow needles which melt at 278° to a pale red liquid. It also crystallizes from ethyl alcohol in bright yellow needles melting at 278°, but which contain *no solvent of crystallization*. The product from methyl alcohol, when heated to 160°, rapidly comes to constant weight, no moisture collects on the cool end of the drying tube and the loss is equivalent to exactly one molecule of methyl alcohol.

Subst., 1.1912; loss, CH<sub>3</sub>OH, 0.0857.

Calc. for C<sub>18</sub>H<sub>11</sub>NO<sub>4</sub>Cl<sub>3</sub>·CH<sub>3</sub>OH: CH<sub>3</sub>OH, 7.19. Found: CH<sub>3</sub>OH, 7.17.

The residue when analyzed for chlorine and nitrogen proved to be the trichloro acid (page 2118).

Subst., I, 0.2006; II, 0.2370; cc. 0.1 N AgNO<sub>3</sub>, I, 14.51; II, 17.16.

Subst., I, 0.6437; II, 0.7126; cc. 0.1 N HCl, I, 15.80; II, 16.94.

Calc. for C<sub>18</sub>H<sub>11</sub>NO<sub>4</sub>Cl<sub>3</sub>: Cl, 25.66; N, 3.38. Found: Cl, I, 25.65; II, 25.68; N, I, 3.44; II, 3.33.

To determine whether the acid is precipitated from a solution of its potassium salt as the trichloro acid or as a hydrate of this acid (page 2118) some of the powdered salt was suspended in cold water, concentrated hydrochloric acid added and the mixture thoroughly shaken to coagulate the trichloro acid set free. This was filtered off and washed with water until free from hydrochloric acid. At the same time, some of the potassium salt was dissolved in boiling water and the trichloro acid precipitated from this solution by the addition of concentrated hydrochloric acid. Moisture determinations were made on the two air-dried products:

Subst., I, 0.4151; II, 0.3867; loss, H<sub>2</sub>O, I, 0.0104; II, 0.0176.

Calc. for C<sub>18</sub>H<sub>11</sub>NO<sub>4</sub>Cl<sub>3</sub>·H<sub>2</sub>O: H<sub>2</sub>O, 4.16. Found: H<sub>2</sub>O, I, 2.50; II, 4.55.

(I) was made on the trichloro acid precipitated from the boiling solution, while (II) was made on the acid precipitated cold. The heating was begun at 115° and at the end of each hour the material was weighed,

returned to the drying tube and the temperature increased until the final heating was at  $175^{\circ}$ . In (I), the substance lost no weight after heating for one hour at  $115^{\circ}$ , while in the other case it was heated for one and one-half hours at  $115^{\circ}$  and one hour at  $140^{\circ}$  before it reached constant weight. In neither case did any moisture collect on the cool end of the drying tube. These results show that the acid precipitated in the cold from its potassium salt is obtained as the hydrate (page 2118), which readily loses a molecule of water of constitution and that it loses part of this water when precipitated out of a boiling solution of the salt with acids.

The trichloro acid is soluble in methyl alcohol, ethyl alcohol and glacial acetic acid, less soluble in acetone; insoluble in water. It is very stable toward alkalis, no chlorine being removed even when it is boiled with alcoholic caustic potash. It is highly probable that the yellow product obtained by Bloch (page 2104) is the trichloro*dimethylaminoxanthone*-carboxylic acid.

**Action of Dry Ammonia Gas on the Dried Trichloro Acid.**—When a weighed quantity of the trichloro acid, dried at  $160^{\circ}$ , is treated with dry ammonia gas it rapidly absorbs more than one molecule of ammonia with no noticeable change of color.

Subst., 0.7068; gain,  $\text{NH}_3$ , 0.0406.

Calc. for  $\text{C}_{18}\text{H}_{14}\text{NO}_4\text{Cl}_3\cdot\text{NH}_3$ :  $\text{NH}_3$ , 3.95. Found:  $\text{NH}_3$ , 5.43.

This compound, when exposed to dry air, loses its excess of ammonia over one molecule very rapidly. The monoammonium salt left is hygroscopic but stable.

**Action of Acetic Anhydride on the Trichloro Acid.** Ten grams of the trichloro acid were boiled for 3 hours with 70 g. of acetic anhydride. On cooling, a product separated which was filtered off, washed with cold absolute alcohol and air-dried. It crystallizes in bright yellow needles, melts at  $188\text{--}190^{\circ}$ , with slight decomposition and on drying at  $120^{\circ}$ , loses no appreciable weight. Analyses on the dried product gave the following results:

Subst., I, 0.1902; II, 0.1686; cc. 0.1  $\text{N}$   $\text{AgNO}_3$ , I, 12.52; II, 11.12.

Calc. for  $\text{C}_{18}\text{H}_{12}\text{NO}_4\text{Cl}_3(\text{COCH}_3)$ : Cl, 23.30. Found: Cl, I, 23.34; II, 23.39.

The yellow acetate is soluble in acetic anhydride, methyl alcohol, ethyl alcohol, acetone and benzene; insoluble in water. When crystallized from acetone, a yellow powder is obtained which melts very indefinitely at about  $185^{\circ}$ . This was heated at  $155\text{--}160^{\circ}$  for 25 hours before it reached constant weight and showed a loss of 11.20%. A current of dry air was passed over the compound while it was being heated and on leaving the drying tube this current of air was led through a gas wash bottle containing distilled water. After the compound had reached constant weight, the water in this wash bottle gave a strong iodoform

test for acetone. The product after heating melts at  $278^{\circ}$ , the melting point of the trichloro acid.

Subst., 0.5428; loss, acetone, 0.0608.

Calc. for  $C_{18}H_{14}NO_4Cl_3(C_3H_5O)$ : acetone, 12.28. Found: acetone, 11.20.

Hence, the acetate when crystallized from acetone forms an acetate of the trichloro acid (page 2119).

A portion of the yellow acetate was boiled with ethyl alcohol for six hours and the solution cooled. A product separated in the form of bright yellow needles, melting at  $278^{\circ}$ , the melting point of the trichloro acid. On drying at  $160^{\circ}$ , this material lost no weight.

The product obtained by the action of acetic anhydride on the trichloro acid is therefore a mixed anhydride rather than a true acetate (pages 2102, 2118).

Attempts to make the methyl ester of the trichloro acid by the catalytic method of esterification resulted in failure. This is in accord with the fact that the acetyl group is removed from the mixed anhydride when it is boiled with ethyl alcohol but the product formed is the free acid and not the ester.

#### **Action of Dry Hydrochloric Acid Gas on the Dry Trichloro Acid.—**

A weighed amount of dry trichloro acid was treated with dry hydrochloric acid gas. At the end of three hours it showed no change in appearance and had absorbed only 0.3% of hydrochloric acid. When concentrated hydrochloric acid is added to the trichloro acid, it does not go into solution, but turns white. This white hydrochloride when filtered off and dried in the air loses hydrochloric acid as it dries, and turns yellow.

**Action of Dry Hydrochloric Acid Gas on the Mixed Anhydride of the Trichloro Acid and Acetic Acid.**—The mixed anhydride dried at  $120^{\circ}$  absorbs one molecule of hydrochloric acid gas in two hours and has a pale yellow color. At the end of six hours it reaches constant weight, having absorbed more than one molecule and is colorless.

Subst., 0.4016; gain, HCl, 0.0414.

Calc. for  $C_{20}H_{16}NO_5Cl_3.HCl$ : HCl, 7.40. Found: HCl, 9.35.

The hydrochloride loses all its hydrochloric acid on standing over night at room temperature in dry air.

#### **Theoretical.**

Hydroxyphenyldiethylammonium - diethylamino - *m* - hydroxybenzoyl-tetra-chlorobenzoate is the product resulting from the condensation of diethyl-*m*-aminophenol and tetrachlorophthalic acid anhydride under such conditions that tetrachlororhodamine formation does not take place. It seems highly probable that the reaction proceeds in two stages (page 2106), and that the tetrachloro acid is first formed. However, the *final product* is always the substituted ammonium salt of the tetrachloro

acid, whether the condensation is brought about in toluene solution or by direct heating of the two components.

Formula (I) for this salt explains the readiness with which it is decomposed into the tetrachloro acid, (II) and diethyl-*m*-aminophenol by the action of alkalis and mineral acids and also the color of the compound. That the ketone group occupies the *ortho* position to the hydroxyl, follows from the ease with which the tetrachloro acid is converted into the trichloro acid by weak alkalis (page 2111) and also from the color of the compound, Staedel<sup>1</sup> having shown that the *ortho*hydroxybenzophenones are yellow. That the diethylamino group is in the *para* position is proved by the fact that the tetrachloro acid is so readily converted into tetrachlororhodamine.<sup>2</sup> The decomposition of tetraethylrhodamine into *p*-diethylamino-*m*-hydroxybenzoyl-*o*-benzoic acid (page 2102) and diethyl-*m*-aminophenol:

is also in accord with the above view of the structure of the tetrachloro acid.

Like the phthaleins, the tetrachloro acid yields derivatives of a tautomeric form such as the diacetate and the free acid may be a mixture of this form (II) with the ketone form (I) (page 2116).

When the tetrachloro acid is treated with dry ammonia, it first forms the true ammonium salt, and then absorbs a second molecule of ammonia

<sup>1</sup> *Ann.*, **283**, 175 (1894).

<sup>2</sup> *Bull. soc. chim.*, **25**, 747 (1901).

to neutralize the phenol hydroxyl group. This diammonium salt loses the molecule of ammonia absorbed by the hydroxyl group very readily in dry air at room temperature giving a stable monoammonium salt. This behavior is evidence of the strong acid character of the molecule. The fact that the tetrachloro acid forms esters so readily by the catalytic method of esterification, unlike the tetrachloro acid of Haller and Umbgrove (page 2102), is worthy of note, since it forms an exception to the Victor Meyer rule.

The behavior of the tetrachloro acid with acetic anhydride shows that it acts as a tautomeric substance.

The yellow product, melting at  $174-180^\circ$  is a derivative of Formula (I), while the colorless product melting at  $230-231^\circ$  is a derivative of Formula (II).

That the yellow product has the formula assigned to it is confirmed by its forming esters of the monoacetate when boiled with alcohols according to the equation

It is not then a true diacetate of the tetrachloro acid, but the monoacetate of the mixed anhydride of the tetrachloro acid and acetic acid as shown above.

Its color is probably due to the ketone group connected with the two benzene residues as in the case of the tetrachloro acid. The white product

is a true diacetate of the tetrachloro acid, as it is not changed by boiling with alcohols and has no color. The absence of color is due to the fact that the ketone group is no longer present.

The behavior of the tetrachloro acid toward dry hydrochloric gas shows its basic nature. It absorbs more than one molecule, but loses the excess quite readily in dry air at room temperature. The monohydrochloride is yellow while the salt containing an excess of hydrochloric acid is colorless. The excess of hydrochloric acid may be absorbed by the ketone group, forming an oxonium salt or a carbonium salt.

Oxonium salt.

Carbonium salt.

Both formulas show why the salt having an excess of hydrochloric acid is colorless, as both in the oxonium salt and in the carbonium salt the ketone group is no longer present. The hydrochloric acid absorbed by the ketone group is the first to be lost in dry air and the yellow color returns. When the acid group is neutralized by a methyl or ethyl radical, the ester forms a dihydrochloride which is colorless for the same reason that the tetrachloro acid containing an excess of hydrochloric acid is colorless. It is not until the phenol hydroxyl group as well as the carboxyl group is neutralized that a hydrochloride stable at room temperature is formed. The methyl ester of the monoacetate of the tetrachloro acid absorbs two molecules of hydrochloric acid and the dihydrochloride is colorless. It loses one molecule of its hydrochloric acid at room temperature and the monohydrochloride is yellow and stable.

The removal of chlorine from the tetrachloro acid by even such weak alkaline solutions as ammonium hydroxide and sodium carbonate is of special interest as it is the first case of its kind to be noticed in this laboratory where the tetrachloro compounds have received considerable attention. As the alkali salts do not precipitate from 10% solutions of the caustic alkalis until the solutions are diluted or heated, it is very probable that the reaction in which the chlorine is removed takes place in stages as follows:

The fact that the salt of the trichloro acid and the acid itself are much more *highly colored* than the corresponding tetrachloro compounds is also in accord with this view, as ring formation is frequently attended with an increase of color.

The free trichloro acid is readily obtained by decomposing its salts with mineral acids. It is precipitated from its potassium salt in the cold as a hydrate (page 2112), while from a boiling solution it is obtained nearly anhydrous.

It is rather curious that it should crystallize from methyl alcohol with a molecule of methyl alcohol, while it crystallizes from ethyl alcohol with no solvent of crystallization. This is probably due to the fact that methyl alcohol is more nearly like water in its properties than is ethyl alcohol.

The trichloro acid and its hydrate are hence derivatives of xanthone and have the following structures:

The name of the acid is, therefore, 2,3,4-trichloro-6-diethylamino-xanthone-1-carboxylic acid.

Like the tetrachloro acid, the trichloro acid combines with dry ammonia to form a monoammonium salt which is stable at room temperature.

There being no hydroxyl groups present in the molecule, the trichloro acid reacts with acetic anhydride to form a mixed anhydride (page 2113) as in the case of the acid obtained by Haller and Umbgrove (page 2102). This mixed anhydride is very unstable as is shown by the fact that the acetyl group is removed by boiling with ethyl alcohol and the acid is set free instead of ester formation taking place. The acetate of the trichloro acid formed when the mixed anhydride is boiled with acetone probably has the following structure:

The fact that the trichloro acid does not form a methyl ester by the catalytic method of esterification is probably due to steric hindrance.

The trichloro acid does not absorb hydrochloric acid gas as the diethylamino group is here neutralized by the carboxyl group. When the hydrogen atom of this carboxyl group is replaced by an acetyl group the mixed anhydride absorbs more than one molecule of hydrochloric acid and is colorless. The excess of hydrochloric acid is probably taken up in this case by the ketone group forming an oxonium or a carbonium salt as in the case of the hydrochlorides of the tetrachloro compounds.

### Summary.

The results of this investigation may be briefly stated as follows:

1. The condensation of diethyl-*m*-aminophenol and tetrachlorophthalic acid anhydride has been effected in both an indifferent solution medium and by the direct heating of a mixture of the two components. The result of the condensation is always hydroxyphenyldiethylammonium-diethylamino-*m*-hydroxybenzoyl-tetrachlorobenzoate.
2. The tetrachloro acid has been prepared by decomposing the substituted ammonium salt first formed with mineral acids or alkalies.
3. The ammonium and silver salts, the methyl and ethyl esters, the acetate of the mixed anhydride of the tetrachloro acid and acetic acid, and the methyl and ethyl esters of the monoacetate of the tetrachloro acid have been prepared. All these compounds are colored and are derivatives of the keto-form of the tetrachloro acid.
4. A white diacetate has been prepared. This is a derivative of the tautomeric lactoid form of the tetrachloro acid.
5. The action of dry hydrochloric acid gas on the tetrachloro acid, its methyl ester and the methyl ester of its monoacetate has been studied.
6. One atom of chlorine has been removed from the tetrachloro acid together with an atom of hydrogen and the resulting trichloro acid, a xanthone derivative, has been obtained and studied.
7. The potassium and ammonium salts of the trichloro acid, the acetate of the trichloro acid and the mixed anhydride of the trichloro acid and acetic acid have been prepared.
8. The action of dry hydrochloric acid gas on the trichloro acid and on the mixed anhydride of the trichloro acid and acetic acid, has been studied.

**STUDIES IN THE PREPARATION OF NITRILES. II. THE PREPARATION OF ALIPHATIC NITRILES.**

BY G. D. VAN EPPS AND E. EMMET REID.

Received August 2, 1916

**Introduction.**

For the preparation of nitriles we have had the old method of Letts<sup>1</sup> as improved by Krüss,<sup>2</sup> which was to heat an acid, such as benzoic acid, with lead thiocyanate. This method was easy to carry out and gave fair yields. Several years ago,<sup>3</sup> in this laboratory, this method was studied and it was found that far better yields could be obtained by substituting the zinc salt of the acid for the free acid, but only aromatic acids were experimented with. The present work was taken up to test the applicability of this improved method to aliphatic nitriles and to find the best conditions for their preparation.

The preparation of acetonitrile has been studied most extensively on account of the importance and the availability of acetic acid. Various methods of heating have been experimented with. Zinc salts of acetic, propionic, butyric, isovaleric, stearic, phenylacetic, phenylpropionic, cinnamic, and terephthalic acids, and the lead salts of some of these acids, have been heated with lead thiocyanate. Several other thiocyanates have been used and the results compared with those obtained with the lead salt. Calcium, copper, stannous, manganous, nickel, cobalt, magnesium, strontium, barium and basic ferric acetates have been tried.

**Historical.**

E. A. Letts<sup>4</sup> of London, in 1872, studied the action of potassium thiocyanate on acids. In case of acetic acid, he could not obtain the nitrile, but with isobutyric acid and valeric acid he found both amide and nitrile, the amide being the main product. With benzoic acid the nitrile was almost the sole product, only traces of the amide being found.

Pfankuch<sup>5</sup> heated barium benzoate with excess of barium thiocyanate and got benzonitrile but mixed with large quantities of other products. Barium acetate and barium thiocyanate gave similar results, the other products being in excess of the acetonitrile.

Kekulé<sup>6</sup> reviewed the work up to his time and speculated as to the mechanism of the reaction, but made no advance in its application.

G. Krüss<sup>7</sup> complained of the yield in Letts' process and improved the

<sup>6</sup> *Ber.*, **6**, 111 (1873).

<sup>7</sup> *Ibid.*, **17**, 1766 (1884).

method by substituting lead thiocyanate for the potassium salt. Krüss gives the equation

He reported a yield of 60 to 55 g. of benzonitrile from 100 g. of benzoic acid, or double what he was able to obtain by the method of Letts.

Reid<sup>1</sup> studied this reaction quantitatively and showed that it is not represented correctly by the equation given. He concluded that the nitrile is formed by interaction between the lead thiocyanate and the lead salt of the organic acid, this salt being formed by reaction between the free acid put in and a part of the lead thiocyanate. This led to a substitution of the previously prepared salt of the organic acid for the free acid, and to extended experiments with different salts, the conclusion being that the best yield is obtained when the zinc salt of the organic acid is used. Reid's method left little to be desired in the preparation of benzonitrile and other aromatic nitriles, both as to yield and convenience of work, but was not extended to aliphatic.

**Materials.**—*Lead thiocyanate* was prepared by precipitation from lead nitrate and ammonium thiocyanate. The precipitated salt was well washed with water, and twice with alcohol. The air-dried salt was further dried in an air-bath at 120°. The salt is pure white but turns somewhat yellow on long keeping. It blackens somewhat when dried in the air-bath.

*Zinc thiocyanate* was prepared by boiling ammonium thiocyanate with excess of zinc hydroxide till no more ammonia came off. The solution was filtered hot and evaporated to crystallization. The crystals were centrifuged. It is difficult to dry this salt as it fuses easily and begins to decompose at low temperatures. The salt is somewhat hygroscopic.

*Cuprous thiocyanate* was prepared by mixing copper sulfate and ammonium thiocyanate in the presence of sulfur dioxide. The gray salt was well washed with water and dried in an air-bath. It turns yellow.

*Zinc acetate, calcium acetate, zinc butyrate, zinc propionate, and zinc isovalerate* were prepared by boiling water solutions of the acids with excess of the carbonate of the metal. The solutions were filtered hot and evaporated to crystallization. The latter three salts were dried over sulfuric acid in a vacuum, the others were dried in an air-bath.

*Zinc stearate, lead phenylacetate, zinc phenylacetate, lead cinnamate, zinc cinnamate, zinc hydrocinnamate, lead benzoate, and zinc terephthalate* were prepared by double decomposition from the neutral ammonium or sodium salts of the acids and lead nitrate or zinc sulfate. All of these salts were dried in air-bath at 120°.

*Potassium thiocyanate, lead acetate, copper acetate, barium acetate, basic*

<sup>1</sup> *Am. Chem. J.*, **43**, 162 (1910).

*ferric acetate, stannous acetate, manganous acetate, nickel acetate, cobalt acetate, magnesium acetate, and strontium acetate* were good commercial preparations.

**Method of Work.**—In each experiment the salts were thoroughly dried and powdered. The weighed amounts were thoroughly mixed before the heating was begun. As the heat is applied the mixtures melt and blacken and bubbles of gas and vapors come from the pasty mass. Usually the nitrile begins to drop from the retort neck in a very short time. The reaction proceeds regularly and spreads through the whole mass, which becomes more or less liquid throughout. At the end of the reaction, the nitrile ceases to come off and the residue sets to a hard mass of the sulfides of the metals.

Five methods of heating the mixtures were tried. In the tables the experiments are marked with the letters, *a*, *b*, *c*, *d*, and *e* to show in which of these ways the operation was carried out.

*a.* Heating in an iron retort under reduced pressure. The retort used was such as is sold for the distillation of mercury and was of 500 cc. capacity. The lid was luted on with a ring of asbestos paper wet with glycerine. Reduced pressure was maintained by a water pump. The heating was so regulated that the pressure was kept 50 to 100 mm.

*b.* Heating in the iron retort under atmospheric pressure. In this the same retort was used. In both cases the retort was heated by a ring burner which supplied the heat uniformly to the walls of the retort, additional heat being supplied by a Bunsen burner to complete the reaction. The distillates from the iron retort were somewhat more colored than those from glass, owing to small amounts of iron dissolved.

*c.* Heating in a glass retort. The retorts used were of 250 and 500 cc. capacity without tubulature. The heating was done by means of a Bunsen burner held in the hand, and the heat was applied at first one spot and then another on the side and finally at the bottom. The retort may be cleaned with nitric acid and used repeatedly. With the glass retort, the course of the reaction is readily followed and it is readily kept under control.

*d.* Heating in a horizontal glass tube. The tube used was of hard glass, 175 mm. long and 22 mm. in diameter, and closed at one end. The open end was closed by a cork through which a narrower tube passed to the condenser. The heating was done by a burner held in the hand. This was used for small scale experiments. It has the advantage that the nitrile does not condense and run back and does not remain so long in contact with the highly heated material.

*e.* Heating in a horizontal glass tube surrounded by a brass block. In this case the tube was of soft glass, 300 mm. long and 22 mm. in diameter, and closed at one end. The block was of cast brass and was 50

mm. square by 300 mm. long. A centrally located hole 25 mm. in diameter extended from one end to the other. The open end of the glass tube was closed by a cork carrying a smaller tube as in *d*. The end carrying the cork projected far enough out of the brass block to avoid burning the cork. The advantage in this method of heating is that the heat is applied regularly throughout the whole length of the tube and the intense local heating, caused by the direct application of the flame, is avoided. As all parts of the tube are above the boiling point of the nitrile, there is no condensation and running back of the nitrile. The brass block was heated by two Bunsen burners properly spaced.

In no case was much trouble experienced with foaming except with the mixture containing zinc thiocyanate. The last two methods gave much purer products, but the yields are much more uncertain, owing to the difficulty of working up the small amounts of the products. The losses of nitrile are proportionately greater than with the larger amounts. With these tubes only small amounts of materials can be used.

**Working up Products.**—The methods of separating the nitriles from the crude distillates were those commonly used in organic preparations.

The distillate containing acetonitrile or butyronitrile was diluted with half its volume of water, treated with solid potassium carbonate or ammonia gas to saturation, the upper layer separated and fractioned. In some cases, the total distillate containing acetonitrile was fractioned up to 85° and the distillate put through this treatment.

Propionitrile was separated by calcium chloride and the upper layer fractioned. Isobutyl cyanide was separated by fractionation.

In the cases of stearic, cinnamic, hydrocinnamic, and phenylacetic nitriles, the crude distillates were treated with a little water and a slight excess of ammonia and steam distilled. The nitrile was separated and the water layer extracted with ether. Stearic nitrile was also separated from the crude distillate by fractionation in a vacuum. It was never obtained pure.

The crude terephthalic nitrile was purified by sublimation. This gave beautiful short white needles melting at about 200°.

**Results.**—The results of the various experiments are brought together below in tables. Under "Ratio" is given the ratio of amount of the thiocyanate used to the calculated amount. Under "Prod." is given the weight of the crude product obtained by the distillation of the mixture of salts, and, in the next column, the weight of the nitrile isolated from such crude product. In the last column is given the yield in per cent. of the calculated.

### Discussion of Results.

From Table I, in which are given experiments in which acetates of various metals were heated with lead thiocyanate, it appears that the

acetates of the most of these metals give considerable yields of the nitrile. Nickel acetate gave little and magnesium acetate none that could be isolated. The distillates in Experiments 7 and 9 from mixtures containing magnesium and barium acetates had fearful, suffocating odors which may have been due to the presence of isocyanates. In an experiment, not included in the table, 75 g. of potassium thiocyanate were heated with 25 g. calcium acetate and only 1.2 g. of crude distillate was obtained. This had a similar bad odor.

TABLE V.

Lead Salts of Phenyl Acetic and Cinnamic Acid with Lead Thiocyanate.

No.	Method.	Acid.	Pb(CNS) <sub>2</sub>	Pb $\bar{A}$ <sub>2</sub> <sup>1</sup>	Ratio.	Time.	Prod.	Nitrile.	Calc.	Yield.
43	<i>a</i>	ph. ac.	35 g.	50 g.	1.03	120	15 g.	6.0 g.	24 g.	25%
44	<i>a</i>	cin.	100	75	2.04	150	...	8.0	37	21

In most of the first 9 experiments the amounts of materials used were small and the amounts of acetonitrile worked with were quite small. On this account the losses in handling the nitrile were proportionately great and the results given, representing the amounts isolated, are probably much too low. It appears from these experiments that manganese and zinc acetates are the most suitable for the preparation of the nitrile. The manganese acetate gave a particularly high yield and a clean pure product, but as zinc salts are so much more readily obtained than those of manganese, the zinc salts are to be preferred for practical work.

Experiments 10, 11, 12, and 13 with copper and lead acetates, in glass retorts using larger amounts of materials, are to be compared with Experiments 15, 17, and 18 of Table III in which zinc acetate was used under the same conditions. It thus appears that zinc acetate gives nearly twice the yield that lead acetate does. The stability, fusibility, and mutual solubilities of the fused salts are probably the determining factors in the matter of the yields from various mixtures.

From the results in Table II, it appears that thiocyanates of other heavy metals can be used. In Experiment 14 an excellent yield was obtained from cuprous thiocyanate. In this case the yield is calculated from the thiocyanate present instead of from the acetate as in all the

<sup>1</sup>  $\bar{A}$  stands for one equivalent of the acid indicated by abbreviation in 3rd column.

other experiments. The results obtained with zinc thiocyanate suggest that it might be substituted for the corresponding lead salt to advantage, but its physical properties make against its use. Lead thiocyanate, being insoluble in water, is readily obtained by precipitation, and is easily dehydrated. Zinc thiocyanate is very soluble in water and hence inconvenient to prepare and is difficult to dehydrate. For these reasons the lead salt is better for practical work.

From the results given in Table III, it appears that much better results are obtained by methods *c* and *b* in which larger quantities of materials are used in glass or iron retorts. Contrasting Experiment 16 with Experiment 17 in which double the calculated amount of the lead sulfo-cyanate was used, it appears that little or nothing is gained by the use of this large excess.

From the experiments in Table IV, it appears that the yields are better with the higher molecular weight acids than with acetic, isovaleric giving 86% of the calculated amount of nitrile. This may be only apparent, since the higher nitriles, on account of their being less volatile and less soluble in water, are much easier to isolate than is acetonitrile. The results with stearic acid are not regarded as reliable as no good method is available for the isolation of this nitrile.

Comparing Experiments 37 to 39 with 40 and 41, we see the effect of the ethylene group in cinnamic acid. A much larger yield of hydrocinnamic nitrile is obtained than of the cinnamic. The use of diminished pressure during the distillation in Experiments 37 and 38 did not materially increase the yield. The high yield of hydrocinnamic nitrile, when the mixture of salts is heated in a plain glass retort, is surprising. This shows that the method is available for the preparation of nitriles of high molecular weight, provided there are no interfering groups in the molecule.

In this work, the mixed aromatic-aliphatic acids in which the carboxyl group is not in the ring are considered as aliphatic.

Experiment 42, with terephthalic acid, an aromatic acid, does not properly belong to this study, but was tried to test the applicability of the method for di-nitriles.

The experiments in Table V, with lead salts, are to be compared with those with the corresponding zinc salts in Table IV. The comparison is to the advantage of the zinc salts as it was with the acetates in Table I.

According to Liebig and Rammelsburg<sup>1</sup> and also Voelckel,<sup>2</sup> thiocyanic acid decomposes when heated, in presence of water, into carbon dioxide, carbon disulfide, and ammonia.

<sup>1</sup> *Pogg. Ann.*, **56**, 94 (1842).

<sup>2</sup> *Ibid.*, **58**, 135 (1843); *Ann.*, **43**, 74 (1842).

It was thought that possibly some of these decomposition products might act on the lead salt of an acid to give the nitrile. Accordingly an experiment was performed to determine the effect of the decomposition products of thiocyanic acid on the lead salt of benzoic acid. Dry ammonia was passed through carbon disulfide which was sufficiently warmed to give it the proper vapor tension. The mixture of the vapors of ammonia and carbon disulfide was passed over lead benzoate (39 g.), which was heated in an oil bath to a temperature of  $220^\circ$ . *Results:* a mixture of benzoic acid and benzonitrile condensed on the cooler part of the lead benzoate flask and also in the condenser. A few drops of a pale yellow liquid passed through the condenser. This had an odor of carbon disulfide. All the lead benzoate was converted into a black residue of lead sulfide, with black mirror of same around the upper part of the flask. The amount of benzonitrile formed was insignificant. This shows that readily formed  $\text{CS}_2$  and  $\text{NH}_3$  do not produce the same results as the lead thiocyanate.

In another experiment, a mixture of ammonia and carbon dioxide was passed over a mixture of 35 g. of lead benzoate and 5 g. of sulfur, heated in an oil bath to a temperature of  $240^\circ$ . *Results:* Solid ammonium carbonate was deposited on the walls of the lead benzoate flask and in the condenser and also in the receiver. Sulfur sublimed and deposited on the upper part of the flask. The odor of benzonitrile was apparent but the amount formed was insignificant.

In Experiment 20, to determine whether the nitrile is decomposed by side reactions, etc., into the free acid, the mixture of zinc acetate and lead thiocyanate was heated in an oil bath with reflux condenser. The blackening began between  $150$  and  $170^\circ$  and the reaction began at about  $250^\circ$ . The mixture was kept at this temperature for a considerable time and then the bath was removed and the heating completed with a luminous flame. The nitrile was finally distilled off. The yield was less than usual, showing that prolonged contact of the nitrile with the heated mass lowers the yield.

Stannous and basic ferric acetates were heated with lead thiocyanate but the mixtures did not fuse and gave no nitrile. In the case of the ferric salt, a white solid was deposited in the condenser. This proved to be ammonium carbonate.

In several experiments, the issuing gases were measured and examined. No hydrogen sulfide was found. A small amount of carbon monoxide was found. The amount of carbon dioxide corresponded closely to that calculated from the reaction given below.

### Conclusions.

1. Aliphatic nitriles, as well as aromatic, are readily prepared, with good yields, by distilling mixtures of well dried heavy metal salts of the acids with slight excess of lead, or other thiocyanate.

2. All things considered, the best mixture is the *zinc* salt of the organic acid with *lead* thiocyanate.

3. The reaction takes place, in the main, according to

4. Excess of the thiocyanate and use of vacuum do not materially increase the yields.

5. *Preparation of Acetonitrile*.—A mixture of one part well dried zinc acetate and two parts, by weight, of lead thiocyanate is heated in a plain glass retort till no more distillate comes over. The crude distillate is mixed with half its volume of water, saturated with solid potassium carbonate or ammonia gas and the nitrile separated and fractioned.

## STUDIES IN THE PREPARATION OF NITRILES. III. THE CATALYTIC PREPARATION OF NITRILES.

By G. D. VAN EPPS AND E. EMMET REID

Received August 2, 1916.

### Introduction.

Numerous experiments have recently been described, in which substances have been made to react, with elimination of water, by passing them, in vapor form, over certain metallic oxides, notably alumina and thoria. Thus Senderens<sup>1</sup> prepared ethers by passing vapors of the alcohols over alumina at 240–260°. Sabatier and Mailhe<sup>2</sup> found that alcohols yield ethylene hydrocarbons and water with thoria and alumina at 300–350°, and that various phenols<sup>3</sup> when mixed with methyl alcohol give the methyl ethers of the phenols with thoria at 390–420°, or the diphenyl ethers<sup>4</sup> when the alcohol is left out. The same authors<sup>5</sup> found that, when a mixture of the vapors of an acid and an alcohol is passed over titania or thoria at 280°, esterification takes place with great rapidity, the limit of esterification being reached in minutes instead of the hours required at 154° or 200°, without catalyst.

Since the formation of a nitrile from the acid and ammonia

<sup>1</sup> *Compt. rend.*, **148**, 227–8 (1909)

<sup>2</sup> *Ibid.*, **150**, 823–6 (1910).

<sup>3</sup> *Ibid.*, **151**, 359–62 (1910).

<sup>4</sup> *Ibid.*, **151**, 492–4 (1910).

<sup>5</sup> *Ibid.*, **152**, 494–497, 1044–47 (1911), *Chem. Ztg.*, **35**, 193 (1911).

may be regarded as a dehydration reaction, it was thought that it might take place under similar circumstances. The experiments have justified this supposition, since it has been found that excellent yields of acetonitrile may be obtained directly from acetic acid and ammonia, by passing their vapors over alumina or thoria at 500°.

The study of this reaction may throw some light on the mechanism of the other reactions since, in this case, we are well acquainted with ammonium acetate which may be formed as an intermediate product in the reaction.

Acetic acid has been the only acid studied, but it is probable that other acids will yield nitriles under similar circumstances.

As usually made, from acetamide and phosphorus pentoxide, both of which are rather expensive, acetonitrile is an expensive substance and one difficult to prepare in large quantities. By the present method in which it is made in a direct continuous process from acetic acid, and ammonia, both cheap materials, it becomes one of the most accessible compounds.

### Experimental.

**Materials.**—A high grade glacial acetic acid containing very near 100% acid was used. Weighed amounts of this were diluted with weighed amounts of water for the acids of 95%, 90%, etc., strength. The other chemicals used were good commercial products. The ammonia was drawn directly from a cylinder of the liquefied gas.

**The Catalyst.**—Pumice stone, broken to pieces 3 to 5 mm. in diameter, was soaked in a concentrated solution of aluminium sulfate, treated with ammonium hydroxide, and well washed. The pumice stone with the adhering aluminium hydroxide was at first dried in an air bath, but later was dried in the copper tube in a current of ammonia.

For the thoria catalyst, the pumice stone was wet with a concentrated solution of thorium nitrate and heated to about 500° in a current of ammonia.

**Apparatus.**—The catalyst was placed in a very thick walled copper tube 762 mm. long and 32 mm. bore, heated by long burners. This will be more fully described elsewhere. The acid was run in through a brass tube containing a trap to prevent the exit of vapors. This ended about 80 mm. inside the copper tube so that the acid was vaporized on entering. Around this tube was a larger but shorter tube, through which the ammonia was introduced. Thus the acid vapor was introduced directly into an atmosphere of ammonia at the reaction temperature.

The exit end of the copper tube was connected through a Liebig condenser with a receiver from which a tube led to a flask of dilute sulfuric acid to absorb any excess of ammonia gas.

The temperature of the copper tube was measured by an arrangement

by which the expansion of the tube itself was made to move a hand on a dial.

**Procedure.**—The acid or other liquid was dropped into the funnel of the trap tube from a small dropping funnel at a rate of one drop per second. The ammonia was passed in at such a rate that white vapors filled one-half the condenser tube. This shows presence of sufficient excess of ammonia.

Usually the product in the receiver forms two layers, the upper one being nearly pure nitrile, and the lower containing some nitrile and much ammonium acetate. Acetonitrile is salted out of water by ammonium acetate. On completion of each experiment, the upper layer of nitrile was separated and distilled up to 85°. The lower layer was fractionated up to 90°, the fraction being redistilled up to 82–84°. The total nitrile obtained is the sum of these two portions. In cases where no layer was observed the whole product was fractionated up to 90°, the lower fraction being redistilled up to 85°.

**Results.**—The first experiment with alumina at above 500° showed the production of nitrile. Then a large number of experiments were made in order to find the best conditions as to catalyst, temperature, relative amounts of ammonia, etc. The results of these are given below in tabular form.

It was thought possible that ethyl acetate might react with ammonia

and accordingly this was tried with alumina at 510°, but no nitrile was obtained. It is known that acetone passed over pumice at 500° gives ketene<sup>1</sup> which might possibly react with ammonia to form the nitrile.

Accordingly, acetone vapor and ammonia were tried at 500° with alumina, but no nitrile was obtained.

It was thought that acetic anhydride might give better yields with ammonia than acetic acid, since less water would have to be split off. Accordingly, two experiments were tried, using the anhydride at 500–530° and at 520–560°. These gave 31.3 and 24.4% of the calculated amount of nitrile. As these were lower yields than were usually obtained with the 100% acid the use of the anhydride appears to be of no advantage and no further experiments were tried with it. The anhydride would, doubtless, have given better yields with the better catalyst that was used in later work with acetic acid.

In order to ascertain whether a catalyst is required, two experiments were tried in which acetic acid and ammonia were passed through the

<sup>1</sup> Schmidlin and Bergman, *Ber.*, 43, 2821 (1910).

hot tube filled with broken pumice stone at 400° and at 500° but no nitrile could be isolated in either case. The product seemed to be mainly acetamide.

The next experiments were to determine the relative activity of the two catalysts, alumina and thoria at various temperatures with 100% acetic acid. The four experiments with alumina were run with same catalyst without removing it from the copper tube and the four with thoria likewise. The results are given in Table I and graphically in Fig. 1.

TABLE I.

Temp.	Acid used.	Time in minutes.	With thoria.		With alumina.	
			Grams.	Per cent.	Grams.	Per cent.
305°	20.0 g.	..	None	....	....	....
300°	107.5	80	....	....	6.0	8.2
405°	57.9	65	3.5	8.8	....	....
400°	118.0	65	....	....	15.0	18.6
500°	66.0	75	15.4	34.1	....	....
500°	89.0	60	....	....	21.5	35.3
550°	83.5	85	10.5	18.4	....	....
575°	120.0	55	....	....	21.8	26.6

For the lower temperatures the alumina gives decidedly better results. About 500° appears to be the best temperature with both catalysts. The results are plotted in curves with the percentage yield against temperature.

Too much reliance must not be put in these figures, since the results given below show that there is great variation in the yields without apparent cause, and that different preparations of the same catalyst give widely different results. As the alumina appears to be slightly more effective

than the expensive thoria, the alumina catalyst was used exclusively in the remainder of the work. In the experiments at 300° and 400° with both catalysts, acetamide seemed to be present in the product, but it was not positively identified.

The remaining experiments are all given in Table II, the two main variables being percentage of acetic acid and the preparation of the catalyst. Experiments were run with differing concentrations of the acid with one lot of catalyst, and then the copper tube would be cleaned out and another lot of catalyst put in and more experiments run. A blank space

across the table indicates this change to a new lot of catalyst, the double space at Expt. 39 indicates change in method of preparation of catalyst. The temperature was near 500° in all. The experiments are numbered in the order in which they were run.

The catalyst becomes covered with a black deposit and loses its activity. The method of estimating the nitrile gives, only approximate results. It represents not the amount formed, but the amount that may be isolated according to methods in use in ordinary organic preparations. The accuracy of the work naturally increases toward the end.

### Discussion of Results.

In Expt. 3 a small excess of ammonia was used and in Expt. 4 a much more rapid current of ammonia. The smaller amount gave 50.2% against 43.9% for the larger. This seems strange, at first sight, but the rapid current of ammonia hurries the acid vapor through the hot tube and does not give it time to react. In Expt. 5 the flow of the acid was four times as rapid as in Expt. 3 and only about half as large a yield of nitrile was obtained, but twice as much nitrile per minute was formed.

A calculation as to the rapidity of the reaction is of interest. Since 60 g. of acetic acid is 1 mol its vapor should occupy at 500°,  $\frac{22.4 \times 773}{273} =$

63 l. = 63,000 cm. As the bore of the tube is 32 mm., its area is 8.0 sq. cm. Dividing 63,000 by 8, we have 7,875 as length of a tube of this size required to contain the acetic acid vapor. In Expt. 50, this amount of acid vapor passed through the tube in 55 minutes, from which the linear velocity of the vapor must be  $7875 \div 55 = 143$  cm. per minute. As the length of the tube is 76.2 cm. the vapor must pass through the tube in one-half minute. This calculation has been made assuming that there is nothing in the tube but acetic acid vapor, while in the actual experiment there was more than an equal volume of ammonia. This more than

doubles the linear velocity and reduces the time that any one portion of the vapor is in the tube to one-fourth of a minute or less. Hence, a mixture of acetic acid vapor and ammonia, at  $500^{\circ}$ , in contact with alumina is 85% transformed to nitrile in less than 15 seconds. If this is the average velocity for the whole mass of vapor, the velocity of the reaction in the layers of the vapor in actual contact with the alumina must be enormous.

It appears from many experiments that the addition of moderate amounts of water to the acetic acid does not prevent the formation of the nitrile. In fact, in the earlier part of the work, it seemed that the yields were increased by the addition of water, but the later and more reliable experiments show a diminution of yield with increase of water present. Since water has a much smaller molecular weight than acetic acid, the molecular percentage of water in the mixture is much larger. The effect of the water is seen from Table III in which some of the experiments from Table II are presented in a different way. In the last column the yields obtained, with the diluted acids, are calculated as per cents. of the yield from 100% acetic acid.

TABLE III.  
Showing Effect of Water on Yield.

Experiment.	Per cent. acid.	Actual yield.	Mol. % of acid.	Yield $\div$ 85.
50	100	84.6	100	100%
51	100	85.8	100	100%
53	95	71.2	85	83%
54	90	65.5	73	77%
56	85	59.0	63	70%

The results are as we should expect from the mass law, since the rate of formation of nitrile appears to be roughly proportioned to the concentration of the acid in every case. The water found in the reaction diminishes the effect of the water initially present so that it is not surprising that the weaker acids give better yields than would be expected from the initial composition of the mixture. Good yields, 42 to 45%, were obtained with even 70% acetic acid. The average of 8 experiments with 75% acid is 56% of nitrile, which is better than any results obtained with 80% acid. It is not safe to draw too definite conclusions, as there is a large variation in the results. This variation comes partly from errors in the method of estimation of the nitrile, but mostly from slight changes of conditions in the various experiments, conditions that it is very difficult to control.

Inspection of consecutive experiments shows that the activity of the catalyst gradually diminishes with use and a jump in the yield is noticed on the introduction of a new lot of catalyst.

In one experiment, not included in the table, ammonium acetate dissolved in an equal weight of acetic acid was used instead of the acid.

Only a little nitrile was obtained. In Expt. 2 the lower layer of the distillate was passed through the apparatus again, but only a small additional amount of nitrile was produced.

It appears from Table II that most of the nitrile is found in the upper layer and, when 100% acid is used, a good yield of the nitrile is obtained even when the lower layer is discarded. As we would expect, in the experiments with weaker acid, particularly the 70% acid, a larger amount, in some cases, half or more of the nitrile, is found in the lower layer.

It is intended to continue this work, particularly with the study of the formation of other nitriles.

### Summary.

1. It is found that acetic acid vapor, mixed with a moderate excess of ammonia and passed over alumina or thoria at 500°, gives a large yield, up to 85%, of acetonitrile.

2. This reaction does not take place in case the catalyst is omitted.

3. The yield depends on the activity of the catalyst and may vary greatly for what appear to be trifling differences in the method of preparation of the catalyst.

4. So far as the present work goes, alumina appears to be the best catalyst and about 500° the best working temperature.

5. This method of preparation of acetonitrile is a continuous process requiring very little attention, and is adapted to use for the preparation of large quantities.

<sup>3</sup> *Z. physiol. Chem.*, 51, 457 (1907).

olism of flesh food. The following year Engeland duplicated this work of Kutscher's and confirmed his original observations by isolating the same substance in the form of its gold salt from beef extract and urine.<sup>1</sup> Kutscher obtained no chemical evidence upon which to base a structural formula, but assigned to the amine, however, the provisional Formula III, to show its possible relationship to the other bases found with it in urine, *viz.*, guanidine, methylguanidine, dimethylguanidine and creatine.

If *vitiatine* is to be considered as a *mono*-methyl derivative of ethylene-guanidine<sup>2</sup> (I) there are just three structural formulas to which it can theoretically conform, namely: the carbon-substituted derivative represented by Formula II, and the two isomeric nitrogen-substituted compounds corresponding to Formulas III and IV, respectively.

None of these have been prepared. The structure of all three combinations (II, III and IV) would be established by their behavior on hydrolysis. The combinations (II) and (IV) would be productive of diaminopropane<sup>3</sup> (VI) and ethylenediamine (V), respectively, with formation of ammonia and monomethylamine, while a compound having the structure assigned to *vitiatine* (III) would give four proportions of ammonia and monomethylethylenediamine. In other words, the basic nucleus of *vitiatine*, if Kutscher's formula is correct, is the monomethylated base (VII), which has not been described in the literature. The primary object of this investigation was to develop a method of synthesizing this unknown amine.

(V).

(VI).

(VII).

A successful method of synthesizing this compound (VII) was not developed until after we had considered and tried, without success, a number of different methods which seemed feasible of application. No attempts were made by us to prepare the methyl derivative from ethylenediamine by direct alkylation, because Schneider<sup>4</sup> has already shown that this base undergoes exhaustive alkylation by treatment with methyl iodide giving the diquaternary salt  $\text{I}(\text{CH}_3)_3\text{N} \cdot \text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_3\text{I}$ . The

<sup>1</sup> *Z. untersuch. Nahr. und Genussm.*, 16, 658 (1909); *Z. physiol. Chem.*, 57, 49 (1908).

<sup>2</sup> This simple guanidine has never been synthesized.

<sup>3</sup> Hoffmann, *Ber.*, 6, 308 (1873).

<sup>4</sup> *Ber.*, 28, 3073 (1895).

synthesis of the symmetrical dimethyl derivative was accomplished by Schneider by alkylation of the phenylsulfonamide (VIII) with methyl iodide and then hydrolyzing the resulting dialkyl derivative (IX), with hydrochloric acid. He did not succeed in obtaining by alkylation the monomethyl derivative of the sulfonamide (X). We have applied a

similar reaction with the dibenzylsulfon derivative of ethylenediamine,

and have succeeded in isolating, after alkylation, both the corresponding dimethyl and methyl derivatives. The yield of the latter, however, was so small that the synthesis was of no practical value for the preparation of the free amine. The application of Mendius' reaction was considered by us and the nitrile of sarcosine  $\text{CH}_3\text{NHCH}_2\text{CN}$ <sup>1</sup> and the corresponding phenylsulfon derivative,  $\text{C}_6\text{H}_5\text{SO}_2\text{N}(\text{CH}_3)\cdot\text{CH}_2\text{CN}$ ,<sup>2</sup> were reduced with sodium and alcohol, but in neither case was the operation productive of combinations from which we were able to separate the methyl-ethylenediamine (XII). The action of ammonia on bromoethylmethylamine,  $\text{CH}_3\text{NHCH}_2\text{CH}_2\text{Br}$ , and the corresponding chlorine compound was not investigated. Marckwald and Frobenius,<sup>3</sup> who prepared these amines, have shown that they interact abnormally with alkalis with formation of the cyclicimide,  $\text{CH}_2\cdot\text{CH}_2\cdot\text{N}\cdot\text{CH}_3$ . Bromoethylphthalimide (XI),

also shows irregularities in its behavior towards amines. Ristenpart<sup>4</sup> attempted to prepare the phthalyl derivative of methylethylenediamine by heating this bromide with methylamine, but found, contrary to his expectation, that they interacted in an entirely different manner giving a mixture of the bromoamide (XII), and the corresponding vinyl derivative represented by Formula XIII. Diethylamine, on the other hand, reacted normally with formation of the diamino combination (XIV), but the yield was poor.

<sup>2</sup> Johnson and McCollum, *Am. Chem. J.*, 35, 59 (1906).

<sup>3</sup> *Ber.*, 34, 3544 (1901).

<sup>4</sup> *Ibid.*, 29, 2526 (1896).

The synthesis of methylethylenediamine (VII), has now been accomplished by a method which involves the use of bromoethylphthalimide. We find that this halide interacts with the potassium salt of benzylsulfonamide giving the corresponding acid amide (XV). This undergoes alkylation smoothly with methyl iodide, forming the methyl derivative (XVI), which gives on hydrolysis with hydrochloric acid the amine (VII), phthalic acid, sulfur dioxide and benzyl chloride. The transformation is a quan-

titative one with the exception of the first phase involving the formation of the amide (XV). The first attempts to prepare this were made by allowing the potassium salt of benzylsulfonamide to react with bromoethylphthalimide in alcohol. This method proved a failure as the bromide was decomposed by the alkali with displacement of the halogen by hydroxyl and production of  $\beta$ -hydroxyethylphthalimide.<sup>1</sup> Phenylsulfonamide was tried in place of benzylsulfonamide with the same result. Modifications in procedure were made by changing the strength of alcohol used and varying the time of heating; catalytic agents were introduced and the operation of preparing the salt of the sulfonamide was modified, but in no case was the desired combination formed. Attempts were then made to bring about the change by digesting the bromide with the potassium salt of the amide in benzene, toluene and petroleum ether but no reaction took place under such conditions. Formation of the amide was finally accomplished by fusing the dry potassium salt with bromoethylphthalimide. The best yield, however, that could be obtained by this procedure was 40% of the theoretical. The potassium salt of phenylsulfonamide interacts with bromoethylphthalimide under similar conditions, giving the corresponding phenylsulfonamide (see experimental part).

In the course of our work we had occasion to investigate the behavior on hydrolysis of several alkyl derivatives of benzylsulfonamide. In every case examined, such combinations always broke down when heated with hydrochloric acid with complete destruction of the sulfonic acid. The hydrolysis generally takes place quantitatively below 140°, and by evaporation of the resulting solution the hydrochloride of the amine is obtained free from sulfur compounds. Johnson and Ambler<sup>2</sup> utilized benzylsulfonamide in developing a synthesis of sarcosine. We have ap-

<sup>1</sup> Gabriel, *Ber.*, 21, 572 (1888).

<sup>2</sup> *THIS JOURNAL*, 36, 372 (1914).

plied their method of synthesis and prepared the amino acid—alanine. The potassium salt of benzylsulfonamide interacted smoothly with  $\alpha$ -bromopropionamide in alcohol solution forming the corresponding sulfonamide (XVII). When this was digested with barium hydroxide in aqueous solution it was saponified smoothly with formation of the corresponding acid (XVIII). The latter was decomposed quantitatively when heated with hydrochloric acid at  $130^\circ$ , giving the hydrochloride of alanine (XIX). Benzyl chloride and sulfur dioxide were the secondary products of this change.

Our researches on amines will be continued.

### Experimental Part.

The benzylsulfonchloride which was used in this investigation was prepared according to Pechmann's<sup>1</sup> directions by interaction of phosphorus pentachloride with the sodium salt of benzylsulfonic acid. This was converted into its corresponding amide,  $\text{C}_6\text{H}_5\text{CH}_2\text{SO}_2\text{NH}_2$ , but the action of ammonia.

**Potassium Salt of Benzylsulfonamide,  $\text{C}_6\text{H}_5\text{CH}_2\text{SO}_2\text{NHK}$ .**—This salt was prepared by dissolving a molecular proportion of potassium hydroxide in absolute alcohol and adding to the solution the required amount of the sulfonamide. After heating to boiling for one-half an hour the solution was cooled when the potassium salt separated in the form of micaceous flakes. The salt was separated by filtration and washed carefully with ether. For the success of the next operation this washing was essential in order to remove the mother liquor which contained traces of free alkali and unaltered amide. If dilute alcohol was used the salt separated in a more compact crystalline form and contained little free alkali. The salt did not melt below  $300^\circ$ . It was dried at  $100^\circ$ .

**The Action of Bromoethylphthalimide on the Potassium Salt of Benzylsulfonamide: Phthalimidobenzylsulfonethylenediamine (XV).**—In our preliminary work the potassium salt of benzylsulfonamide was prepared by dissolving 2.2 g. of potassium hydroxide in 40 cc. of alcohol and then dissolving 6.7 g. of the amide in the solution. After boiling for one-half an hour, 10 g. of bromoethylphthalimide were introduced and the solution finally digested until it gave no alkaline reaction. This operation requires from 2 to 3 hours. The precipitate which deposited was filtered off and the mother liquor evaporated to dryness. From the precipitate a theoretical yield of potassium bromide was obtained. The filtrate on evaporation left a yellow, gummy mass, which could not be

<sup>1</sup> Ber., 6, 534 (1873).

crystallized from alcohol, water or ether. The substance became very viscous on warming and solidified to a gum in a freezing mixture. When the material was hydrolyzed in a bomb tube with hydrochloric acid, phthalic acid, benzyl chloride and benzyisulfonamide were formed and identified but no amine was obtained.

A number of experiments were afterwards made using modifications of the above, in which the time of heating, the quantity of alcohol and the strength of the alcohol were varied but without the desired results. It was found that the bromine atom of the phthalimide combination was replaced by a hydroxyl group in the alkaline solution and  $\beta$ -oxyethylphthalimide<sup>1</sup> was formed. The latter compound was isolated and identified by its melting point ( $126-127^\circ$ ). Similar results were obtained by the action of bromoethylphthalimide on an alcoholic solution of the potassium salt of phenylsulfonamide. In every experiment the sulfonamide was recovered unaltered. From these results it was concluded that bromoethylphthalimide cannot be used in alkaline alcoholic solution for such reactions. The above difficulties were finally partially overcome by working under the following conditions:

Molecular proportions of the potassium salt and bromoethylphthalimide were ground together in a mortar and the mixture heated in a flask at  $100-110^\circ$  for 4-5 hours. At the end of this time the melt was a black, viscous liquid, which solidified on cooling. There was no reaction at  $80^\circ$  and no increase in yield was obtained by heating above  $110^\circ$  or longer than 5 hours. This residue was digested with water to remove potassium bromide. After filtering, the residue was subjected to the same treatment several times to remove the last trace of bromide and finally purified by digestion with 50% acetic acid in the presence of animal charcoal. On cooling, the ethylenediamine derivative separated and was further purified by recrystallization from glacial acetic acid. On concentrating the acetic acid filtrates more of the same product was obtained. Glacial or 50% acetic acid were the only solvents in which the compound could be digested with animal charcoal with removal of the coloring material.

From the water filtrate 80% of the theoretical quantity of potassium bromide was isolated, along with unaltered benzyisulfonamide and a low melting substance, which was identified as a mixture of bromoethylphthalimide and the sulfonamide.

The yield of phthalimidobenzyisulfonethylenediamine was 40% of theory. If alkali was present in the potassium salt used in its preparation this yield was decreased and more resinous material was obtained. The compound crystallized from acetic acid in slender prisms which melted at  $175-176.5^\circ$  to a clear oil. It is soluble in benzene, chloroform, methyl

<sup>1</sup> Gabriel, *Ber.*, 21, 572 (1888).

alcohol, ethyl alcohol and acetic acid; insoluble in water and slightly soluble in ether. It was dried for analysis at 100°.

Calc. for  $C_{17}H_{18}O_4N_2S$ : N, 8.14%. Found: N, 7.90, 8.2.

Before using this compound for methylation in the next experiment it was found advisable to crystallize it from alcohol, as there was a tendency for the amide to occlude acetic acid when crystallized from that solvent. Unless this was carefully removed unsatisfactory results were always obtained during alkylation, because the acid present interacted with the sodium alcoholate incorporated and a mixture of unaltered material and the methyl derivative obtained.

**Alkylation of Phthalimidobenzylsulfonamide with Methyl Iodide. Phthalimidobenzylsulfonmethylethylenediamine (XVI).**—Two grams of phthalimidobenzylsulfonethylenediamine were added to 25 cc. of methyl alcohol, in which had been dissolved 0.3 g. of metallic sodium, a slight excess over two molecular proportions. After boiling on the water bath for 45 minutes the solution was cooled and 4 g. of methyl oxide (4 mols) added. The mixture was allowed to stand for a half hour and found to be alkaline; it was then heated to the boiling temperature and digested for an hour or until neutral. Upon cooling the methylated product separated in the form of colorless, prismatic crystals. The yield was 0.7 g. The mother liquor was evaporated to dryness and the residue digested with water until the excess of iodide and alcohol was expelled. An insoluble precipitate was obtained which proved to be the methyl derivative. The total yield of this product was almost theoretical. Sodium iodide was found in the water filtrates in theoretical quantity.

If the original amide was treated with one molecular proportion of sodium instead of two, the methylation was only partially complete and a mixture resulted, from which it was difficult to separate the methylated from the unmethylated amide. Methyl alcohol, as a solvent, gave better results than ethyl alcohol, as in the latter methylation seemed to be incomplete and mixtures resulted from which pure substances could not be isolated. From the analysis of a product obtained under such conditions, it appeared that ethyl groups had replaced the phthalyl group. It was our experience that better yields of the methylated product were obtained when 2 g. portions were alkylated than when larger quantities were taken.

This ethylenediamine derivative crystallized in slender prisms. It is soluble in acetic acid and difficultly soluble in methyl alcohol. It melts at 177–178° to a clear oil. A mixture of this compound and the unmethylated derivative melted at 150–165°.

Calc. for  $C_{18}H_{20}O_4N_2S$ : N, 7.82, S, 8.9. Found: N, 7.94, 7.84, 7.97; S, 8.99.

**Mono-Methylethylenediamine Hydrochloride,  $CH_3NH.CH_2CH_2NH_2 \cdot 2HCl.H_2O$ .**—In order to obtain this salt phthalimidobenzylsulfonmethyl-

ethylenediamine was hydrolyzed by heating with an excess of concentrated hydrochloric acid at  $120^{\circ}$  for 4 hours. At the end of this time benzylchloride had formed a dark layer on the surface of the acid solution and phthalic acid had deposited in a crystalline condition. The contents of the bomb tube were diluted with water, filtered through a wet fluted filter and evaporated to dryness. The colorless residue left behind was triturated with a small amount of cold water and the insoluble phthalic acid filtered off. The aqueous solution of the amine hydrochloride was then evaporated to dryness and the hydrochloride dissolved in boiling 98% alcohol. On cooling, it separated in the form of colorless, micaeous flakes. After recrystallization from 98% alcohol it was then dried for analysis in a vacuum desiccator over concentrated sulfuric acid and potassium hydroxide. When dry hydrochloric acid gas was passed into the alcohol solution the hydrochloride separated very quickly. The amine distils with steam slowly. The hydrochloride melted at  $130-132^{\circ}$  with effervescence and the yield was practically theoretical.

Calc. for  $C_6H_{10}N_2 \cdot 2HCl \cdot H_2O$ : N, 16.98%. Found: N, 17.00, 17.20.

This base is not precipitated from an aqueous solution of its hydrochloride by mercuric chloride. Platinum chloride solution precipitates it from concentrated solutions in the form of square tabular prisms or plates, which melt at  $240-242^{\circ}$  with decomposition. The picrate of the base crystallizes from water in the form of prisms. They turn brown when heated and decompose at  $220-222^{\circ}$  with effervescence.

**Dibenzylsulfonethylenediamine**,  $C_6H_5CH_2SO_2NHCH_2CH_2NHSO_2CH_2C_6H_5$ .—This amide was prepared by heating the potassium salt of benzylsulfonamide with ethylenebromide at  $130^{\circ}$  for 5 hours. At  $110^{\circ}$  a vigorous reaction took place and it was necessary to cool the flask in order to retard the reaction. After the change was complete the reaction product was triturated with ether and the insoluble material washed with water to dissolve potassium bromide. The amide was then purified by crystallization from glacial acetic acid. It melted at  $202-204^{\circ}$ . The yield was 30% of theory. From the ether extract the unaltered dibromide and benzylsulfonamide were recovered. This amide crystallizes in the form of plates.

Calc. for  $C_{16}H_{20}O_4N_2S_2$ : N, 7.60%. Found: N, 7.63, 7.50.

Attempts to improve this yield were unsuccessful. In one experiment 3.6 g. of potassium hydroxide were dissolved in 50 cc. of absolute alcohol 10 g. of benzylsulfonamide were added and the mixture boiled until all the amide dissolved. One-half a molecular proportion of ethylenedibromide (5.4 g.) and 9.5 g. of potassium iodide were added and the solution digested until neutral. On cooling, the amide deposited mixed with potassium iodide and bromide. After washing with water the amide was purified by crystallization from alcohol. It melted at  $202-204^{\circ}$ . The yield

was very small. When ethylenebromide was used in excess the yield was not improved and unaltered amide was always recovered.

This same dibenzylsulfonamide can also be prepared by application of the Schotten and Baumann reaction with ethylenediamine and benzylsulfonchloride. From 5 g. of the amine and 15 g. of the sulfonchloride we obtained 4.5 g. of the purified amide melting at  $204^{\circ}$ . Two and five-tenths grams of acid chloride were recovered and the remainder was decomposed by the alkali.

**The Alkylation of Dibenzylsulfonethylenediamine with Methyl Iodide. The Formation of Dibenzylsulfonmethylethylenediamine,  $C_6H_5CH_2SO_2 \cdot N(CH_3)CH_2CH_2NH \cdot SO_2CH_2C_6H_5$ , and Dibenzylsulfondimethylethylenediamine,  $C_6H_5CH_2 \cdot SO_2 \cdot N(CH_3)CH_2CH_2N(CH_3) \cdot SO_2 \cdot CH_2C_6H_5$ .**—Ten grams of dibenzylsulfonethylenediamine and 2 molecular proportions of potassium hydroxide were dissolved in 150 cc. of 95% alcohol and the solution boiled for one hour. Six grams of methyl iodide were then added and the heating continued until the solution failed to respond to an alkaline reaction. After cooling, the insoluble material was separated and the filtrate saved (see below). This material was washed with cold water to remove potassium iodide and then triturated with a cold 10% solution of sodium hydroxide to remove any monomethylated amide and the insoluble material crystallized from glacial acetic acid. Four grams of material were obtained melting at  $217-219^{\circ}$ .

Calc. for  $C_{18}H_{22}O_4N_2S_2$ : N, 7.07%. Found: N, 7.08, 6.96.

From the alcohol filtrate and the sodium hydroxide washings (after acidifying) 1.5 g. of material were obtained. This product was partly soluble in cold alkali and alcohol. After treatment with alkali and reprecipitating with acid the amide was finally obtained pure and melted at  $137^{\circ}$ . The yield, however, was so small that there was not enough material for hydrolysis.

Calc. for  $C_{17}H_{22}O_4N_2S_2$ : N, 7.33%. Found: N, 7.33, 7.35.

**Dimethylethylenediamine Hydrochloride,  $CH_3NHCH_2CH_2NHCH_3 \cdot 2HCl$ .**—This salt was obtained by hydrolysis of dibenzylsulfondimethylethylenediamine with concentrated hydrochloric acid at  $120-130^{\circ}$ . The contents of the bomb tube were diluted with water, the solution filtered and finally evaporated to dryness. The amine hydrochloride was obtained in a crystalline condition and agreed in melting point and solubility with the dimethylethylenediamine hydrochloride described by Schneider.

**Phthalimidophenylsulfonethylenediamine,**  $C_6H_4 \begin{array}{c} \diagup CO \\ \diagdown CO \end{array} N \cdot CH_2CH_2 \cdot$

$NHSO_2C_6H_5$ .—This was obtained by heating 2.2 g. of bromoethylphthal-

imide with 1.7 g. of the potassium salt of phenylsulfonamide for 4 hours at 100°. After washing with water to remove potassium bromide the amide was decolorized by digesting in 50% acetic acid with animal charcoal and then recrystallized from this same solvent. It crystallized in short, flat prisms which melted at 175°.

Calc. for  $C_{16}H_{14}O_4N_2S$ : N, 8.50%. Found: N, 8.8.

**Di-(*p*-nitrobenzyl)-benzylsulfonamide**,  $C_6H_5CH_2SO_2N(CH_2.C_6H_4NO_2)_2$ .—This amide and its corresponding *mono*-nitrobenzyl derivative were formed by alkylation of benzylsulfonamide with *p*-nitrobenzylchloride. They were separated by trituration with dilute sodium hydroxide solution (10%). The disubstituted derivative was insoluble and was purified by crystallization from glacial acetic acid. It separated in needles and melted at 193–194°.

Calc. for  $C_{21}H_{19}O_6N_3S$ : N, 9.52%. Found: N, 9.40, 9.39.

Acids precipitated from the alkaline washings the *mono*-nitrobenzylbenzylsulfonamide,  $C_6H_5CH_2SO_2NHCH_2C_6H_4NO_2$ . This was purified by crystallization from glacial acetic acid and melted at 182–183°. The yield was small.

Calc. for  $C_{14}H_{14}O_4N_2S$ : N, 9.15%. Found: N, 9.20.

**Di-(*o*-nitrobenzyl)-benzylsulfonamide**,  $C_6H_5CH_2SO_2N(CH_2.C_6H_4NO_2)_2$ .—This crystallized from glacial acetic acid in prisms, which melted at 169–170°.

Calc. for  $C_{21}H_{19}O_6N_3S$ : N, 9.52%. Found: N, 9.35, 9.32.

***o*-Nitrobenzylbenzylsulfonamide**,  $C_6H_5CH_2SO_2NHCH_2C_6H_4NO_2$ .—This crystallizes from alcohol and melts at 124–126°. It is soluble in 10% sodium hydroxide solution.

Calc. for  $C_{14}H_{14}O_4N_2S$ : N, 9.15%. Found: N, 9.0, 8.9.

**Preparation of Di-(*o*-nitrobenzyl)amine Hydrochloride**,  $(NO_2.C_6H_4CH_2)_2NH.HCl$ .—This was easily obtained by heating its corresponding sulfonamide (see above) with concentrated hydrochloric acid at 130–140°. It melted at 245° after crystallization from water. Gabriel and Jansen<sup>1</sup> have described this salt and assigned to it a melting point of 220°.

Calc. for  $C_{14}H_{13}O_4N_3.HCl$ : N, 12.9%. Found: N, 12.3, 12.4.

**Di-(*p*-nitrobenzyl)amine Hydrochloride**,  $(NO_2.C_6H_4CH_2)_2NH.HCl$ .—This was obtained by hydrolysis of its sulfonamide with strong hydrochloric acid. It crystallized from water and melted at 212°. Strakosch<sup>2</sup> has described this salt and assigned to it a melting point of 212°.

Calc. for  $C_{14}H_{13}O_4N_3.HCl$ : N, 12.9%. Found: N, 12.9.

<sup>1</sup> *Ber.*, 24, 3093 (1891).

<sup>2</sup> *Ibid.*, 6, 1056 (1873).

**Benzylsulfonaminopropionamide, (XVII).**—The  $\alpha$ -bromopropionbromide used in this experiment was prepared according to the directions of Zelinsky<sup>1</sup> and converted into the corresponding  $\alpha$ -bromopropionamide by the method described by Bischoff.<sup>2</sup> Twenty-eight and two-tenths grams of benzylsulfonamide were converted into its potassium salt and the latter digested in alcohol with 25 g. of  $\alpha$ -bromopropionamide for 6 hours. The liquor was still alkaline at the end of this time due to the presence of ammonia formed by hydrolysis. On cooling the propionamide deposited mixed with potassium bromide. This was washed with water and purified by recrystallization from hot water. It crystallized in prisms and melted at 167°. The compound is soluble in alcohol, water and acetic acid, and difficultly soluble in benzene and ether. The yield was 15 g.

Calc. for  $C_{10}H_{14}O_2N_2S$ : N, 11.57%. Found: N, 11.6, 11.56.

**Benzylsulfonalanine, (XVIII).**—The amide described above was hydrolyzed by boiling with a strong aqueous solution of barium hydroxide or until no ammonia was evolved. The barium was then exactly precipitated as barium sulfate and the filtrate evaporated to dryness. The acid remained as a crystalline residue and was purified by crystallization from boiling water. It separated in the form of plates which melted at 164–165°. A mixture of this with the unaltered amide melted at 155°.

Calc. for  $C_{10}H_{14}O_4NS$ : N, 5.75; S, 13.16. Found: N, 6.0, 5.8; S, 13.6.

**Hydrolysis of Benzylsulfonalanine with Hydrochloric Acid. Alanine Hydrochloride, (XIX).**—This change was accomplished by heating the sulfonamide with hydrochloric acid for 2 hours at 130°. After filtering the solution was evaporated to dryness and the alanine hydrochloride purified by crystallization.<sup>3</sup>

Calc. for  $C_3H_7O_2N.HCl$ : N, 11.2%. Found: N, 11.3.

<sup>5</sup> *Am. Chem. J.*, 43, 505 (1910).

<sup>6</sup> *Ibid.*, 38, 259, 260 (1907).

perimental evidence that, in some catalytic reactions, the acceleration may take place not only through the action of the ions, but also to a large extent through the nonionized portion of the salt.

The work of Shadinger,<sup>1</sup> and later, Nirdlinger and Rogers,<sup>2</sup> and Chandler,<sup>3</sup> showed that in absolute alcohol both the 1-phenyl-3-thiouazole anions and the nonionized sodium 1-phenyl-3-thiouazole react with alkyl halides.

In working with the phenolates, Robertson<sup>4</sup> found that both the phenolate ion and the nonionized sodium phenolate react with the alkyl halides, and Marshall,<sup>5</sup> Harrison,<sup>6</sup> and Myers<sup>7</sup> observed that both the ions and molecules of sodium, potassium and lithium ethylates are concerned in the catalytic effect of these compounds on the reversible addition of alcohol to acetonitrile, benzonitrile, *p*-bromobenzonitrile and others.

Other reactions studied, and which uphold this theory, are those of methyl iodide, ethyl iodide, and ethyl bromide with sodium, lithium, and potassium ethylates at 25°.

Any results which shed light upon the mechanism of organic reactions are of such extreme importance, that it was considered advisable to extend this study to other reactions, and to study some of the same reactions at different temperatures. Since at different temperatures the per cent. of ionization changes, it might be possible to decide whether the nonionized molecule or both ions together react, as we have pointed out in earlier articles,<sup>8</sup> and especially for the reactions of water.<sup>9</sup>

With this idea in view, the authors took up the study of the reactions of sodium, lithium, and potassium ethylates with methyl iodide at 0°, and also the effect of added sodium iodide on the reaction between sodium ethylate and methyl iodide at 25° which will appear in a later publication.

If both the ethylate ion and the nonionized ethylate salt react with the molecular alkyl halide, we have two reactions proceeding simultaneously, one proportional to the ionized part of the ethylate,  $\alpha$ ,<sup>10</sup> and the other proportional to the nonionized part,  $1 - \alpha$ . It follows that

$$(1) \frac{dx}{dt} = K_i \alpha (C_{\text{ethylate}} - x)(C_{\text{alkyl halide}} - x) + K_m (1 - \alpha)(C_{\text{ethylate}} - x)(C_{\text{alkyl halide}} - x),$$

in which  $K_i$  is the velocity constant for the ionic reaction, and  $K_m$  is the constant for the molecular reaction in a normal solution, and  $x$  is the change in the concentration in the time  $t$ . If A represents  $C_{\text{ethylate}}$ , and B is substituted for  $C_{\text{alkyl halide}}$  we obtain by integration the equation

$$(2) K_N = VK_V = K_i \alpha + K_m (1 - \alpha) = \frac{1}{At} \frac{x}{(A - x)} \text{ if } C_{\text{ethylate}} \text{ is equal to } C_{\text{alkyl halide}},$$

or

$$(3) K_N = VK_V = K_i \alpha + K_m (1 - \alpha) = \frac{1}{(B - A)t} \ln \frac{A(B - x)}{B(A - x)}$$

if  $C_{\text{ethylate}}$  is not equal to  $C_{\text{alkyl halide}}$ .

Substituting the data obtained for  $t$ ,  $x$ , A, and B, we obtain a set of constants for  $K_V$  and  $K_N$  for each concentration of ethylate used.  $K_N$  represents the molecular velocity constant, or the velocity which that reaction would have if the concentration were normal, but the ionization corresponds to the concentration  $1/V$ , when  $V$  is the number of liters containing one gram molecule. For each ethylate there are given two representative tables, I to VI, inclusive, showing the values of  $K_V$  for the different time periods and the average  $K_V$  and  $K_N$  for the particular value of  $V$ . In Tables VII, VIII and IX, are given the summaries for  $K_N$  for all of our 55 duplicate tables<sup>1</sup> corresponding to I to VI. To determine  $K_i$  and  $K_m$  for the separate ionic and molecular reactions, it is only necessary to substitute the proper values in the following simultaneous equations and solve for  $K_i$  and  $K_m$ :

$$K_N = K_i \alpha + K_m (1 - \alpha)$$

$$K'_N = K_i \alpha' + K_m (1 - \alpha'), \text{ etc.}$$

Values for  $K_i$  and  $K_m$  are thereby obtained for every pair of concentrations, and the average of these is taken as the accepted value, and recorded in Table X. By substituting in the equation  $K_N = K_i \alpha + K_m (1 - \alpha)$ , these values found for  $K_i$  and  $K_m$  and the values for  $\alpha$  and  $(1 - \alpha)$  corresponding to the different concentrations of the various ethylates, we obtain the theoretical values for  $K_N$  given in Tables VII, VIII and IX, under the heading " $K_N$  calculated." These are compared with the corresponding values of " $K_N$  found," and the experimental errors, called "Per cent. error," are thus obtained. The percentage of the reaction due to the ethylate ions is given under  $K_i \alpha / K_N$  and the percentage due to the nonionized ethylate molecules is given under  $K_m (1 - \alpha) / K_N$ . For a complete mathematical and theoretical discussion of these equations,

<sup>1</sup> See B. M. Brown, Dissertation, Johns Hopkins University, 1913.

see Johnson and Acree,<sup>1</sup> and the dissertations of Robertson<sup>2</sup> and of Harrison.

Robertson<sup>2</sup> and Marshall<sup>3</sup> discussed the possibility and probability of other reactions taking place simultaneously with those given above. We must consider, for example, the catalytic effect of the salt formed, or even of the ethylate itself, which we could designate as a "salt effect," and perhaps a side reaction, as well, in which olefines may be formed.

Since we obtain, however, from the equations used two constant values for  $K_i$  and  $K_m$ , we can state that we have either two reactions, or two or more sets of reactions, taking place, one being a function of the concentration of the ions, and the other of the nonionized portion.

If  $K_i$  represents the velocity constant of the reaction between the ethylate ion  $C_2H_5O^-$ , and methyl iodide, we would expect to find experimentally that the value for  $K_i$  is the same whether the methyl iodide is allowed to react with sodium, lithium, or potassium ethylates. Considering the greater difficulty in carrying out these reactions at  $0^\circ$  and the possibility of greater errors, there is quite satisfactory agreement between the values of  $K_i$  for the sodium, potassium, and lithium ethylates, namely, 0.00486, 0.00525, and 0.00524, respectively. Dr. W. A. Taylor<sup>4</sup> also obtained the value  $K_i = 0.00496$  for sodium ethylate. The values for  $K_m$  would not necessarily be the same, and might be entirely different, because of the fact that the nonionized molecules of these three ethylates are different substances. In conformity with the theory we find the values 0.00303, 0.00337 and 0.00197 for  $K_m$  for sodium, potassium, and lithium ethylates, respectively, and Dr. W. A. Taylor's value 0.00294 for  $K_m$  for sodium ethylate agrees well with ours. The lower activity for the molecules of lithium ethylate has been observed in every one of a large number of other reactions.

Since viscosity may play an important part in the reaction velocities at  $0^\circ$ , especially in the more concentrated solutions, it will be extremely interesting, as well as important, to obtain all the necessary data, so that corrections can be made for the viscosity, and all other important physical factors.

To make the constants from the different concentrations of ethylate comparable, the reactions were allowed to run to about the same percentage completion, which was usually 50 to 60%, and an average value for the reaction velocity was obtained by taking the mean of the constants for the different time periods. When the last constants were low they were in some cases omitted and the remaining values averaged and

It will be seen from the results that it makes very little difference in the calculated values for  $K_N$  when these starred values are used in place of the other values.

In the case of lithium ethylate the reaction was so much slower than in the other cases, that it was difficult to obtain the desired time periods, since it was, of course, impossible to titrate by artificial light. For this reason, in some of the more dilute solutions the reactions were 70 to 80% completed. But since the constants in these solutions did not decrease appreciably, there is practically no change introduced by using these values for the longer time periods.

It can be seen from the tables that there is very little difference between the values of  $K_N$  for the different concentrations of potassium ethylate, and that in some of the more dilute solutions, the values vary to such an extent that they nearly overlap for the different concentrations. The only remedy for this is to diminish the error as much as possible by taking the average of a large number of determinations. It was impossible to use solutions more concentrated than  $N/4$  because the potassium iodide formed precipitated out almost immediately, and the ionization of the remaining potassium ethylate consequently changed. It was, therefore, thought advisable to find values for  $K_N$  for  $3N/16$  and  $3N/32$  potassium ethylate so as to give a few more calculated values for  $K_i$  and  $K_m$  and reduce the error.

It can be seen from the data given that the work at 0° is not quite as satisfactory as that at 25°. Although four significant figures are given in some of the tables, the experimental errors vary from 1 to 2%.

### Experimental.

**Preparation of Materials.**—The method used in preparing the solutions and carrying out the reactions at 25° is described in detail by Robertson.<sup>1</sup>

The methyl iodide used was of special purity. To insure a large yield of a constant boiling material, two kilograms of the alkyl halide were shaken with dilute sodium carbonate solution to remove any traces of hydriodic acid, washed twice with water, and then shaken for a few minutes with anhydrous sodium sulfate, and filtered through glass wool. A considerable quantity of phosphorus pentoxide was added and allowed to remain overnight, after which the methyl iodide was distilled. This treatment with the phosphorus pentoxide was repeated, and the product thus obtained was fractionated. Special care was taken to have the condenser and all apparatus perfectly dry, and with these precautions, a product was obtained, the total quantity of which boiled within a few hundredths of a degree. A table is given below showing the boiling points of the different fractions, the barometric pressure and the boiling points at 760 millimeters after all the necessary corrections are made.

<sup>1</sup> *Loc. cit.*

Observed b. p.	Barometer.	Corrected b. p.	Observed b. p.	Barometer.	Corrected b. p.
42.80-42.83	769.4 mm.	42.31-42.33°	42.91-42.86	770.6 mm.	42.35-42.35°
42.82-42.82	769.3	42.33-42.35	42.86-42.82	769.5	42.35-42.34
42.82-42.81	769.3	42.34-42.33	42.82-42.80	768.9	42.34-42.34
42.81-42.81	769.2	42.33-42.33	42.80-42.78	768.2	42.34-42.36
42.93-42.91	771.2	42.35-42.35	42.78-42.79	767.7	42.36-42.37

The rise in boiling point observed in the last fraction was probably due to superheating. No correction was necessary for the exposed stem, because the distilling flask with a long neck made especially for the purpose was used, which made it possible to surround the total column of mercury with the vapor of the alkyl halide. In correcting for the atmospheric pressure the value used was 0.03° per millimeter. The total amount of methyl iodide recovered in these ten fractions was 1,772 g. out of the 2,000 g. used. This is a very satisfactory yield for such a volatile substance. In order to decrease the loss due to the volatility of the methyl iodide, ice-water was continually run through the condenser by means of a fine lead coil of several turns surrounded by ice, and the receiving bottles cooled by ice-water and fairly tightly stoppered with cotton. Another sample purified in the same way boiled at 42.34-42.36°. A sample purified in the same way but distilled with the stem exposed and without special precautions boiled at 42.30-42.32°. A sample of good methyl iodide stood over summer and was then distilled once from phosphorus pentoxide. When fractionated it gave a large middle portion boiling at 42.34-42.36°. Another sample of methyl iodide made by the method used by Robertson boiled at 42.35-42.39°.

It would seem from the boiling points obtained that the methyl iodide used in the reactions was of especial purity. Nevertheless, it was not only a wise precaution but a point of great interest to determine the composition of such samples by analysis.

Satisfactory results were obtained by using small weighing tubes with ground glass stoppers which were especially made for the purpose and held about 2 cc. The alkyl halide could thus be weighed accurately and without loss. The weighing tube containing the alkyl halide was then placed in a regular Carius tube containing an excess of sodium ethylate, sealed, and heated a sufficient length of time in a water bath. It was necessary, of course, to mix the contents thoroughly before heating. The stopper in the little weighing tube was easily removed by warming the tube slightly and then shaking it gently. When the reaction was complete the contents of the tube were washed into a beaker, and then filtered into a calibrated flask, diluted to the mark and weighed. Each portion taken out for analysis was then weighed, since this procedure was much more accurate than the volume method.

In the following analyses Sample I and Sample II are taken from different samples of methyl iodide.

Sample I.					Sample II. B.				
AgI obt.	Air wt.	AgI calc.	Vac. wt.	% error.	AgI obt.	Air wt.	AgI calc.	Vac. wt.	% error.
2.0346		2.0327		+0.12	1.7232		1.7243		—0.03
2.0336		2.0339		+0.01	1.7264		1.7280		—0.08
1.9956		1.9953		+0.04	1.7271		1.7273		+0.01
Sample II. A.					Sample II. C.				
1.5890		1.5889		+0.02	1.5493		1.5500		—0.03
1.5886		1.5889		0.00	1.5489		1.5495		—0.02
1.5894		1.5898		0.00	1.5488		1.5499		—0.05

It is seen that we can easily make alkyl halides with a high degree of purity and that this method of analysis is very accurate. The percentage error is corrected to vacuum weights.

**The Machine.**—Since methyl iodide is so very volatile it would be impossible to transfer the solution to the reaction flasks by the use of an ordinary pipet, without losing a large amount of the alkyl halide. A special apparatus called the "machine" was devised to transfer these solutions with the least possible loss. This machine was described in detail by Robertson.

A large number of determinations were also carried out to see whether the 0.3% excess of methyl iodide ordinarily added was sufficient to make up for any loss of the alkyl halide during the preparation and transfer of the solution. While keeping the conditions the same as those used for studying the reactions, 10 cc. of the solution were run into a small reaction flask containing a 50% alcoholic solution of silver nitrate. The results obtained are given in the tables below. The calculated values given for the silver iodide include the excess added which is given in the parentheses under "Strength of solution."

At 0°.				At 25°.

2.3495	2.3598	(100.5%)	—0.43				

Average, —0.27

The average of the above analyses shows that the 0.3% excess of methyl iodide seems to be sufficient, although there is considerable variation in the results. However, in a number of reactions 0.5% excess was added.

<sup>1</sup> Same solution.

## Reaction Velocities at 0°.

For the study of the velocity of the reaction between methyl iodide, sodium, lithium, and potassium ethylates at 0° an ice bath was used which gave very satisfactory results. This consisted of a copper bath ten inches deep and fourteen inches in diameter which was tinned on the inside, and placed in a wooden box containing lamb's wool. The bottom was protected with a thick felt pad about one inch thick, and the top by a tightly fitting metal cover, over which were placed several pads of felt and wool. The metal cover was made in two pieces, one of which was removed when it was necessary to take out the flask, start the reaction, etc. Special attention is called to the stirring device. The motor is supported by an iron framework which is bolted firmly to the wall to prevent vibration. Motion is imparted to the propeller shaft by a friction pulley, by means of which the speed can be easily controlled.

Tests with a Beckmann thermometer showed that all parts of the bath remained within a few thousandths of a degree of zero. The ethylate solutions were made up at 0°, and transferred at this temperature into the

reaction flasks by surrounding the pipet with a jacket containing cracked ice and water. Ice-water from the bath was run continuously through the jacket of the machine by means of a pump run by a small electric motor. Although the exposed circulation was made as short as possible, the temperature of the water returning to the bath had risen several degrees. Even when this current of water was returned to the bath in the vicinity of the thermometer, no change in the temperature could be detected unless the water played directly upon the thermometer. In that part of the bath which contained the reaction flasks, no change in temperature could be detected. The delivery tube of the machine and all exposed connecting tubes were protected by several layers of binding tape, and that liquid in the most exposed part of the delivery tip was discarded just before each 10 cc. portion was run out. The reaction flask containing the ethylate solution was lifted from the bath in a beaker containing cracked ice and water, and after the alkyl halide solution had been transferred to it, the flask was returned to the bath as rapidly as possible. Tests made with the thermometer showed that by this method the temperature was kept below 0.5°, and the zero point was quickly reached by shaking the flask two minutes in the bath. For the work with the *N*/16 and *N*/32 solutions 40 cc. portions were used instead of the usual 20 cc., and the solutions were mixed by inverting and shaking the flasks under the ice-water. The corks were protected by rubber fingers over the necks of the flasks. A rise in the temperature of even several tenths of a degree for one minute would have but little effect on the constants, especially those for the dilute solutions for which the time periods were so long.

#### Summary.

1. It was shown how to purify and analyze methyl iodide. A number of samples boiled at about 42.35° and contained not over 0.05% impurities.
2. Special apparatus and baths for work at 0° are described.
3. The rates of a large number of reactions between methyl iodide and sodium, potassium, and lithium ethylates at 0° were studied. The concentration of the ethylates ranged from *N*/1 to *N*/32.
4. When the reaction velocities  $K_N$  and the ionization  $\alpha$  for the different concentrations for any given ethylate are substituted in the equation  $K_N = K_i\alpha + K_m(1 - \alpha)$  good constants are obtained for  $K_i$  and  $K_m$ .
5. The activity  $K_i$  of unit concentrations of the ethylate ion should be, and is, the same whether sodium, potassium, or lithium ethylate be employed, and averages about 0.0051 at 0°.
6. Since the nonionized molecules of sodium, potassium, or lithium ethylate are different substances, the values of  $K_m$  vary with the ethylate. For sodium ethylate it is about 0.0030, for potassium ethylate it is about 0.0034, and for lithium ethylate it is about 0.0020.
7. Since these solutions are concentrated and not ideal, the physical

constants such as viscosity, specific gravity, dielectric constant, refractive index,  $\alpha$ ,  $K_V$ , etc., are modified by the different substances present and corrections must be applied later to the data presented here. Only in this way can we obtain the final data freed from all normal and abnormal salt and solvent effects. It is believed from data obtained by adding some of these substances that these corrections will not be large enough to modify the general theory of the activity of both the ions and molecules of acids, bases, and salts.

[CHEMICAL SECTION, IOWA AGRICULTURAL EXPERIMENT STATION.]

## A COMPARISON OF BARBITURIC ACID, THIOBARBITURIC ACID AND MALONYLGUANIDINE AS QUANTITATIVE PRECIPITANTS FOR FURFURAL.

BY ARTHUR W. DOX AND G. P. PLAISANCE.

Received July 27, 1916.

All of the methods for the quantitative determination of pentoses and pentosans in agricultural products are based upon the conversion of pentose into furfural by distillation with a mineral acid, preferably hydrochloric, and subsequent estimation of furfural in the distillate by means of a suitable reagent. Günther, Chalmot and Tollens<sup>1</sup> titrated the furfural with phenylhydrazine, using aniline acetate paper as an indicator. Stone<sup>2</sup> made use of the same reaction, but used Fehling's solution to determine the excess of phenylhydrazine. Later, Flint and Tollens<sup>3</sup> showed that this titration method was not accurate, on account of the levulinic acid resulting from the decomposition of hexoses, as well as the instability of the standard phenylhydrazine acetate reagent used. Jolles<sup>4</sup> titrated the furfural with potassium bisulfite and iodine. In the absence of other reducing substances, the furfural could be determined directly with Fehling's solution. Günther and Tollens<sup>5</sup> precipitated the furfural as hydrofurfuralimide by means of ammonia, while Chalmot and Tollens<sup>6</sup> used phenylhydrazine and weighed the resulting hydrazone. In both cases the condensation product was somewhat soluble.

Councilor<sup>7</sup> was the first to use phloroglucinol for the quantitative determination of furfural. This method was later studied and perfected by Tollens and his co-workers. The phloroglucinol method, although

<sup>7</sup> *Chem. Ztg.*, 17, 1743.

known to be faulty in several respects, is the one in general use to-day, having been adopted as provisional by the Association of Official Agricultural Chemists.<sup>1</sup> It is strictly empirical, since the nature of the reaction and the constitution of the condensation product have not been determined. Kröber<sup>2</sup> compiled a table in which the weight of furfural-phloroglucide obtained is interpreted in terms of furfural, xylose, arabinose or pentose. This table is purely empirical, being based on trial distillations and precipitations of the furfural, or the particular pentose employed, and not upon the molecular weight of the condensation product. Furthermore, this method calls for solubility corrections. Kröber assumes that two molecules of water are split out in the reaction between furfural and phloroglucinol. Goodwin and Tollens<sup>3</sup> claim that only one molecule of water is liberated at ordinary temperature, but if the reaction is carried out at a temperature of 80° three molecules are liberated. A slight variation in the conditions may, therefore, affect the result considerably. Kröber noted the fact also that when the phloroglucide is allowed to stand in the air for a time, it takes up moisture which cannot be expelled by subsequent drying. From this brief survey of the literature, it is obvious that the phloroglucinol method in common use is not altogether satisfactory.

Other reagents have also been tried with varying success. Kerp and Unger<sup>4</sup> used semioxamizine as a precipitant for furfural, but obtained results that were too low. Conrad and Reinbach<sup>5</sup> found that furfural and barbituric acid condensed in the presence of dilute hydrochloric acid. Subsequently, Unger and Jäger<sup>6</sup> applied this reaction to the quantitative determination of furfural. They found that six to eight times as much barbituric acid as the theory required was needed to give the calculated value for furfural. The condensation product had the advantage of being only very slightly soluble in hydrochloric acid (1.22 mg. per 100 cc.). They claim that barbituric acid does not precipitate the furfural derivatives of hexose origin and that these merely tend to color the solution yellow. The reaction is a very simple one, consisting in the condensation of one molecule of furfural and one molecule of barbituric acid, through the aldehyde group of the former and the methylene group of the latter, with the splitting out of one molecule of water. The product was found to contain 13.75% nitrogen, which is in close agreement with the calculated value of 13.63%. When prepared from the furfural distillate from natural sources, the product was found to contain 13.96% nitrogen.

<sup>1</sup> Bureau of Chem., *Bull.* 107, 54 (1905).

<sup>2</sup> *J. Landw.*, 48, 357.

<sup>3</sup> *Ber.*, 37, 315 (1904).

<sup>4</sup> *Ibid.*, 30, 590 (1897).

<sup>5</sup> *Ibid.*, 34, 1339 (1901).

<sup>6</sup> *Ibid.*, 35, 4440 (1902); 36, 1222 (1903).

Fromherz<sup>1</sup> used barbituric acid as a precipitant for methyl furfural and found the condensation product to be not appreciably soluble. Fallada, Stein and Ravinka<sup>2</sup> found that barbituric acid and phloroglucinol gave very nearly the same results when pure xylose and arabinose were distilled and precipitated. On the other hand, when sucrose was added to the pentose, the results were very much higher when phloroglucinol was used as a precipitant than when barbituric acid was employed, the latter giving normal values. This substantiates the statements of other workers who found that hydroxymethylfurfural was not precipitated by barbituric acid.

The barbituric acid method possesses, therefore, certain advantages over the phloroglucinol method, in that the reaction is more specific and a definite condensation product is formed. The precipitate, however, is sufficiently soluble to render a solubility correction necessary. Then again, a large excess of the reagent appears to be necessary, indicating that possibly an occlusion of the precipitant leads to a compensation of errors.

The possibility of obtaining better results by using some derivative of barbituric acid will be discussed in the experimental part of this paper.

### Experimental.

Barbituric acid is ordinarily prepared by the condensation of urea with the sodium salt of malonic ester. The corresponding thio derivative was prepared by Michael,<sup>3</sup> and by Gabriel and Colmann<sup>4</sup> by condensing thio-urea with sodium malonic ester, and the imino derivative was prepared by Michael<sup>5</sup> and by Traube<sup>6</sup> from guanidine and malonic ester. These two derivatives are analogous in many respects to barbituric acid, as will readily be seen by a glance at the structural formulas given below.

It remained to be determined whether they would react in a similar manner with furfural, and possibly give a more complete precipitation.

The barbituric acid used in this work was a Kahlbaum preparation, which we purified further by recrystallization from water. Analysis showed it to contain 21.80% nitrogen; theory, 21.87%.

Our first preparation of thiobarbituric acid was made according to

<sup>1</sup> *Z. physiol. Chem.*, **50**, 241 (1910).

<sup>2</sup> *Oesterr.-ung. Z. Zuckerind.*, **43**, 425.

<sup>3</sup> *J. prakt. Chem.*, **35**, 456 (1887); **49**, 37 (1894).

<sup>4</sup> *Ber.*, **37**, 3657 (1904).

<sup>5</sup> *Loc. cit.*

<sup>6</sup> *Ber.*, **26**, 2553 (1893).

the method of Gabriel and Colmann. 2.3 g. of sodium were dissolved in 50 cc. absolute alcohol, and 16 g. malonic ester added, then 7.6 g. dry thiourea, previously dissolved in absolute alcohol. The mixture was heated on a water bath for ten hours. The white pasty mass which resulted was then treated with 80 cc. water and 7.6 cc. hydrochloric acid and gently warmed until it had dissolved. Upon standing, thiobarbituric acid crystallized out. The yield was about 30% of the theory. In preparing a further quantity of thiobarbituric acid we found that a much better yield was obtained when less solvent was used and the mixture heated for 15 hours in a sealed tube at 105° with twice the theoretical amount of sodium, as recommended by Fischer and Diltney<sup>1</sup> in their preparation of methylethyl- and dimethylthiobarbituric acid. The product, after acidifying with hydrochloric acid, was a slightly yellowish crystalline powder containing 19.61% nitrogen, whereas the theory calls for 19.45%. The yield in this case was 45% of the theory.

Malonylguanidine was made according to Traube from free guanidine and malonic ester. The condensation took place readily and gave an excellent yield. The product was used directly without further purification. It contained 32.71% nitrogen; theory, 33.06%.

Parallel determinations were now conducted, using barbituric acid (malonylurea), thiobarbituric acid (malonylthiourea) and malonylguanidine as precipitants for furfural. For this work a stock solution of pure, freshly distilled furfural of exactly 1% strength was prepared, and a 5 cc. aliquot taken for each determination. The furfural was diluted with 12% hydrochloric acid and solutions of the different precipitants in 12% hydrochloric acid added, the total volume of the reaction mixture being 400 cc. The conditions were, therefore, similar to those obtaining in pentosan determinations. Unless otherwise indicated, a slight excess of the precipitant was employed, the reaction carried out at room temperature, and the precipitate allowed to stand overnight before filtering on Gooch crucibles and drying to constant weight at 100°. The analytical results are set forth in the following tables.

From Table I it is at once apparent that the results with barbituric acid are uniformly low. The last three determinations show the effect of increasing amounts of the precipitant. With barbituric acid and furfural in molecular proportions of sixteen to one, the result is nearly quantitative. This observation is in accord with the statement of Unger and Jäger that eight times the theoretical amount of barbituric acid is necessary for complete recovery of the furfural.

With thiobarbituric acid, as shown in the table, the precipitation is quantitative without using a large excess of the reagent. The results

<sup>1</sup> *Ann.*, 335, 350 (1904).

tend even to run just a trifle over the theory. The last two determinations show that the reaction should not be allowed to occur at a high temperature, since this leads to results that are too low.

TABLE I.

The condensation of furfural with malonylguanidine is not quantitative. The best yield in the determinations quoted above was only a little more than half the theory, hence under these conditions, malonylguanidine is not applicable for the quantitative determination of furfural.

Having shown that thiobarbituric acid in moderate excess gives quantitative results under the conditions of the above experiments, whereas barbituric acid under the same conditions gives less than 95% of the theoretical yield, it remains to compare these two reagents as regards their sensitiveness to smaller amounts of furfural. In the determinations recorded in Table II, four times the theoretical amount of barbituric acid was used.

TABLE II.—BARBITURIC ACID.

Gram furfural taken.	Wt. of precipitate.	Gram furfural calculated.	Error. Mg.	Furfural recovered. %.
0.0117	None	None	No ppt.	None

0.0350	0.0640	0.0298	— 5.2	85.1

It is obvious, therefore, that the barbituric acid method is inapplicable to the determination of small quantities of furfural.

In Table III, varying amounts of furfural are treated with varying amounts of thiobarbituric acid.

<sup>1</sup> Precipitated with a little more than the theoretical amount of barbituric acid.

<sup>2</sup> Precipitated with 4 times the theoretical amount of barbituric acid.

<sup>3</sup> Precipitated with 16 times the theoretical amount of barbituric acid.

<sup>4</sup> Precipitated at 60°.

Furfuralmalonylurea . . . . .	13.60	13.65	.....	.....
Furfuralmalonylthiourea . . . . .	12.61	12.61	14.47	14.41
Furfuralmalonylguanidine . . . . .	15.61	16.01	.....	.....

The furfuralmalonylurea is a bright lemon-yellow, somewhat granular, precipitate which settles readily. Furfuralmalonylthiourea is also a brilliant lemon-yellow precipitate but very flocculent and voluminous. No difficulty was experienced in filtering and washing it, although the filtration was somewhat slow. It was practically insoluble in cold dilute mineral acids and only slightly soluble in hot acids. It was practically insoluble in alcohol, ether, petroleum ether, methyl alcohol, acetic acid, benzene, carbon disulfide and turpentine. In ammonia, pyridine and caustic alkalies it dissolves with ease, giving at first a greenish blue solution which gradually loses its color. From the alkaline solution it can be recovered by neutralizing with acid. The filtrates from both the furfuralmalonylurea and the furfuralmalonylthiourea had a very slight tinge of

yellow. Furfuralmalonylguanidine, on the other hand, is a very dark green, flocculent precipitate, appreciably soluble in hydrochloric acid. The filtrate is an intense greenish brown.

It was early noted that unless the thiobarbituric acid was carefully purified, the precipitation of furfural was not complete, only 90 to 95% of the latter being recovered, and the filtrate possessed a red color or sometimes a green color. In one set of determinations the difficulty was traced with reasonable certainty to the presence of cyanacetic ester in the malonic ester from which the thiobarbituric acid was made. In preparing malonic ester from chloroacetic acid in the usual way, some cyanacetic ester is apt to remain unless precautions are taken to carry the saponification to completion. This is difficult to separate from the malonic ester because the boiling points of the two substances lie only a few degrees apart. The cyanacetic ester in all probability reacts with the thiourea forming a di-cyandiacylthiourea. On fractional crystallization of one of our impure preparations of thiobarbituric acid, white needle shaped crystals were obtained, which on analysis yielded 26.66% nitrogen; calculated for di-cyandiacylthiourea, 26.65% nitrogen. These crystals when dissolved in 12% hydrochloric acid gave an intensely green precipitate with furfural, just as did the thiobarbituric acid before purification. For the preparation of thiobarbituric acid it is, therefore, recommended that the malonic ester be subjected to a repetition of the simultaneous saponification and esterification before condensation with thiourea, and that the thiobarbituric acid be purified by one or two crystallizations of its sodium salt.

**Methylfurfural.**—Methylpentosans often accompany the pentosans commonly found in plant structures. On hydrolysis they yield a methylpentose, usually rhamnose or fucose, and this on distillation with mineral acid is converted into methylfurfural which closely resembles furfural in most of its properties. Qualitatively, methylfurfural may be distinguished from furfural by the color reaction with aniline acetate which in this case is yellow instead of red.<sup>1</sup> When, however, furfural greatly predominates in the mixture, as is usually the case, the color test is not conclusive. Methylfurfural is precipitated by the same reagents which precipitate furfural, for example—phloroglucinol<sup>2</sup> and barbituric acid.<sup>3</sup> Ishida and Tollens<sup>4</sup> make use of the difference in solubility of the phloroglucides in alcohol for quantitative determinations, the loss in weight after extraction with alcohol being taken as representing the amount of methylfurfural phloroglucide. We have not been able to obtain satisfactory results by this method. For example, the phloroglucide prepared from pure furfural

<sup>1</sup> de Chalmot, *Am. Chem. J.*, 15, 278 (1893).

<sup>2</sup> Votocek, *Ber.*, 30, 1195 (1897).

<sup>3</sup> Fromherz, *loc. cit.*

<sup>4</sup> *J. Landw.*, 1911, 70.

was appreciably soluble when subjected to continuous extraction with alcohol. At the same time the insoluble residue sometimes increased in weight during this operation. The loss in weight and the direct weight of the extracted material seldom agreed, the difference running as high as 25 mg.

Pure methylfurfural could not be obtained from the chemical supply houses or from other institutions, and the amount of rhamnose at our disposal was very limited, hence the reaction could not be carried out quantitatively with definite amounts as was done in our previous work with furfural. In the few experiments which we were able to carry out with methylfurfural, the distillate obtained by distilling rhamnose with 20% sulfuric acid was used. This was made 12% acid with hydrochloric acid and treated with thiobarbituric acid as already described. A flocculent yellow precipitate resulted, which closely resembled the corresponding furfural derivative, and showed practically the same solubilities as the latter. The filtrate was only slightly colored and gave no reaction with aniline acetate paper.

Calc. for  $C_{10}H_8N_2O_3S$ : N, 11.86%; S, 13.56%. Found: N, 11.91; S, 13.50.

It will be noted that methylfurfuralmalonylthiourea contains only 0.75% less nitrogen than furfuralmalonylthiourea. Owing to the relatively large size of the molecule, the introduction of a single methyl group makes only a slight difference in the percentage composition. The presence of methylfurfural in the proportion of one to three of furfural could undoubtedly be detected by analysis of the thiobarbituric acid condensation product. In mixtures where the ratio is less than one to four the lowering of the nitrogen content would be within the limit of analytical error, and hence inconclusive as evidence of the presence of methylfurfural.

### Discussion.

Our experiments, quoted above, show that thiobarbituric acid condenses readily with furfural in the presence of 12% hydrochloric acid. The reaction is quantitative, giving a voluminous precipitate which can be filtered, dried and weighed. As a precipitant for furfural, thiobarbituric acid is superior to phloroglucinol, in that no correction for solubility of the product is necessary. It is also preferable to barbituric acid for the reason that the reaction is quantitative with as small amounts of furfural as 12 mg. and a large excess of the precipitant is not necessary, thus avoiding possible errors due to inclusion. Unlike the phloroglucinol product, the resulting furfurylmalonylthiourea is a definite substance resulting from the condensation of one molecule of furfural with one molecule of thiobarbituric acid by the elimination of one molecule of water, and a definite chemical formula can be assigned to it. It has a further advantage in that the percentages of nitrogen and sulfur, which agree with those

calculated from the formula, can be determined by analysis and used as a positive means of identification of the product to distinguish it from, or detect the presence of similar products which might result in case homologs of furfural were present. For example, if a mixture of furfural and sufficient methylfurfural were precipitated, the determinations of nitrogen and sulfur on the product should enable us to compute the relative amounts of these two aldehydes, and, therefore, the relative amounts of pentosans and methylpentosans in the original sample. At present the only means of estimating separately the furfural and methylfurfural present in a mixture such as is frequently met with in analysis, is the supposed differential solubility of their phloroglucides in alcohol, and this is admittedly unreliable.

It is suggested that thiobarbituric acid, which is not difficult to prepare in a pure state, may be found useful in the analysis of agricultural products, in place of phloroglucinol or barbituric acid, for the determination of pentoses and pentosans.

## CONDENSATION OF THIOBARBITURIC ACID WITH AROMATIC ALDEHYDES.

BY ARTHUR W. DOX AND G. P. PLAISANCE.

Received August 19, 1916.

The condensation occurring between aldehydes and the methylene group of malonic acid or its ester is well known. Less known, however, is the fact that the same reaction can be made to occur between aldehydes and the ureides of malonic acid. Conrad and Reinbach<sup>1</sup> condensed malonylurea (barbituric acid) with benzaldehyde, salicylaldehyde, *o*-nitrobenzaldehyde, *o*-aminobenzaldehyde, cinnamic aldehyde, and furfural. The reaction was carried out in aqueous solution at the temperature of the water bath. Salicylic aldehyde condensed with two molecules of barbituric acid, but in every other instance the condensation was in equimolecular proportions. Weinschenk<sup>2</sup> condensed barbituric acid with *p*-hydroxybenzaldehyde and with *p*-dimethylaminobenzaldehyde, heating the mixtures with alcohol on the water bath. Later, Whiteley<sup>3</sup> condensed 1,3-diphenylbarbituric acid with benzaldehyde and with cinnamic aldehyde, by heating with alcohol under a reflux. The same reaction was subsequently carried out by Whiteley and Mountain,<sup>4</sup> using 1,3-diphenylthiobarbituric acid. Jäger and Unger<sup>5</sup> found that in the pres-

<sup>1</sup> *Ber.*, **34**, 1339 (1900).

<sup>2</sup> *Ibid.*, **34**, 1685 (1900).

<sup>3</sup> *J. Chem. Soc.*, **91**, 1330 (1907).

<sup>4</sup> *Proc. Chem. Soc.*, **25**, 121 (1909).

<sup>5</sup> *Ber.*, **35**, 4440 (1902).

ence of 12% hydrochloric acid, barbituric acid and furfural condense quantitatively in the cold. This reaction has been applied by the writers<sup>1</sup> to the condensation of thiobarbituric acid with furfural and methylfurfural as a quantitative method for furfural in preference to the barbituric acid method. The two resulting products, furfuralmalonylthiourea and methylfurfuralmalonylthiourea, have been described in a previous paper.

In the present paper this reaction has been extended to other aromatic aldehydes and a number of new derivatives are here described.

**Benzalmalonylthiourea.**—Molecular proportions of benzaldehyde and thiobarbituric acid were dissolved in 12% hydrochloric acid and the solutions mixed. A lemon yellow precipitate at once formed. After standing a few moments, it was filtered, washed thoroughly with hot water, and finally with alcohol and ether. The product was only slightly soluble in alcohol and glacial acetic acid, but readily soluble in pyridine and in caustic alkalies. In ether, petroleum ether, benzene and carbon disulfide it was practically insoluble.

Calc. for  $C_6H_5CH : C_4H_2O_2N_2S$ : N, 12.07%; S, 13.79%. Found: N, 12.19; S, 13.71.

**o-Hydroxybenzalmalonylthiourea.**—Salicylaldehyde and thiobarbituric acid in 12% hydrochloric acid reacted in like manner, giving an immediate precipitation of a bright vermilion colored product. It showed the same solubilities as the corresponding product previously described. With dilute ammonia or caustic alkalies it gave a deep wine red color which rapidly disappeared.

Calc. for  $HO.C_6H_4.CH : C_4H_2O_2N_2S$ : N, 11.30%; S, 12.94%. Found: N, 11.41; S, 12.61.

**o-Nitrobenzalmalonylthiourea.**—Under the above conditions, nitrobenzaldehyde gave a greenish yellow product, with the same solubilities.

Calc. for  $NO_2.C_6H_4.CH : C_4H_2O_2N_2S$ : N, 15.00%; S, 11.55%. Found: N, 15.07; S, 11.29.

**p-Methoxybenzalmalonylthiourea.**—With anisic aldehyde and thiobarbituric acid, the product was a deep yellow precipitate, insoluble in the usual solvents except alkalies.

Calc. for  $CH_3O.C_6H_4.CH : C_4H_2O_2N_2S$ : N, 10.70%; S, 12.21%. Found: N, 10.58; S, 12.05.

**3-Methoxy-4-hydroxybenzalmalonylthiourea**—Vanillin condensed readily with thiobarbituric acid, giving a brilliant orange colored precipitate. In caustic alkalies the product gave a mahogany red solution, but the color rapidly faded.

Calc. for  $(CH_3O)(HO)C_6H_3.CH : C_4H_2O_2N_2S$ : N, 10.07%; S, 11.87%. Found: N, 10.05; S, 11.79.

**3,4-Methylenedioxybenzalmalonylthiourea.**—In the same manner piperonal condensed with thiobarbituric acid, with the formation of a bright orange colored precipitate, soluble only in alkalies.

<sup>1</sup> THIS JOURNAL, 38, 2156 (1916).

Calc. for  $\text{CH}_3\text{O}_2 = \text{C}_6\text{H}_5\text{CH}:\text{C}_6\text{H}_5\text{O}_2\text{N}_2\text{S}$ : N, 12.07%; S, 13.79%. Found: N, 12.19; S, 13.71.

**3,5-Dihydroxyphthalaldimalonylthiourea.**—Resorcinoldialdehyde condensed with two molecules of thiobarbituric acid. The product was a reddish brown precipitate, soluble in alkalis, to a mahogany red solution.

Calc. for  $(\text{HO})_2\text{C}_6\text{H}_2(\text{CH})_2 (= \text{C}_6\text{H}_5\text{O}_2\text{N}_2\text{S})_2$ : N, 13.40%; S, 15.40%. Found: N, 13.90; S, 15.50.

**Cinnamylidenemalonylthiourea.**—Cinnamic aldehyde yielded with thiobarbituric acid a bright orange red precipitate, soluble only in alkalis.

Calc. for  $\text{C}_6\text{H}_5\text{CH}:\text{CHCH}:\text{C}_6\text{H}_5\text{O}_2\text{N}_2\text{S}$ : N, 10.85%; S, 12.40%. Found: N, 10.69; S, 12.15.

None of the substances described above could be melted without decomposition. The temperatures at which decomposition and charring began varied from  $220^\circ$  to  $300^\circ$ , but in no case was the decomposition temperature sufficiently sharp to serve as a means of identification. It is of interest to note that the condensation products of thiobarbituric acid with the three aldehydes which contain a hydroxyl group on the benzene nucleus gave a deep red coloration with caustic alkalis, while the others remained colorless under this treatment. In all cases the yield was practically quantitative.

The precipitation of aromatic aldehydes by thiobarbituric acid in the presence of 12% hydrochloric acid appears to be a general reaction. The products all have an intense yellow or yellowish red color. Three aliphatic aldehydes tried—formaldehyde, acetaldehyde and citral—failed to react under these conditions.

## RESEARCHES ON ORGANIC PERIODIDES.

### II. PERIODIDES OF ANTIPYRINE, IODOANTIPYRINE AND PYRAMIDONE.

By W. O. EMERY AND S. PALKIN.

Received August 9, 1916.

#### Introduction.

The earliest available record of the action of iodine on antipyrine is that of Manseau,<sup>1</sup> who found that in aqueous solution and in the absence of free acid a relatively small but constant quantity of iodine was absorbed, which behavior he proposed to utilize as a basis for the proximate assay of antipyrine. Beyond noting the fact that apparent substitution took place until a point was reached when further addition of iodine produced a tarry precipitate, no attempt was made to ascertain the nature of the reaction or of the compounds formed. From a quantita-

<sup>1</sup> *Bull. soc. pharm. Bordeaux*, 1889, 148.

tive standpoint, better results were obtained by Schuyten,<sup>1</sup> who titrated very small amounts of antipyrine in relatively large volumes of water with an aqueous solution of iodine. Clearer insight into the mechanism of reaction between iodine and antipyrine is afforded by the work of Bougault,<sup>2</sup> who caused these two substances to react in alcoholic solution and in the presence of mercuric chloride, thereby effecting an absorption of approximately 1 molecule of iodine for every molecule of antipyrine involved. It was further noted by this investigator that, when a neutral aqueous solution of antipyrine was treated with iodine and the liquid kept neutral or even slightly alkaline by an antiacid like sodium acetate, or better according to our own experience, sodium bicarbonate, reactions take place whereby primarily formed antipyrine diiodide splits off a molecule of hydriodic acid, with the result that an atom of hydrogen in antipyrine is replaced by an equivalent of iodine, thus yielding iodoantipyrine,  $C_{11}H_{11}N_2IO$ , identical with the substance first prepared by Dittmar<sup>3</sup> from antipyrine and iodinetrichloride. In fairly concentrated alcoholic or strongly mineral acid solutions, however, there is practically no substitution, hence it follows that in all operations looking to the formation of antipyrine periodides solely, careful attention must be paid to the nature and concentration of the solvent media employed.

In the course of an investigation designed to test the availability of Wagner's reagent (an aqueous solution of iodine and potassium iodide) in alkaloidal assay, Kippenberger<sup>4</sup> reported a method for estimating antipyrine based on the formation of a periodide. He found that when this reagent was added to a moderately concentrated solution of antipyrine in the presence of a mineral acid, a dark brown precipitate was formed, which, on shaking a few minutes, separated as a tarry uncrystallizable mass, leaving a clear supernatant liquid more or less colored with iodine. In the absence of any considerable excess of iodized potassium iodide, the separation proved to be quantitative, a fact we have made use of in the development of a recently published gravimetric method for the estimation of antipyrine.<sup>5</sup> According to Kippenberger's views, all the iodine of the tarry precipitate or periodide, to which he ascribed the composition,  $C_{11}H_{11}N_2O.HI.I_2$ , was derived solely from free iodine of the reagent, the hydriodic acid portion emanating from the interaction of free iodine with water, thus:  $2I + 2H_2O = 2HI + H_2O_2$ . This rather startling theory as viewed from the conditions of the experiment was very promptly attacked by Scholtz,<sup>6</sup> who, not satisfied with declaring the

<sup>1</sup> *Chem. Ztg.*, 19, 1786 (1895).

method worthless, pronounced the analytical results untrustworthy and the theory of the periodide formation untenable, whereupon a lengthy controversy ensued,<sup>1</sup> in the course of which Kippenberger, while admitting certain inaccuracies in his method, still insisted that the iodine of the hydriodic acid had its rise in free iodine itself. That Kippenberger obtained a tar of the above formula in certain definite concentrations of iodine, can hardly be questioned, but that a compound of the composition indicated always precipitates with only two "exterior" iodine atoms, irrespective of the quantity of iodine employed, was partly disproved by a number of experiments which he himself records, and we have ourselves obtained results fully substantiating the criticisms advanced by Scholtz and demonstrating beyond the possibility of doubt that Kippenberger's theory of periodide formation, in general, and his antipyrine method, in particular, are quite fallacious. As will presently appear from a presentation of experimental data, the unsightly tars ordinarily obtained by the action of iodine on antipyrine may consist of one or several periodides, of which we finally succeeded, after no little trouble and experimentation, in isolating and characterizing the following in crystalline form:

All attempts to prepare a crystalline periodide of the composition favored by Kippenberger yielded negative results.

With a view to clearer presentation, the experimental portion of this paper has been subdivided into: I. Behavior of antipyrine toward iodized potassium iodide, and composition of the resulting tars; II. Crystalline periodides of antipyrine; III. Crystalline periodides of iodoantipyrine; IV. Crystalline periodides of pyramidone.

### Experimental.

**Behavior of Antipyrine toward Iodized Potassium Iodide, and Composition of the Resulting Tars.**—In the following series of experiments, 10 cc. of a 1% solution of antipyrine were introduced into each of four 100 cc. volumetric flasks provided with glass stoppers, then treated with 40 cc. water and 30 cc. 0.965 *N*/20 iodine (equivalent to 28.95 cc. *N*/20 iodine). To the several flasks were thereupon added 2.5, 5, 10 and 12 cc. of concentrated hydrochloric acid (about 37%), respectively. After shaking for about five minutes, the liquid was diluted to 100 cc., again shaken to uniformity, then filtered through a funnel stoppered with glass wool overlaid with asbestos. A 50 cc. aliquot of the filtrate was titrated with sodium thiosulfate. Results of these experiments are set forth in tabulated form in Table I.

<sup>1</sup> *Z. anal. Chem.*, 38, 230, 278, 280 (1899); *Arch. Pharm.*, 238, 135, 301 (1900).

TABLE I.

	Antipyrine. Gram.	N/20 iodine. Cc.	Concd. HCl. Cc.	N/20 Na <sub>2</sub> S <sub>2</sub> O <sub>3</sub> for unexpended iodine in		N/20 iodine consumed. Cc.
				50 cc.	100 cc.	
1.....	0.1000	28.95	2.5	1.75	3.5	25.45
2.....	0.1000	28.95	5.0	1.90	3.8	25.10
3.....	0.1000	28.95	10.0	2.50	5.0	23.95
4.....	0.1000	28.95	12.0	3.35	6.7	22.25

Examination of the foregoing data shows that iodine consumption varied with changing amounts of acid, gradually decreasing with increasing concentration of acid, and furthermore that, even with the minimum expenditure of iodine, there was no absorption equivalent to two atoms of iodine per molecule of antipyrine, although an approach to that relationship is indicated. Thus, it will be noted that as the acid increased from 2.5 cc. to 12 cc., the consumed iodine fell from 25.45 to 22.25 cc. N/20 iodine. Theoretically, 0.1000 g. antipyrine would require 21.3 cc. N/20 iodine for the formation of a tar or periodide corresponding in composition to Kippenberger's formula.

Such results quite naturally led us to consider what effect, if any, varying quantities of iodine would have on iodine absorption, all other factors remaining constant. To this end, 0.1000 g. portions antipyrine were introduced into 100 cc. volumetric flasks, as in the first series of experiments, along with 5 cc. concentrated hydrochloric acid, the mixture diluted somewhat, and from about 30 to 80 cc. standard iodine added. After shaking until the solution was clear and diluting to mark, 50 cc. aliquots were taken as before and titrated with thiosulfate. The results are shown in Table II.

TABLE II.

	Antipyrine. Gram.	N/20 iodine. Cc.	HCl. Cc.	N/20 Na <sub>2</sub> S <sub>2</sub> O <sub>3</sub> for unexpended iodine in		N/20 I. Cc.	Atoms I consumed per mol antipyrine.
				50 cc.	100 cc.		
1.....	0.1000	28.95	5	2.05	4.1	24.85	2.33
2.....	0.1000	33.75	5	2.70	5.4	28.35	2.66
3.....	0.1000	38.60	5	3.50	7.0	31.60	2.97
4.....	0.1000	48.25	5	5.95	11.9	36.35	3.42
5.....	0.1000	67.60	5	12.80	25.6	42.00	3.95
6.....	0.1000	77.20	5	15.50	31.0	46.20	4.30
7.....	0.1000	77.20	5	16.40	32.8	44.40	4.17

From these results it is evident that increase in iodine concentration causes a marked increase in the quantity of iodine absorbed, Experiments 1-6 showing a range of 2.33 to 4.3 atoms of iodine per molecule of antipyrine. In order to ascertain what affect heat might have on the reaction, Expt. 7 was carried out—identical in every way with Expt. 6 except that the liquid was heated to 60°—with the result that apparently less iodine was consumed than when the reaction took place in the cold. This is contrary to what might have been expected and is perhaps due to loss of

iodine by volatilization rather than through difference in iodine absorbed or increased solubility of the tar in the reacting menstruum.

In the preceding experiments, conclusions relative to the nature of the tars produced were drawn solely from titrations of the unexpended iodine of the filtrates. In order to obtain a more direct index of the additive iodine content of the tar, estimations of halogen were made in the tarry residues themselves. The question naturally suggesting itself was whether all the iodine consumed in the operation was expended in the form of additive iodine for periodides and hence titratable, or whether some was used in other ways, notably in the formation of hydriodic acid or in direct substitution, whereby two atoms of iodine would be required for every atom substituted.

Accordingly, a series of experiments was run involving constant quantities of antipyrine in like concentrations of acid but varying volumes of *N*/20 iodine. The various operations of filtering and washing of the resultant tars were carried out in the manner already described, the aliquot portions of filtrates titrated with standard thiosulfate, while the tarry residue was dissolved in chloroform and titrated separately, being subjected to vigorous shaking in a glass-stoppered flask during titration to a complete discharge of color. The standard solutions were so adjusted that  $I^- = 0.0507 N = Na_2S_2O_3$ . The results are set forth in Table III.

TABLE III.

	Anti- pyrine. Gram.	HCl Cc.	<i>N</i> /20 iodine. Cc.	<i>N</i> /20 thio- sulfate. Cc.	Total I consumed. Cc.	Atoms I consumed per mol antip.	$Na_2S_2O_3$ required for tar. Cc.	Atoms I consumed per mol antip.	Iodine un- accounted for. Cc.

from which it appears that by far the greater portion of the expended iodine was present in titratable form, presumably in periodide combination, while a relatively smaller, yet variable, portion found application in other ways. Experiments 8 and 9 were carried out with a view of determining whether it would be possible under a somewhat modified treatment to realize a more nearly complete iodine recovery. To this end, chloroform was added to the flask after precipitation and the resulting mixture containing both the tar and unexpended iodine subjected to titration. Since the entire operation thus took place in the original closed

<sup>1</sup> Total supernatant liquid and tar titrated in original flask.

<sup>2</sup> As in the preceding, except that titration was effected after standing 2½ hours.

system, mechanical loss of iodine was reduced to a minimum. Even under such conditions, practically the same discrepancy was found to exist between the quantity of iodine applied and recovered as in Expts. 1 and 5. It will be noted that the "unaccounted for" iodine ranges from 0.4 to 4.0 cc. *N*/20, an equivalent of about 0.04 to 0.4 atom per molecule of antipyrine, or an average of not more than 0.16 atom of iodine per molecule. This apparent loss—comparable in a way with that observed by Holmes<sup>1</sup> in somewhat similar work on the alkaloids: morphine, codeine and heroine—is in the case of antipyrine unquestionably due to a secondary reaction amounting in the end to substitution, the chief controlling factors of which are concentration of iodine and of mineral acid.

If one examines the constitution of antipyrine—as exemplified in its generally accepted formula—with respect to the possibilities or extent of iodation, it will be seen that, aside from additive tendencies centering about the nitrogen atoms, the pyrazolone ring is made up of two double bonded carbon atoms, which under certain conditions readily unite with iodine to yield antipyrine diiodide, the latter subsequently passing into iodoantipyrine and hydriodic acid, thus:

a reaction, which in reality forms the basis of procedures already mentioned in the introduction and developed by Manseau, Schuyten and Bougault. Examination of the data obtained in the foregoing series of experiments will show that the limit of iodine addition was approximately four atoms to the molecule of antipyrine, since by the use of 100 cc. *N*/20 iodine to 0.1 g. antipyrine (equivalent to nearly ten atoms iodine (Expt. 7.)) there was actually present in the tar only slightly over four atoms (4.14, to be exact) in titratable form, although the total consumption amounted to 4.5 atoms per molecule. This, taken in conjunction with the fact that antipyrine is a monoacid base, might justify the assumption that the above cited treatment with iodine and hydriodic acid would yield an addition product of the formula:  $\text{C}_{11}\text{H}_{12}\text{N}_2\text{O} \cdot \text{HI} \cdot \text{I}_4$ , which of course in no way accounts for the molecular distribution of the added components. It might be stated in this connection, however, that any iodine expended in the saturation of double bonded carbon atoms could hardly be so loosely held as to react with thiosulfate in the ordinary course of titration; furthermore, the behavior of iodine in the formation of addition products with organic bases is generally quite irregular and without regard to nitrogen valence; finally, since the periodides of anti-

<sup>1</sup> *Phil. J. Sci.*, 6, 253 (1911).

pyrine as ordinarily obtained are noncrystalline tar-like masses, they may well, and doubtless do, act in the nature of solvents for iodine, beyond that required for addition products of definite composition. All such considerations, however, relative to the manner in which the iodine is actually consumed, would be of no great consequence from an analytical standpoint, provided a constant behavior could be assured, for the reason that the value of any method designed to secure quantitative results must necessarily depend on that feature.

### Conclusions.

When an aqueous-acid solution of antipyrine is treated with a solution of iodized potassium iodide in excess:

(1) The quantity of iodine consumed varies inversely with the amount of mineral acid present.

(2) The quantity of iodine consumed varies directly with its concentration.

(3) Two atoms of iodine per molecule of antipyrine, as found by Kippenberger, is not the limit of possible iodine consumption. On the contrary, the quantity of additive iodine corresponds more nearly to four atoms.

(4) Some iodine is expended in substitution, controlling factors of which are concentration of iodine and of mineral acid.

**Crystalline Periodides of Antipyrine.**—In Kippenberger's investigations on the so-called periodides of antipyrine, special mention was made that all efforts to obtain definite crystalline compounds from the various tars examined were futile. Manseau likewise merely noted the formation of a tarry precipitate on treating an acid solution of antipyrine with iodine in excess. Bougault<sup>1</sup> reported that when an alcoholic solution of antipyrine was treated with iodine there is formed an addition product which first precipitated in the form of a black oil but, on long standing, yielded needle-like aggregates with greenish reflection. These he claimed decomposed easily, dissociated in almost all solvents with liberation of free iodine, and, as a consequence, were not susceptible of isolation in a pure state. Further than the above, no attempts apparently have been recorded with a view to the preparation of antipyrine periodides of definite composition. A systematic investigation of the possible ways of obtaining such compounds involved not only experimentation with a large number of solvents and solvent mixtures, but also application of various solvents to each of a large number of periodides which in themselves differed widely in iodine content. In a general way it may be stated that the following facts were observed, affecting the solubility of most of the periodides examined: They are, for example, practically insoluble in cold aqueous acids; only very slightly soluble in petroleum ether (b. p. 30–60°) and

<sup>1</sup> *Loc. cit.*

carbon bisulfide; moderately soluble in cold, more so in hot ethyl acetate; very slightly soluble in cold ether, moderately soluble when warmed; quite soluble in all alcohols, more so in methyl than ethyl, and more in ethyl than amyl alcohol; chloroform is a very good solvent, while acetone is the best of all. From this it will be readily understood what an infinite field of possibilities opens up to the investigator who attempts an exhaustive study of all combinations of solvents, both pure and mixed, with the various periodide tars and under varying degrees of temperature. Nevertheless, a large number of experiments carried out in this field gradually forced the conviction that crystalline products could be best obtained by the use of organic solvents, of which alcohol, ether and ethyl acetate, yielded the most promising results. Thus, it was found possible, by the judicious application of the last mentioned solvent media—either singly or in admixture—to the tars themselves, to isolate three distinct periodides, derivatives of antipyrine.

For the sake of convenience and clearness it has been deemed expedient in a further presentation of the subject to divide the iodine addition products emanating from antipyrine itself into two general classes: (1) Periodides of antipyrine hydriodide, and (2) Periodides of iodoantipyrine hydriodide. Representatives of Class 1 were prepared in a more or less acid medium while those of Class 2 were isolated from media maintained quite neutral or slightly alkaline. Reference has already been made to certain principles underlying the conditions which inhibit or favor iodine substitution in the pyrazolone nucleus. Thus, the presence of a strong mineral acid or excess of an organic solvent such as alcohol, prevents substitution almost entirely, while carbonates, bicarbonates and even acetates of the alkali metals, as also diminution of the organic solvent (alcohol) by dilution with water, favor substitution to such a degree that with sufficient iodine available the reaction becomes complete as regards the eventual replacement of one hydrogen atom of the antipyrine by an equivalent of iodine. It should be noted, however, in this connection, that Class 1 differs further from Class 2 in that in the latter case an alkaline or neutral medium is maintained only until complete substitution has taken place, that is, until iodoantipyrine has been produced, the medium from there on being rendered acid, whereas in Class 1 the condition of the medium throughout the entire operation of periodide formation is one of acidity.

For the actual preparation of crystalline derivatives, two general methods naturally suggested themselves, either to prepare the indefinite tars by rapid precipitation in a medium in which they are quite insoluble (absence of organic solvent), followed by solution in a second medium more favorable to crystallization, or to bring together all the ingredients as antipyrine, hydriodic acid and iodine under conditions immediately

favorable to crystallization (organic solvents), thus entirely eliminating all intermediate steps for preparing the tar. As a matter of fact, the former method is the one which first yielded crystalline derivatives, and for a time at least it was found impossible to obtain them by any other treatment. Later, however, better success was had with the second and more direct procedure, purer products being obtained and far more expeditiously than with the earlier method. The second method will therefore be described exclusively in the preparation of the several compounds presently to be enumerated.

**Triantipyryne Dihydriodotet iodide,  $(C_{11}H_{12}N_2O)_3 \cdot (HI \cdot I_2)_2$ .**—This compound is readily obtained by dissolving its components: antipyryne, hydriodic acid and iodine in about equimolecular proportions in alcohol and allowing the resulting liquid to slowly deposit crystals. Thus, one sample was obtained in the following manner: 6.5 g. iodine were weighed out in a 50 cc. beaker and treated with a previously prepared solution of hydriodic acid<sup>1</sup> in alcohol in small portions, the mixture being stirred and subsequently decanted from any undissolved iodine into a 250 cc. beaker, until by this progressive treatment complete solution of iodine was effected. The iodized hydriodic acid was thereupon warmed to about 60° and slowly added with constant stirring to a warmed solution of 5 g. antipyryne in 20 cc. alcohol, the resulting liquid then diluted with a warmed mixture of 25 cc. alcohol and 25 cc. water, stirring the while, the beaker covered with a watch glass and set aside 24 hours. Slow crystallization favors the formation of large crystals, especially when the solution is seeded with one or more crystals. After standing the allotted time, the resulting product was filtered by suction through a small filter plate, the crystals thereupon returned to the beaker and washed several times by decantation with water, then subjected to renewed suction on the filter, dried in the air on filter paper, and finally in a desiccator until no odor of iodine could be detected. An additional crop of crystals can be obtained, either by chilling the alcoholic filtrate in a refrigerator or by slowly diluting same with a little warm water until the solution appears faintly turbid, then allowing to stand as before. This second treatment is not advocated, however, for the reason that the product resulting therefrom not infrequently shows an iodine content differing materially

<sup>1</sup> 6.7 g. potassium iodide were dissolved in the least possible quantity of water contained in a 50 cc. lipped Erlenmeyer flask, 4 cc. concentrated hydrochloric acid added, followed more gradually and with constant agitation with 20 cc. absolute alcohol. The liquid was made to pass through a small folded filter, or better through a small suction plate and filter, the filtrate and washings (two 10 cc. portions absolute alcohol) being in the latter event collected in a test tube contained in the suction Erlenmeyer flask. In the case where the ordinary folded filter was used, both filtrate and washings were collected in a second 50 cc. Erlenmeyer flask. This method will be found most convenient for the rapid preparation of alcoholic hydriodic acid,

from that of crystals first separating. Attention might properly be called at this point to the proportions in which the essential ingredients are employed, namely: 1 molecule of antipyrine, 2 atoms of iodine and 1 molecule of hydriodic acid, the purpose being to produce a compound of the same composition as the tarry substance described by Kippenberger and alleged to have the formula  $C_{11}H_{12}N_2O.HI.I_2$ . No such compound resulted, however, as will presently be shown by the analytical data obtained. The above cited proportions are susceptible of considerable variation, with some consequent change in the yield, but little or none in the composition of the resultant periodide. Crystals from repeated experiments were small to large steely blue needle-like prisms with metallic luster, odorless when perfectly dry, quite stable in the air and having no water of crystallization. They are extremely soluble in acetone, less so in chloroform, moderately soluble in methyl and ethyl alcohol, sparingly so in iodized potassium iodide solution, and quite insoluble in water. The specific gravity of these crystals was found to be 1.91, the melting point  $79-80^\circ$ . In determining the composition of the periodide, recourse was had to elementary analysis with respect to carbon, hydrogen and nitrogen, to the estimation of total and of "exterior" or additive iodine, as also of antipyrine itself.

Aside from complications incident to the presence of nitrogen, considerable difficulty was experienced in the carbon and hydrogen determinations, owing to the relatively high iodine content and its resistance to fixation. Extraordinary precautions were therefore necessary to provide against possible passage of this element into the absorption train. In spite of all safeguards, however, as interposition of silvered copper between the lead chromate and reduced copper spirals, sufficient iodine escaped to materially affect the values for carbon and hydrogen.

In the otherwise comparatively simple operation of determining iodine by titration with thiosulfate, numerous difficulties presented themselves. As previously pointed out, when antipyrine and iodine are brought together in a neutral or alkaline medium, conditions favorable to substitution at once obtain, so that by dissolving the periodide in alcohol, or other organic solvent, and adding aqueous thiosulfate, the tendency to such reaction becomes more and more pronounced, progressively so in fact with increasing quantities of the aqueous reagent, hence treatment under the conditions mentioned invariably yielded low values for iodine. Since the total consumption of this element is in quantity twice that actually substituted, even slight substitution may involve a very material expenditure of iodine, in fact it is possible by continuous shaking and addition of water to divert practically all the "exterior" iodine to the formation of iodoantipyrine. If, on the other hand, titration is carried on in the presence of a strong mineral acid, little or no substitution takes place, but here again

obstacles arise in the form of conditions favoring oxidation, so that even with moderate shaking the hydriodic acid liberated by the mineral acid is subjected to uninterrupted oxidation. Furthermore, since the sodium iodide formed in the course of the titration is continuously converted into hydriodic acid, the cycle becomes practically complete and iodine values are limited only by the willingness of the operator to persist in shaking and titrating. It will be readily appreciated from the above how extremely difficult it is to create and maintain conditions effectively excluding both substitution and oxidation. Nevertheless, it developed that the use of solid potassium or sodium bicarbonate in the alcoholic solution of the periodide, together with a few cubic centimeters of glacial acetic acid, yielded fairly concordant results. Titration also of the periodide in alcoholic solution with standard alcoholic thiosulfate gave equally satisfactory values for the "exterior" or additive iodine. Total iodine was determined by treating the sample either according to Carius or with sulfur dioxide<sup>1</sup> in aqueous-acetic acid solution, followed by precipitation with silver nitrate.

The estimation of antipyrine was effected in form of its iodo derivative by dissolving 0.5 g. of the periodide in about 10 cc. alcohol-free chloroform and shaking vigorously at intervals in a separatory funnel with a mixture of 10 cc. sodium bicarbonate solution, 25 cc. 0.1 *N* iodine and 50 cc. water. After standing a few minutes, excess of iodine is removed by the addition of a crystal of thiosulfate, and the resulting iodoantipyrine isolated by extraction with three 25 cc. portions chloroform, each portion being subsequently washed in a second separatory with 5 cc. water prior to withdrawal through cotton to a 100 cc. beaker, and later evaporated to apparent dryness on the steam bath. The residual iodoantipyrine is thereupon dried one-half hour at 110° in an air bath, then cooled and weighed. The conversion factor for antipyrine is 0.5990. The values resulting from the estimation of this substance as a whole were found to be more reliable than those obtained in determining the elemental constituents carbon and hydrogen, for reasons already pointed out.

Molecular-weight determinations made by the boiling point method, involving absolute alcohol and chemically pure acetone, yielded the values 344 and 346, respectively. These values, while concordant enough in themselves, are unquestionably low and indicate marked dissociation. The molecular weight of the simplest possible formula is, as will presently appear, 442.9. No determinations were attempted by the freezing point method owing to the lack of suitable solvents.

In view of the method of preparation, as also of the fact that antipyrine as such is recoverable from the crystalline periodide, any idea that iodoantipyrine may participate in its formation need not receive serious con-

<sup>1</sup> Cf. Emery and Palkin, *J. Ind. Eng. Chem.*, 7, 519 (1915).

sideration. Accordingly, the choice of a suitable formula must be made solely from those involving antipyrine, hydriodic acid and iodine as component parts of the periodide molecule. Of the many possible combinations, only three perhaps deserve mention, namely:  $C_{11}H_{12}N_2O.HI.I$ ,  $(C_{11}H_{12}N_2O)_2.HI.I_3$  and  $(C_{11}H_{12}N_2O)_3.(HI.I_2)_2$ , the antipyrine and total iodine content of which are approximately the same. Comparison of the analytical findings, however, with the percentage composition of the remaining factors, particularly of "exterior" iodine, tends to confirm the third formula as being the most probable.

**Diantipyrine Hydriodo-diodide,  $(C_{11}H_{12}N_2O)_2.HI.I_2$ .**—This compound was obtained substantially as follows: To a solution of 4.9 g. antipyrine in 25 cc. alcohol (95%) were added 3.37 g. iodine dissolved in 25 cc. alcohol (containing an amount of hydriodic acid equivalent to 4.45 g. potassium iodide and prepared in the manner previously described). The volume of the liquid was further increased by the addition of 50 cc. of alcohol, the whole then warmed on the steam bath to about  $50^\circ$  and thereupon diluted with 25 cc. of water with constant stirring. The solution was allowed to cool very gradually in the open until crystals began to appear, whereupon the cooling was continued in a refrigerator. The resulting product was filtered by suction on a small filter plate, washed several times with 60% alcohol previously saturated with iodine, then dried in the air by spreading over filter paper on a porous plate, and finally by placing in a desiccator for about 24 hours. The periodide appeared in the form of slender glistening ruby-red needles melting at  $96-7^\circ$ . Crystals obtained from the mother liquor were in nearly every instance found to be impure, the product being, as a rule, dull-lustered and lighter in color, and possessing a lower iodine content than the first crop. Recrystallization is inadvisable. On subjecting the crystals to analysis, difficulties developed very similar to those already described for the preceding periodide. By observing the necessary precautions, however, results were obtained satisfactorily confirming the composition as indicated in the caption, namely:  $(C_{11}H_{12}N_2O)_2.HI.I_2$ .

Calc. for  $(C_{11}H_{12}N_2O)_2.HI.I_2$ : 51.0% total I; 33.5% exterior I; 49.6% antipyrine.  
Found: I, 50.9, 50.4, 51.3; I, ext., 32.8, 33.0; antipyrine, 49.7.

**Crystalline Periodides of Iodoantipyrine.**—The isolation of these compounds was effected in two stages, *viz.*: (i) Preparation of iodoanti-

pyrine, and (2) preparation of the periodides themselves. Iodoantipyrene, first reported by Dittmar<sup>1</sup> and prepared by the action of iodine trichloride on antipyrin, may be conveniently made as follows: 2 g. antipyrine and 1 g. sodium bicarbonate were dissolved in 100 cc. of water, the solution heated to 50° and a 0.1 *N* solution of iodine slowly added with constant stirring until a faint yellow coloration persisted. On cooling, colorless needles separated which were filtered by suction and washed several times with a little water. A second crop of crystals may be obtained by concentrating the filtrate on the steam bath and allowing the residual solution to stand for some time in the cold. The crystals as first obtained were recrystallized once from a hot 50% alcoholic solution. When thoroughly dried, the product melted at 160–1°.

Calc. for  $C_{11}H_{11}N_2IO$ : I, 40.4%. Found: I, 40.4, 40.5.

**Di-iodoantipyrene Hydriodo-diiodide**,  $(C_{11}H_{11}N_2IO)_2.HI.I_2$ . — This compound was prepared in the following manner: An alcoholic solution of hydriodic acid (obtained by treating 0.4 g. potassium iodide dissolved in 0.2 cc. water with 0.3 cc. conc. hydrochloric acid and 12 cc. absolute alcohol, and subsequent filtering from potassium chloride) and 0.51 g. iodine was poured into a 100 cc. beaker in which 1.24 g. iodoantipyrene had been previously dissolved in 12 cc. warm alcohol. Water was gradually added with constant stirring to the appearance of a brown amorphous precipitate, which became crystalline in the course of a few minutes. More water was then added until the total volume was about 55 cc. The ruby red needle-like crystals were thereupon filtered by suction, transferred to the original beaker and washed with several portions of water, stirring and decanting each portion as added, again filtered by suction on a perforated plate and finally dried in the air until odorless. The sample was then subjected to analysis, as also a second one obtained by recrystallizing the products from several other experiments, thus: 1.5 g. of the mixed samples were dissolved in 20 cc. warm alcohol, gradually diluted with water to the appearance of an amorphous precipitate, allowed to stand until crystallization set in, then water again very gradually added with constant stirring until the total volume amounted to 35 cc. The resulting ruby-red needles were thereupon filtered, washed and dried as above described. The titration of the iodine of addition by means of aqueous thiosulfate was effected without difficulty in alcoholic solution in the presence of sodium bicarbonate. Total iodine was determined both by the method of Carius and by the sulfur dioxide method.<sup>1</sup> The estimation of iodoantipyrene was made by extraction with chloroform, evaporation of the solvent and subsequent weighing.

<sup>1</sup> *Loc. cit.*

Calc. for  $(C_{11}H_{11}N_2IO)_2.HI.I_2$ : 62.7% total I; 25.1% exterior I; 5.6% N; 62.2% iodoantipyrine.

Found: total I (I) 62.8, 62.5, (II) 62.9; ext. I (I) 25.2, 25.3, (II) 25.5; N, 5.6; iodoantip., 62.2.

This periodide melts at  $124-5^\circ$ , is readily soluble in acetone and chloroform, less so in alcohol and behaves toward other organic solvents very like the periodides of antipyrine itself.

**Di-iodoantipyrine Hydriodo-tetridide**,  $(C_{11}H_{11}N_2IO)_2.HI.I_4$ .—An iodized alcoholic solution of hydriodic acid (prepared in the manner above described for the diiodide, from 0.2 g. potassium iodide, 0.1 cc. water, 0.15 cc. conc. hydrochloric acid, 12 cc. absolute alcohol and 0.41 g. iodine was added to a warm solution of 0.5 g. iodoantipyrine in 5 cc. alcohol. Water was then added with constant stirring to the formation of an amorphous or tarry precipitate, the mixture was allowed to stand 10 minutes, or until the precipitate became crystalline, then more water was cautiously added with stirring until the total volume amounted to about 30 cc., whereupon the product was allowed to stand one-half hour. The resulting crystals were filtered, washed and dried in much the same manner as specified for the preceding compound. The resulting chocolate-colored prisms melted at  $94-5^\circ$  and gave values for additive iodine about 2% below the theory (I). Two recrystallizations carried out in the same manner as indicated above yielded better results (II). The periodide forms chocolate-colored prisms, very soluble in chloroform and acetone, quite so in alcohol, but insoluble in water. It is rather difficult to prepare in a pure condition.

Calc. for  $(C_{11}H_{11}N_2IO)_2.HI.I_4$ : 70.3 total I; 40.2 ext. I.

Found: (II) 69.7; ext. I (I) 37.9, (II) 40.2.

**Di-iodoantipyrine Hydriodo-hexiodide**,  $(C_{11}H_{11}N_2IO)_2.HI.I_6$ .—The alcoholic solution of hydriodic acid and iodine (prepared in the usual way from 0.2 g. potassium iodide, 0.1 cc. water, 0.15 cc. conc. hydrochloric acid and 12 cc. absolute alcohol) was added to 0.415 g. iodoantipyrine dissolved in 25 cc. warm alcohol, the resulting mixture gradually diluted with water until a tarry precipitate formed, set aside until crystallization took place (about 10 minutes), then more water added with constant stirring until the volume totalled 75 cc. The crystals, filtered, washed and dried as in the case of the preceding compound, formed dark green glistening needle-like prisms melting at  $97-8^\circ$ , amounting in weight to 0.81 g. The product was redissolved in 12 cc. alcohol and again brought to crystallization by the gradual addition of 25 cc. water. The resulting crystals, isolated as in the first instance, amounted to 0.57 g. and gave the same melting point as before.

Calc. for  $(C_{11}H_{11}N_2IO)_2.HI.I_6$ : 75.3 total I; 50.2 ext. I; 41.4 iodoantipyrine.

Found: total I, 75.3, 75.0; ext. I, 50.3; iodoantip., 41.4, 41.5.

**Crystalline Periodides of Pyramidone (Dimethylamino-antipyrine).—**In the preparation of these compounds, two essential operations were involved, namely: isolation (1) of the hydriodide of pyramidone, and (2) of the periodide of the latter product.

**Pyramidone Hydriodide,  $C_{13}H_{17}N_3O.HI$ .—**This salt was first reported by Nardelli and Paolini,<sup>1</sup> who employed it medicinally in aqueous solution with pyramidone. Later, Cousin<sup>2</sup> actually isolated the salt and at the same time the periodide,  $C_{13}H_{17}N_3O.HI.I_2$ , the former resulting from operations in aqueous, the latter in aqueous-alcoholic solution. The hydriodide was obtained by us in two ways: 1st. 2 g. pyramidone were dissolved in 10 cc. chloroform, to which was then added an alcoholic solution of hydriodic acid (from 1.66 g. potassium iodide, 1.5 cc. water, 1 cc. conc. hydrochloric acid and 20 cc. alcohol), the resulting liquid further diluted with alcohol to a final volume of about 50 cc. Ethyl ether was then added with constant stirring until the solution became slightly turbid and a white precipitate of the hydriodide began to form. After allowing the precipitate to settle for an hour, more ether was added to the turbidity point and the mixture again allowed to stand. The product was then filtered by suction and washed a few times with ether. For purposes of analysis, recrystallization was resorted to by dissolving in a small quantity of warm alcohol and reprecipitating with ether as above described. The crystalline product was again filtered by suction, washed several times with ether and dried for a day in the air. Thus prepared, pyramidone-hydriodide appeared as a fine white granular powder, darkening at 190° and melting at 196–7° (200° Cousin), and becoming yellow on long standing. 2nd. 5 g. pyramidone were dissolved in 10 cc. ethyl acetate and treated with gaseous hydriodic acid until the liquid ceased to yield a precipitate. The resulting needle-like prisms were filtered by suction, washed several times with ether and dried in the air. The melting point was the same as that observed for the granular preparation.

Calc. for  $C_{13}H_{17}N_3O.HI$ : 35.3% I. Found: 35.4, 35.7.

**Pyramidone Hydriodo-diiodide,  $C_{13}H_{17}N_3O.HI.I_2$ .—**To a solution of 1 g. of the hydriodide in hot glacial acetic acid (30 cc.) were added 0.7 g. iodine dissolved in 10 cc. acetic acid and the mixture allowed to stand one day in a shallow dish. The resulting crystals were filtered by suction, washed a few times with a small quantity of acetic acid (36%) and dried in the air until odorless. The compound had the form of fine ruby red needles, softening at about 180° and melting to a brownish oil at 190°. Titrations of this and the following periodide were carried out in a mixed solution of alcohol and acetic acid.

<sup>1</sup> D. R. P. 180,120 (1905); Friedlaender, *Fortschritte der Teerfarben-Fabrikation*, p. 982 (1905–7).

<sup>2</sup> *J. pharm. chim.*, [6] 28, 158; 29, 49 (1908–9).

Calc. for  $C_{13}H_{17}N_3O.HI.I_2$ : 62.1% total I; 41.4 ext. I. Found: 62.2 total; 41.5 ext.

A periodide of like composition was obtained by Cousin<sup>1</sup> in the form of brown needle-like crystals from an aqueous alcoholic solution of the hydriodide and iodine. He reports also the formation of the same compound by the interaction of pyramidone (1 mol) and iodine (3 mol) in alcoholic solution. No melting point, however, is given.

**Pyramidone Hydriodo-triiodide,  $C_{13}H_{17}N_3O.HI.I_3$ .**—This compound was obtained by dissolving 1.2 g. of the hydriodide in about 50 cc. hot alcohol and treating the solution with 1.6 g. iodine likewise dissolved in warm alcohol (20 cc.). Water was then added to the liquid with constant stirring until a slight turbidity resulted, whereupon the mixture was allowed to stand several hours in the cold. Small, heavy, greenish glistening leaflets somewhat resembling herapathite gradually collected on the bottom of the container. The crystals were filtered by suction, washed several times with 50% alcohol and finally dried in the air until practically odorless. A second crop of crystals was obtained by diluting the filtrate with water and allowing it to stand for several hours. The melting point of this periodide was found to be at  $155-6^\circ$ .

Calc. for  $C_{13}H_{17}N_3O.HI.I_3$ : 51.4% ext. I. Found: 51.4.

It may not be amiss to mention that both periodides of pyramidone herein described can, with equal facility, be prepared directly from the base itself, without first isolating the hydriodide, by dissolving the components in alcohol and allowing the resulting addition product to slowly separate by crystallization.

### Summary.

Conclusions have already been drawn relative to the behavior of antipyrine toward iodized potassium iodide in aqueous solution, and to the nature and composition of the tarry precipitates resulting therefrom. (Cf. p. 2172.)

The hitherto unreported periodides,  $(C_{11}H_{12}N_2O)_3.(HI.I_2)_2$ ,  $(C_{11}H_{12}N_2O)_2.HI.I_2$  and  $(C_{11}H_{11}N_2IO)_2.HI.I_2$ , derivative of antipyrine and iodoantipyrine, respectively, were isolated in crystalline form and characterized from tars obtained by the action of iodized potassium iodide on aqueous acid solutions of antipyrine and iodoantipyrine, respectively.

These same compounds, together with the crystalline periodides,  $(C_{11}H_{11}N_2IO)_2.HI.I_4$  and  $(C_{11}H_{11}N_2IO)_2.HI.I_6$ , were more conveniently prepared and in purer form by dissolving their components in alcohol and allowing the resulting solution to slowly deposit crystals.

Two crystalline periodides of pyramidone,  $C_{13}H_{17}N_3O.HI.I_2$  and  $C_{13}H_{17}N_3O.HI.I_3$ , were prepared and characterized, the latter having never before been described.

## THE COLORS PRODUCED BY RESORCINOL IN SOLUTIONS OF CERTAIN SALTS AND THE USE OF THESE COLORS AS A MEANS OF DETECTING RESORCINOL IN THE PRESENCE OF OTHER PHENOLS.

By FRANCIS C. KRAUSKOPF AND GEORGE RITTER.

Received August 5, 1916.

### Introduction.

It has been found that resorcinol in an ammoniacal solution with zinc salts produces a blue color. This has been used as a colorimetric determination of small quantities of zinc.<sup>1</sup>

In attempting to use this color reaction as a qualitative test for zinc it was found that cobalt, nickel and cadmium also produce characteristic colors. The color produced by cobalt is violet, that by nickel bluish violet, and that by cadmium blue. These colors being similar to that produced by zinc it was found to be impracticable to use this method as a qualitative test for zinc salts.

It was then thought that this color reaction might be used as a means of detecting resorcinol in the presence of other phenols. Since cobalt salts give the most intense coloration, these seemed the most suitable for the purpose.

Accordingly this study is divided into two parts: First, a determination of the conditions under which ammoniacal solutions of these salts and resorcinol will with regularity produce these characteristic colors, and the determination of whether or not other phenols will develop similar colors. Second, the use of these color reactions for the detection of resorcinol in the presence of other phenols.

Pieroni and Girardi<sup>2</sup> found that when a solution of pyrogallol in pyridine, mixed with a pyridine solution of a nickel salt, is diluted with water, various colors are produced, dependent on the relative amounts of nickel, pyrogallol, water and pyridine used. It was also found that salts of silver and mercury, when used in the place of the nickel salts, produced colors of a similar nature.

The authors considered these colors to be caused by the reduction, by means of the pyrogallol, of the salts to the metal in the colloidal state.

It seemed reasonable to suppose that the colors produced by the resorcinol were also due to the reduction of the salt to the metal in the colloidal state. This was confirmed by the fact that the color would not dialyze through parchment, and that the colloidal nature could be easily seen by means of the ultramicroscope.

<sup>1</sup> Cerdan and De la Puente, *Anales Soc. espan. fis. quim.*, 2, 98-108 (1913).

<sup>2</sup> *Kolloid Zeit.*, 15, 159 (1914).

### Part I. Experimental.

In order to determine the best conditions under which these characteristic colors develop, an attempt was made to answer the following questions:

Does the depth or shade of the color developed depend upon the salt of cobalt used?

Does the depth of color vary after a certain concentration of cobalt is reached?

Does the depth of color vary after a certain concentration of resorcinol is reached?

What concentration of ammonia is most favorable for the color development?

Knowing that an access of air influences the reaction, will the color develop most uniformly with total, partial, or non-exclusion of air?

What colors, if any, are produced by some of the other phenols?

**Solutions Used.**—(1) One per cent. solution of each of the following: resorcinol, pyrocatechin, hydroquinone, carbolic acid, pyrogallie acid.

(2) Solutions of cobalt chloride, cobalt nitrate, and cobalt sulfate, each containing 0.0004 g. of cobalt per cc.

(3) Ammonium hydroxide 0.90 sp. gr.

Test solutions as indicated below were prepared in Nessler tubes. These tubes were all of the same size and shape in order to make a fair comparison of the depth and shade of color. These tubes were immediately closed with rubber stoppers and inverted twice to thoroughly mix the liquids. They were then placed in a rack and allowed to stand until the color reaction became pronounced.

**Experiment I.**—Solutions were made up as follows:

Ammonium hydroxide, 4 cc., resorcinol solution, 1 cc., solution of cobalt sulfate, cobalt chloride, or cobalt nitrate, 1 cc., water to make 50 cc. Allowed to stand 3 hours.

The violet color obtained in all cases was of the same depth and shade, which shows that the various salts of cobalt used have the same effect on the reaction.

**Experiment II.**—Each solution contained:

Ammonium hydroxide, 4 cc., resorcinol 1 cc., varying amounts of cobalt chloride, water to make 50 cc. Allowed to stand 3 hours.

0.5 cc. of cobalt chloride produced a faint violet color; any amount between 1 cc. and 5 cc. produced the same shade and depth of violet color, which shows that nothing is to be gained by using more than 1 cc. of cobalt chloride solution.

**Experiment III.**—Each solution contained:

Resorcinol, 1 cc., cobalt chloride, 1 cc., varying amounts of ammonium

hydroxide, water to make 50 cc. Allowed to stand 3 hours. Results are seen in Table I.

TABLE I.

NH <sub>4</sub> OH, 1 cc.	2 cc.	3 cc.	4 cc.	5 cc.
Color . . . brown ppt.	slight violet and brown ppt.	violet and brown ppt.	violet	violet

This shows that if less than 4 cc. of ammonium hydroxide is used with 1 cc. of cobalt chloride, cobalt hydroxide is precipitated and the color is to some extent indistinct. If more than 4 cc. is used the color is not deepened.

**Experiment IV.**—Solutions contained:

Ammonium hydroxide, 4 cc., cobalt chloride, 1 cc., varying amounts of resorcinol, water to 50 cc. Allowed to stand 3 hours. These results are found in Table II.

TABLE II.

Resorcinol, cc. . . . .	0.3	0.5	1	2
Color . . . . .	faint violet	violet	deep violet	deep violet

This establishes the fact that 1 cc. of resorcinol gives the same results as a larger amount, but less than 1 cc. has a tendency to make the color thin and indistinct.

**Experiment V.**—Solutions contained:

Ammonium hydroxide, 4 cc., cobalt chloride, 1 cc., resorcinol, 1 cc., water to 100 cc. or to 115 cc.

In the case where the solution was made up to 100 cc., but 15 cc. of air was left above the solution. Where the solution was made up to 115 cc., air was completely excluded from the tube. This was accomplished by fitting a one-hole rubber stopper with a short glass tube drawn to a capillary at one end. By using this stopper some of the liquid was forced out through the capillary tube, thus excluding all air from the liquid. The tube was then sealed by placing the point of the capillary in a Bunsen flame. In order to obtain the same depth of color as in the solutions used before this, it was necessary to allow the tubes containing 100 cc. of solution and 15 cc. of air to stand five hours instead of three. In the tubes from which the air was completely excluded the colors produced were the most satisfactory as far as the shade was concerned. They were exact duplicates of one another in a given time, but the time required was increased from three hours, in the presence of air, to ten when air was excluded.

In cases where air was in contact with the solutions the beautiful violet color would change to a dull green and finally to a brownish black. An ammoniacal solution of resorcinol turns brown when in contact with air, so that this change to green and then to brown was no doubt caused by this color change of the resorcinol itself. However, when the solution was stoppered so as to exclude all air the violet color develops much more

slowly, but after reaching a certain intensity retains the same color and depth of color for an indefinite time.

**Experiment VI.**—Solutions contained:

4 cc. of ammonium hydroxide, 1 cc. of cobalt chloride, 1 cc. of either carboic acid, pyrocatechin, hydroquinone, or pyrogallic acid and water to 50 cc. Allowed to stand three hours.

The color produced by pyrocatechin, hydroquinone, or pyrogallic acid was brown. Carboic acid produced no color.

**Part II. Experimental.**

Having thus become familiar with the characteristic colors of cobalt and resorcinol when solutions of the two are mixed, and with the conditions under which these color reactions best take place, it was thought that these reactions might be used as a means of detecting resorcinol in the presence of other phenols.

Test solutions similar to those shown in Experiments I to VI were prepared in Nessler tubes. At the beginning of each series of experiments a blank sample containing no resorcinol was run. This formed a basis for color comparison with samples containing resorcinol.

The samples in all cases were treated under the same conditions, and allowed to stand the same length of time before the reading was taken. After the sample was prepared, the Nessler tube was immediately closed with a rubber stopper, inverted twice to mix liquids, and then placed into a rack until the color developed. The amounts of each compound per sample and the results are shown in Tables III to V inclusive.

TABLE III.

H <sub>2</sub> O. Cc.	Res. Cc.	Pyrocatechin. Cc.	Color.	H <sub>2</sub> O. Cc.	Res. Cc.	Pyrocatechin. Cc.	Color.
50	..	1	brown	100	..	1	brown
50	1	1	cherry	100	1	1	cherry
50	1	2	reddish brown	100	1	2	brown
50	1	3	brown	100	1	2	brown

TABLE IV.

H <sub>2</sub> O. Cc.	Res. Cc.	Hydroquinone. Cc.	Color.
50	..	1	brown
50	1	1	brown
100	1	1	brown

TABLE V.

H <sub>2</sub> O. Cc.	Res. Cc.	Pyrogallic acid. Cc.	Color.
50	..	1	brown
50	1	1	brown
100	1	1	brown

Each test solution in Tables III, IV and V contained in addition 1 cc. of cobalt chloride and 4 cc. of ammonium hydroxide.

These tables show that the presence of hydroquinone, pyrocatechin or pyrogallic acid either prevents the development of the violet color produced by resorcinol alone, or the violet color is completely obscured by the brown color which is produced by the hydroquinone, pyrocatechin, or pyrogallic acid. Since the brown color caused by these phenols appears

only when air is in contact with the solution, several solutions similar to the above were prepared with the tubes completely sealed from the air. In these neither the violet color of the resorcinol nor the brown color of the other phenols appeared even on long standing.

With carbohc acid and resorcinol present the solutions developed no color, even when in contact with air. This would indicate that the presence of the other phenols had an inhibiting effect upon the development of the violet color of resorcinol.

It is also shown that in the presence of these other phenols, resorcinol cannot be detected by this method.

Having found that resorcinol cannot be detected by the method indicated in Tables III to V, an attempt was made to produce colors by which it might be done. It was discovered that by decreasing the amount of ammonium hydroxide and adding a few cubic centimeters of alcohol to a test sample containing resorcinol, allowing it to stand about three minutes, and then shaking, a dark green color is produced.

The reaction of carbohc acid treated in this manner gives a colorless solution. Pyrocatechin, hydroquinone, and pyrogallie acid, when present in considerable amounts, develop a brown color.

Solutions similar to those shown in Tables III to V were prepared in Nessler tubes, only that the amount of ammonium hydroxide was decreased and a few cubic centimeters of alcohol were added. The tubes containing these test solutions were immediately closed with a rubber stopper, and after being allowed to stand from three to five minutes, were vigorously shaken.

The portion of each ingredient per sample and the results are shown in Tables VI to IX.

TABLE VI.

Res. Cc.	Pyrocatechin. Cc.	Color.	Res. Cc.	Pyrocatechin. Cc.	Color.
..	1	brown	1	10	dark green
1	1	dark green	1	20	dark green
1	4	dark green	0.5	20	brownish green

Table VI shows that in 50 cc. of solution, 0.005 g. of resorcinol can be detected in the presence of 0.220 g. of pyrocatechin.

TABLE VII.

Hydro- qui- none. Cc.	Color.
.. 1	brown
1 1	dark green
1 10	green
1 20	brownish green

TABLE VIII.

Car- bolic acid. Cc.	Color.
.. 1	colorless
1 1	greenish yellow
1 10	greenish yellow
1 20	greenish yellow
1 30	yellow tinge

TABLE IX.

Pyro- gallie acid. Cc.	Color.
.. 1	brown
1 1	cherry
1 8	cherry
1 20	slightly cherry

Besides the contents shown in the tables, each test solution contained

1 cc. cobalt chloride, 0.3 cc. ammonium hydroxide,<sup>1</sup> 3 cc. of 95% alcohol, and water to make 50 cc.

Table VII shows that in 50 cc. of solution, 0.010 g. of resorcinol can be detected in the presence of 0.200 g. of hydroquinone.

Table VIII shows that in 50 cc. of solution, 0.005 g. of resorcinol can be detected in the presence of 0.300 g. of carboic acid.

Table IX shows that in 50 cc. of solution, 0.010 g. of resorcinol can be detected in presence of 0.200 g. of pyrogalllic acid.

#### Summary.

(1) Resorcinol in an ammoniacal solution of cobalt salts produces a color distinct from that produced by the other phenols tried.

(2) The best conditons for uniformity of this color development have been determined.

(3) The exclusion of the air from the test solution increases the length of time required for color development.

(4) The presence of certain other phenols either inhibit the formation of the resorcinol color, or else obscure it by the colors they themselves produce. Consequently, resorcinol cannot with certainty be detected with an ammoniacal solution of cobalt by the method indicated in Tables III to V, if these other phenols are present.

(5) Resorcinol as low as 0.001 g. per 50 cc. sample, if shaken with a weak ammoniacal solution of a cobalt salt and a few cubic centimeters of alcohol, develops a dark green color. Pyrocatechin, hydroquinone, and pyrogalllic acid under same conditions develop a brown color, carboic acid produces a colorless solution.

(6) The presence of the other phenols tried does not prevent the formation of the dark green color developed by resorcinol. Thus small amounts of resorcinol can be detected in the presence of comparatively large amounts of certain other phenols.

### PREPARATION OF BROMOACETYLGLUCOSE AND CERTAIN OTHER BROMOACETYL SUGARS.

By J. K. DALE.

Received August 19, 1916.

In a recent article<sup>2</sup> E. Fischer published a method for the preparation of bromoacetylglucose which consisted essentially in the action of a saturated solution of hydrobromic acid gas in glacial acetic acid upon glucose pentacetate. Since bromoacetylglucose is an important compound, serving as the basis for the synthesis of many derivatives of glucose, it does not

<sup>1</sup> In Table IX the amount of ammonium hydroxide was 2 cc. for each test solution.

<sup>2</sup> *Ber.*, 49, 584 (1916).

seem out of place to describe a method I have used for its preparation which is somewhat simpler than that given by Fischer.

A saturated solution of hydrobromic acid gas in acetic anhydride was found to react directly with several of the sugars and from the reaction mixture could be isolated the bromoacetyl derivative. By this reaction bromoacetylxylose,<sup>1</sup> bromoacetylcellulose and bromoacetylactose, as well as bromoacetylglucose, were prepared in the crystalline condition with yields of respectively 26, 60 and 77% of the theoretical. Bromoacetylmaltose was also obtained by this method, though only in the amorphous condition. A detailed description of the preparation of bromoacetylglucose is given below; it is typical of the method of preparation of each of the above named compounds.

Twenty-five grams of finely powdered glucose were treated in a large Erlenmeyer flask at room temperature with 125 cc. of acetic anhydride saturated with hydrobromic acid gas. A very vigorous reaction followed, leaving a clear, straw-colored sirup. This was cooled, mixed with 300 cc. of chloroform and the solution washed twice with water, once with enough sodium bicarbonate solution to neutralize the dissolved acids, and then once more with water. After drying with calcium chloride, the chloroform solution was evaporated at 50° under diminished pressure to a thick sirup which was washed into a beaker with a little dry ether. Fifteen to twenty volumes of petroleum ether were added, causing the bromoacetylglucose to precipitate as a thick sirup, which on cooling in an ice bath and being stirred vigorously, solidified in a few minutes to a crystalline mass. It was filtered off on a Büchner funnel and recrystallized by dissolving in 75 cc. of dry ether and evaporating the solution in a current of dry air until it crystallized. The yield of the once recrystallized substance was between 50% and 60% of the theory. Fischer obtained by his method 56% of the theoretical amount.

When bromoacetylglucose was sufficiently pure no trouble was experienced in preserving it in good condition for weeks at a time, but usually more than one recrystallization was necessary for this purpose.

### QUANTITATIVE DETERMINATION OF HIPPURIC ACID IN URINE, BLOOD, MUSCLES AND LIVER: A METHOD.

By Dr. Hiizu Ito.

Received July 28, 1916.

Since Bunge and Schmiedeberg<sup>2</sup> published a well-known method for quantitative determination of hippuric acid in urine in 1876, various

<sup>1</sup> THIS JOURNAL, 37, 2745 (1915).

<sup>2</sup> Bunge u. Schmiedeberg, *Arch. exp. Path. Pharm.*, 6, 233 (1876).

investigators have suggested several methods. These methods may be conveniently classified in three ways: Hippuric acid is determined as such;<sup>1</sup> as nitrogen in glycocholl;<sup>2</sup> as benzoic acid.<sup>3</sup> The method here described follows the third scheme. It is generally acknowledged that, in extracting the experimental material, an extracting apparatus with boiling ether gives a better result than a separatory funnel. For this reason an extracting apparatus, designed as illustrated in Fig. 1 was used. The main tube *a* has two branch-tubes *b* and *c*, one of which, *b*, serves for the ascending petroleum-ether vapor, and the other, *c*, for the returning petroleum ether which, collecting at the lower small opening *d* of the branch tube *c* closes the latter, and prevents the ascent of vapor except through the other branch tube *b*. The flask *f* with petroleum ether is connected with the apparatus, and is immersed in an electric water bath, kept at 80–90°, which keeps the solution boiling. This apparatus is also adapted for extraction with ethyl ether.

Fig. 1.

acid varying concentrations of NaOH were tried. The results obtained after extracting the benzoic acid with petroleum ether are given in Table I.

It was thus found that the maximum result could be obtained by using 25% NaOH and 12 hours' boiling for the hydrolysis, and the following experiments were, therefore, carried out under these conditions. The results of determinations of hippuric acid in urine, blood, muscles and liver are shown in Tables II, III, IV and V.

To establish the purity of the recovered benzoic acid, its melting point was determined and found to be  $116.0-120.0^{\circ}$  ("uncorrected"). Furthermore, microscopical examination of the crystal form of the substance proved its identity with benzoic acid.

Procedures for the quantitative determination of hippuric acid in urine and in other mixtures will be described in detail in the following:

### Experimental.

**1. Urine.**—A quantity of fresh rabbits urine was divided into two equal portions; to the one portion a fixed quantity of hippuric and benzoic acids was added and the other was used as a control. Each portion was made faintly alkaline with sodium carbonate, and evaporated nearly to dryness and the residue was thoroughly extracted with absolute alcohol. After evaporating off the alcohol the residue was dissolved in water. The solution was transferred to the apparatus described above and was extracted for 12 hours with pure dry ethyl ether (in this case the solution must be alkaline), which dissolved the resin substance, while the sodium hippurate and sodium benzoate remained undissolved. The solution

was then transferred to a porcelain evaporating dish, a little animal charcoal was added and the ethyl ether was driven off completely. The solution, after having been poured into the apparatus, was made slightly acid with hydrochloric acid, and extracted with petroleum ether b. p.  $30-60^{\circ}$  for 48 hours. In this case the benzoic acid alone dissolved, while the hippuric acid remained undissolved. After cooling, the petroleum ether in the flask *f* was filtered into the weighed flask *g* and the petroleum ether was evaporated by a stream of dry air. The benzoic acid crystallized beautifully on the inner wall of the flask *g*.

The solution, which contained hippuric acid only, was neutralized

Fig. 2.—Evaporating apparatus. Petroleum ether in the flask (*g*); A = Air, D. A. T. = dry air tubing, P. E. = petroleum ether, and C = connection with a suction tube. Arrows show direction of air current.

cooling, the petroleum ether in the flask *f* was filtered into the weighed flask *g* and the petroleum ether was evaporated by a stream of dry air. The benzoic acid crystallized beautifully on the inner wall of the flask *g*.

with sodium carbonate, and 15 cc. of 50% NaOH were added to it. The mixture was then carefully concentrated to 30 cc., and was boiled in a 200 cc. Kjeldahl flask with an upright condenser for 12 hours. It was then transferred completely to a porcelain evaporating dish concentrated to as small a volume as possible, after adding a little animal charcoal. After it was cooled, 30% hydrochloric acid was carefully added drop by drop with continuous stirring. The acidified solution was now transferred to the extracting apparatus, and extracted with petroleum ether for 72 hours. The petroleum ether was filtered off in the flask mentioned above and evaporated as already described. The hippuric acid was weighed as crystalline benzoic acid. The results are given in Table II.

TABLE II.

Benzoic acid added (80 cc. urine).					Hippuric acid added (80 cc. urine).				
Gram benzoic acid added as sodium benzoate.	Gram benzoic acid recovered.	Benzoic acid in control urine.	Difference.	Percentage of benzoic acid accounted for.	Gram benzoic acid calc. from hippuric acid added.	Gram benzoic acid recovered.	Gram benzoic acid in control urine.	Difference.	Percentage of benzoic acid accounted for.
0.2768	0.2770	0.0039	0.2731	98.7	0.2677	0.2691	0.0090	0.2601	97.2
0.2054	0.2075	0.0045	0.2030	98.8	0.1747	0.1742	0.0077	0.1665	95.3
0.1961	0.2024	0.0067	0.1957	99.8	0.1938	0.2018	0.0136	0.1882	97.1
0.1124	0.1138	0.0030	0.1108	98.6	0.0812	0.0848	0.0064	0.0784	96.6

2. **Blood.**—The defibrinated blood of a cow or a rabbit was divided into two equal portions; to one a fixed quantity of hippuric acid was added and the other was used as a control. Each portion was diluted five times with water, neutralized with weak hydrochloric acid, and heated on a water bath. In this treatment, protein coagulated completely with the fats, and deposited at the bottom of the beaker with a clear layer on its top. After 24 hours' standing, it was filtered through by suction, and repeatedly washed with hot water. The residue together with the filter paper was ground in a glass mortar, adding water, and again filtered with suction. This treatment was repeated several times. The filtrate was then made faintly alkaline, evaporated nearly to dryness, and the residue was thoroughly extracted with absolute alcohol. In the case of blood, it was not necessary to remove the benzoic acid, for none was added to it and normal blood does not contain benzoic acid. The subsequent treatment was the same as in urine. The results are tabulated as follows:

TABLE III.

Cc. of blood.	Gram hippuric acid added.	Gram benzoic acid calc. from hippuric acid.	Hippuric acid as benzoic acid recovered.	Hippuric acid, as benzoic acid in control blood.	Difference.	Percentage of benzoic acid accounted for.

40 (blood of rabbit)...	0.2840	0.1935	0.1735	0.0024	0.1734	89.6

**3. Muscle.**—Muscles, which were finely cut, were divided into two equal portions. Each portion was ground in a glass mortar with addition of some water and was then heated. A fixed quantity of hippuric acid was added to the one portion and stirred well, the other was the control. Each portion was filtered through muslin, having been washed with hot water repeatedly, and was pressed dry. The residue was again ground in glass mortar and filtered through muslin as before and this treatment was repeated several times. The filtrate was made neutral or weakly acid, and evaporated. The protein in the filtrate coagulated with the fats upon heating on a water bath and the whole was filtered by suction, and was washed with water several times. The filtrate was evaporated nearly to dryness and the residue was thoroughly extracted with absolute alcohol. After this treatment, the procedure was the same as in the case of blood. The results are given in Table IV.

TABLE IV

Grams of muscles.	Gram hippuric acid added.	Benzoic acid calc. from hippuric acid.	Hippuric acid, as benzoic acid recovered.	Hippuric acid, as benzoic acid in the control.	Difference.	Percentage of benzoic acid accounted for.

50	0.2581	0.1759	0.1566	0.0012	0.1554	88.3

For the determination of hippuric acid the investigators mentioned in the foot-note of p. 2189, took great pains to obtain the purest possible hippuric acid and at the same time to secure the largest quantitative yield. The effort here described has been to simplify the method by means of a suitable extraction apparatus and to obtain the most satisfactory results in both of these respects.

### Summary.

(1) The method proposed can be well applied to the quantitative determination of hippuric acid in urine and similar materials.

(2) The method has the advantage of simplicity of treatment and of giving fairly accurate results.

## MODIFICATION OF THE PRATT METHOD FOR THE DETERMINATION OF CITRIC ACID.

By J. J. WILLAMAN.

Received August 11, 1916.

In working with Pratt's method<sup>1</sup> for the determination of citric acid, considerable difficulty was encountered in getting duplicate determinations to agree. This difficulty was mentioned in the 1912 report of the Association of Official Agricultural Chemists,<sup>2</sup> but no suggestions were made for remedying it. It is believed that the modifications described herein will give very satisfactory results.

### Discussion of Process.

The primary operations in this method are the fractional oxidation of the citric acid to acetone by means of potassium permanganate, the removal of the acetone as fast as formed by distillation, the formation of an insoluble mercury-acetone complex by boiling with mercuric sulfate, and the weighing of this precipitate. A thorough study has been made of each step of the process, in the attempt to discover all the influencing factors and the combination of procedures that would give the most satisfactory results. A discussion of the various investigations follows:

**1. Fractional Oxidation.**—The process is purely empirical, the results varying with each change of conditions. The potassium permanganate attacks any organic substance that may be present along with the citric acid, distributing itself among them according to the ease with which each is oxidized. Among the substances likely to be present in working with plant products are other acids brought down by the barium acetate, and sugars and coloring matter occluded by the barium precipitate. These cannot be washed out completely, hence are always present in greater or less amount and capable of consuming permanganate. Acetone itself, the desired end-product of the oxidation of the citric acid, can of course be further oxidized; hence the necessity of removing it as fast as formed. It was found that the more dilute the solution of citric acid is, the less the acetone obtained. This is undoubtedly due to the fact that if only a small amount of citric acid is present at the point of contact between the drop of permanganate and the boiling liquid, the oxidation will proceed beyond the acetone stage before the acetone can escape and before the drop of permanganate is consumed. Several factors, then, would tend to give larger yields of acetone; *viz.*, (1) more

<sup>1</sup> David S. Pratt, "Determination of Citric Acid," U. S. D. A., Bur. of Chem., *Circ. 88* (1912).

<sup>2</sup> "Proceedings of the Twenty-Ninth Annual Convention of the Association of Official Agricultural Chemists," 1912; U. S. D. A., Bur. of Chem., *Bull. 162*, 60-62.

concentrated solution of citric acid, (2) less concentrated solution of permanganate, (3) the presence of substances other than citric acid to partially consume the permanganate, (4) rapid boiling and slow addition of permanganate.

In Table I are presented the results of a few of the experiments which were made to determine the effect of various changes of conditions on the yield of acetone. The several groups of determinations illustrate the four points enumerated above.

TABLE I.

Effect of Various Changes of Conditions of Oxidation on the Yield of Acetone.

	75	100	0.50	50 mg. tartaric acid	75.2	100.2
	50	100	0.20	10 mg. sucrose	48.9	97.8

It is evident that if constant results are to be obtained, a certain set of conditions must be adopted and then rigidly adhered to. This has been done in the proposed modified procedure. A volume of citric acid solution of 100 cc. at the beginning of the operation was chosen as the most convenient; ordinarily with 100 mg. citric acid present and no other oxidizable material, and the permanganate solution of 0.5 g. per liter dropping in at the rate of 120 to 150 drops per minute, the reaction will be complete with a residual volume of 15 to 25 cc. in the flask. Thus the rate of distillation must be a little faster than the rate of flow of the permanganate. The volume of solution and a slightly increased rate of permanganate flow are the only items changed from Pratt's original specifications. Although the presence of substances other than citric acid does tend toward slightly higher results, the effect has been found to be inconsiderable.

<sup>1</sup> Blank determinations were made with these substances, and no mercury precipitate was obtained.

2. **The concentration of Denigès' Solution**, in which the acetone distillate is boiled, has a very marked influence on the amount of mercury-acetone precipitate obtained; the stronger the solution the less the precipitate obtained. This is shown by the data in Table II and may be due either to increased solubility of the compound, or a change in its composition. Whatever the cause, it can be avoided by always having the same concentration of mercuric sulfate. Pratt's directions call for 30 to 40 cc. of Denigès' solution in the distillate, but do not specify the volume of that distillate. Since the smaller the amount of oxidizable material, the less is the time required for the operation, the smaller is the distillate, and the more concentrated is the mercuric sulfate. The writer has adopted, therefore, a concentration of 15 cc. of Denigès' solution for each 100 cc. of distillate. The reaction is then proportional with all amounts of citric acid, at least those from 25 to 150 mg. Great accuracy in measuring the distillate is not required; a 700 or 800 cc. Erlenmeyer marked at 300 cc., 400 cc., and 500 cc. does very well.

TABLE II.

The Effect of the Concentration of Denigès' Solution on the Yield of the Acetone-Mercury Compound. 50 Mg. Citric Acid Taken.

Vol. of distillate containing 40 cc.

Denigès' soln., cc.....	200	250	300	350	400	500
Recovery of citric acid, %.....	96.4	96.8	99.3	102.0	100.3	100.7

3. **Amount of the Mercury-Acetone Precipitate Formed.**—This was determined by Pratt by weighing on a Gooch. This has been found less easy and trustworthy than the process of determining the mercury in the precipitate by titration. As the precipitate has a tendency to adhere to the sides of the Erlenmeyer flask in which it is formed, it is difficult to remove it completely to a Gooch. It is, however, readily dissolved by hot 5% hydrochloric acid. The resultant mercuric chloride may be titrated against standard potassium iodide solution according to Personne's method.<sup>1</sup> This procedure was used in all the present experiments, and proved to be rapid and accurate.

4. **The flow of Permanganate** into the oxidation flask in the writer's apparatus, is controlled by a screw pinch-cock on a piece of soft rubber tubing, which replaces the glass dropping funnel in Pratt's apparatus. One end of the rubber tubing is connected to a bent glass tube passing through the stopper of the oxidation flask and ending in a fine nozzle; the other end of the tubing connects with a two liter supply reservoir of permanganate. This arrangement gives better control of the flow of permanganate than the glass-stoppered dropping funnel.

5. **Oxidation Flask.**—A 200 cc. Kjeldahl flask with all but three centimeters of the neck removed is very satisfactory. A 200 cc. side-arm distilling flask is equally good.

<sup>1</sup> *Compt. rend.*, 56, 63; also Sutton's "Volumetric Analysis," 10th edition, 1911, 264.

6. **Removing the Citric Acid** from a plant juice with barium acetate. The writer has adopted a medium of 30% alcohol instead of 50%. It throws out all the citric acid, and only a little of the other acids, as pointed out by Jörgensen.<sup>1</sup> The precipitate is also more granular in this case, and thus more easily filtered and washed.

7. **Quantitative Relation.**—In order to determine the quantitative relation between the citric acid and the potassium iodide used to titrate the mercury of the final product, a series of analyses was made with varying amounts of pure citric acid, using the exact procedure as given below. The potassium iodide solution used, contained 26.70 g. KI per liter. The results are given in Table III. In order to compare the accuracy of these figures with those obtained by Pratt in ascertaining the factor to be used with his gravimetric method, an excerpt is given of his table (the last column was computed by the writer).

TABLE III.

Showing the Determination of the Factor for Potassium Iodide, in Comparison with the Factor in Pratt's Gravimetric Method.

Present method.				Pratt's method.			
Gram citric acid.	KI soln. Cc.	KI soln. per 1 g. citric acid. Cc.	Recovery using value of 0.001906. Per cent.	Gram of citric acid used.	Wt. of precipitate.	Calc. factor.	Recovery using factor 0.220. Per cent.
0.025	12.90	516	98.3	0.020	0.104	0.187	114.4
0.025	12.90	516	98.3	0.049	0.234	0.208	105.1
0.025	13.05	522	99.5	0.052	0.227	0.224	96.0
0.050	26.40	528	100.6	0.080	0.343	0.231	94.3
0.050	26.90	538	102.5	0.097	0.453	0.214	102.7
0.100	52.80	528	100.6	0.104	0.430	0.240	91.0
0.100	52.00	520	99.1	0.104	0.451	0.229	95.4
0.150	78.80	525	100.8	0.104	0.445	0.232	94.1
0.150	79.40	529	100.9	0.104	0.442	0.234	93.5
				0.107	0.510	0.210	104.9
				0.128	0.559	0.229	96.1
				0.128	0.556	0.230	95.6
				0.146	0.679	0.215	102.3
				0.246	1.181	0.208	105.6
				0.491	2.364	0.208	106.0
Average, 524.7 or 1 cc. $\equiv$ 0.001906				Average, 0.220			

According to this procedure, then, 1.0 cc. of a solution of potassium iodide containing 26.70 g. of the salt per liter is equivalent to 1.906 mg. citric acid. For convenience, a solution of potassium iodide of 28.0218 has been adopted, 1 cc. of which is equivalent to 2.0 mg. citric acid.

<sup>1</sup> Jörgensen, "Über die Bestimmung einiger der in den Pflanzen vorkommenden Säuren," *Z. Nahr. Genussm.*, 13, 241 (1907).

### The Modified Method in Detail.

The following solutions are required:

1. Hydrochloric acid, 5% (approximately).
2. Sodium hydroxide, 10%.
3. Phosphoric acid, 6%.
4. Denigès' solution, made as follows: Add about 500 cc. of water to 50 g. of mercuric oxide; then add 200 cc. of concentrated sulfuric acid with constant stirring; make up to a liter, heat on steam bath an hour or two, and filter till clear.
5. Potassium iodide; contains 28.0218 g. pure KI per liter. One cc. of this is equivalent to 2 mg. citric acid under the conditions of the experiment.
6. Mercuric chloride; contains 10.8038 g.  $\text{HgCl}_2$  and 25 g. NaCl (to assist in solution) per liter. It is equivalent to the potassium iodide solution volume for volume. It is best made up by weighing out a slight excess of the salt, then standardizing against the potassium iodide solution and diluting to the proper strength.
7. Potassium permanganate, 0.5 g. per liter.
8. Barium acetate, 10%, in 30% alcohol by volume.

The complete method of analysis follows. The directions are the same as given by Pratt, except where the present modifications enter in.

Throw out the pectins by adding twice the volume of 50% alcohol. When the precipitate has settled, filter through paper on a Büchner funnel, and wash twice with 65% alcohol, sucking the gelatinous precipitate as dry as possible. Dilute the filtrate with water to give approximately a 30% alcohol content by volume and add slowly 5 cc. of the barium acetate solution. When the barium citrate has settled to the bottom, filter through asbestos in a Gooch, wash once with 30% alcohol, and dry in a water oven. The barium citrate is next dissolved with hot 6% phosphoric acid solution, using three portions of 20 cc. each, and followed by hot water. The filtrate and washings should be about 100 cc. They are transferred to the oxidation flask and the latter connected with a spiral condenser and with the device for adding potassium permanganate. To prevent bumping, introduce into the flask a piece of glass tubing sealed at the upper end, and long enough to remain upright. Sometimes a few glass beads are also necessary. The adapter of the condenser dips into 40 cc. of Denigès' solution contained in a 500 cc. Erlenmeyer flask. Heat the citrate solution over a naked flame, then allow the permanganate to drop into the briskly boiling solution at the rate of 20 to 25 drops in 10 seconds. When a deep pink color has persisted for a couple of minutes the reaction is complete. If the volume of liquid in the flask becomes too small, successive portions of 20 cc. of water may be added, care being taken to shut off the flow of per-

manganate a few moments before the distillation is stopped and the system is opened. The distillate is made up to 300 cc., put under a reflux condenser and boiled gently for 45 minutes. If the distillate is over 300 cc., more Denigès' solution should be added at the rate of 15 cc. for each 100 cc. of distillate in excess of 300 cc.

The precipitate is filtered hot through paper, washed by decantation twice with hot water, then the filter paper washed thoroughly. The precipitate in the Erlenmeyer is dissolved in two or three small portions of 5% HCl by heating, each portion being poured through the filter containing the rest of the precipitate and collected in a 100 cc. flask. The acid solution is returned through the filter till all precipitate is dissolved. After thoroughly washing the filter and flask with hot water, the filtrate is cooled, very nearly neutralized with 10% sodium hydroxide, and made up to 100 cc. The mercury can now be titrated by either one of the two following methods: (a) The whole or an aliquot of the mercury solution can be poured into an excess of the potassium iodide solution, and the excess potassium iodide titrated back with the standard mercuric chloride solution. The amount of potassium iodide solution necessary for the whole sample can then be calculated, together with the citric acid equivalent. (b) The mercuric chloride solution under examination can be placed in a buret and titrated directly against say, 10 or 15 cc. of the standard potassium iodide, and the amount of citric acid in the whole sample computed. For amounts of citric acid of 100 mg. or over, (b) is the preferable procedure. If (a) is used, the aliquot used should not be less than one-fourth.

Malic, tartaric (except quantities of 0.5 g. or over), oxalic, and aconitic acids do not interfere with this determination. The presence of much sugar, or other substances capable of reducing permanganate, tends to give slightly high results, but the difference is inconsiderable.

TABLE IV.

The Analysis of Certain Plant Products for Citric Acid.

Y....	$\left\{ \begin{array}{l} 0.824 \\ 0.836 \\ 0.787 \\ 0.840 \end{array} \right.$	H. C. G....	$\left\{ \begin{array}{l} 0.81 \\ 0.80 \\ 0.73 \\ 0.87 \\ 0.80 \\ 0.84 \end{array} \right.$

In order to show the accuracy of duplicate determinations by the modified method, several products were analyzed for citric acid. The results are shown in Table IV. For the sake of comparison, the table of results given in the 1912 report of the A. O. A. C. is also reproduced.

These results seem to warrant the conclusion that the modified method, if followed rigidly, will give much more satisfactory results than the original one. It is hoped that other workers will give the proposed method a trial, as a trustworthy method for determining citric acid in plant products is needed.

## AN EXAMINATION OF CERTAIN METHODS FOR THE STUDY OF PROTEOLYTIC ACTION.

By H. C. SHERMAN AND DORA E. NEUN.

Received August 9, 1916.

There is no lack of methods for the study of proteolytic action but, in general, each method has been devised to meet the needs of a particular line of investigation, or to determine whether or not a commercial pepsin or trypsin complies with the standard arbitrarily established for it. As a preliminary to research upon the proteases, it seemed desirable to study some of these methods with reference to their accuracy and delicacy and their adaptability to proteases of more than one type. The methods studied were: The determination of total digested nitrogen, the increase of amino nitrogen as measured by the Van Slyke method, the acidimetric titration of digestion products, the change in electrical conductivity, and in rotation of polarized light, the Mett method, and the biuret and ninhydrin reactions. The work of Long and Barton<sup>1</sup> published soon after the present investigation was begun, made it unnecessary for us to include certain other well-known methods in our comparison. We have used commercial pepsins and trypsins of good quality and have arranged our experiments with a view to ascertaining to what extent the various methods will permit comparisons of these two types with each other. In the following pages typical results obtained by each of the methods tested are presented very briefly, the work on the ninhydrin reaction being further abbreviated in view of the investigations of Van Slyke and his associates<sup>2</sup> and of Harding and MacLean,<sup>3</sup> the results of which have become available while our studies were in progress.

### Mett Method.

This method which has long been popular because of the convenience of observing results, and which is the only one in which we have used egg white as substrate, may be described first.

Utilizing the improvements proposed by Cobb<sup>1</sup> and introducing slight modifications in the interest of greater accuracy, we have carried out this method as follows:

Glass tubing of 2.5 to 3 mm. bore is cut into 20 cm. lengths and washed successively with cleaning mixture, water, alcohol, and ether. The ends are then drawn to a capillary and broken off. The white of a fresh egg is thoroughly cut with scissors, filtered through cheesecloth, placed under vacuum for an hour to eliminate air and prevent the subsequent formation of air bubbles, and then sucked up into the prepared glass tubes and the ends of the latter sealed by fusing. The egg-white is coagulated by immersing the tubes in water heated at 95°. In doing this the tubes are laid horizontally upon a wire gauze about 1 cm. below the surface of the water, the temperature of 95° is maintained for 15 minutes after the introduction of the tubes, then the source of heat is removed and the whole allowed to stand until the water is cold, lest by cooling too rapidly a large part of the tube be rendered useless by retraction of the egg-white from the glass walls. In view of the experience of Nirenstein and Schiff,<sup>2</sup> we have always used tubes less than three days old. In making the digestion test, 20 cc. portions of the solution of pepsin in 0.05 *M* HCl<sup>2</sup> (or of trypsin in 0.05 *M* Na<sub>2</sub>CO<sub>3</sub><sup>3</sup>) were placed in flat bottomed cylindrical jars of 5 to 6 cm. diameter, the depth of the solution being thus about 1 cm.; the tubes of coagulated egg-white were cut into 2 cm. lengths with smooth, square ends, and two of these lengths immediately placed in each of the jars containing the enzyme solutions and the whole enclosed in a thermostat kept at 40°. At the end of the 20 hours allowed for the digestion test the tubes were removed and the length of column digested was measured four times at each end of both tubes, making 8 measurements on each tube or 16 measurements on the pair of tubes by which each enzyme solution was tested. These measurements were made under a microscope fitted with a mechanical stage and vernier (Leitz No. 141) and a micrometer eyepiece. Under these conditions it is believed that the error in case of pepsin digestions should never be greater than 0.1 mm. in any one reading<sup>4</sup> and that the average of the 16 readings taken for each enzyme solution is reasonably accurate to the second decimal place (expressed in mm.). It is this final average of 16 measurements which appears under the heading of "column digested" in Table I.

In the case of pepsin the Mett method with digestion for 20 hours at 40°, permitted measurements of activity of as little as 2 parts of the commercial enzyme in 1,000,000 of the test solution or 0.04 mg. in the 20 cc. used for a test, thus showing a fairly high degree of delicacy. For quantitative comparisons, however, this method is open to the objection that the observed result of the enzyme action increases only very slowly with the amount of enzyme present, unless this amount be very small. This is

<sup>1</sup> *Am. J. Physiol.*, 13, 448 (1905).

<sup>2</sup> *Arch. f. Verdauungskrankh.*, 8, 599 (1903).

<sup>3</sup> These being the concentrations of acid and alkali which in our experience are most favorable to the activity of pepsin and trypsin, respectively.

<sup>4</sup> In trypsin digestions the alkalinity of the solution affects the surface of coagulated eggwhite and greatly increases the error in the reading as explained beyond.

shown by the data of Table I and perhaps more clearly by the curves in Fig. 1. Here the upper solid line (A), which on the scale here used appears nearly vertical, is what would represent a direct linear relationship between the amount of pepsin present and length of column digested. Curve B represents the square root relationship predicated by the Schütz-

FIG. 1.—Comparison of (A) linear relationship, (B) square-root relationship, with results shown by Mett method in testing three commercial preparations of pepsin.

Borissow rule,<sup>1</sup> and Curves I, II, and III show the results actually obtained with the three pepsins represented in Table I.

Our results like those of Nirenstein and Schiff<sup>2</sup> and of Cobb<sup>2</sup> indicate that the Schütz-Borissow rule fails before the pepsin reaches a sufficient concentration to digest 4 mm. of the column in 20 to 24 hours. With increasing concentrations of enzyme the discrepancy increases rapidly. Taking the best result obtained among the three pepsins tested, 80 mg. actually digested only as much as should have been digested by 36 mg. according to the Schütz-Borissow square root rule, or as would be digested by 6 mg. if the observed result were in direct arithmetical proportion to the amount of enzyme present, which is obviously the desired relationship in quantitative testing of enzymes and is very nearly realized in the testing of amylases and in some of the methods available for testing proteases as will appear below. In Fig. 2 the results obtained with the smaller

Fig. 2.—Comparison of linear and square-root relationships with results shown by Mett method in testing very small amounts of pepsin.

amounts of Pepsin I are plotted in the manner of Fig. 1, but on a larger scale in order to permit observations of the relationships in low concentrations of enzyme. Here it will be seen that the curve of actual results and the two "theoretical" curves are hardly distinguishable during the first millimeter of digestion but that to digest two millimeters, which in the case of a linear relationship would require 2 mg. and according to the square

<sup>1</sup> E. Schütz, *Z. Physiol. Chem.*, 9, 577 (1885); J. Schütz, *Ibid.*, 30, 1 (1900).

<sup>2</sup> *Loc. cit.*

root rule should have required 4, actually required 5 mg.; while 10 mg. actually accomplished only what should have been done by 6.5 mg., according to the square root rule.

Hence it appears that the observed result in this method is approximately proportional to the amount of pepsin only at the very lowest concentrations with which of course the length of column digested is too short for any high degree of accuracy in measurement.

With trypsin all the measurements are likely to be inaccurate, because the alkali of the solution acts upon the coagulated albumin, causing a jelly-like meniscus which is very difficult to read. Moreover, the results show plainly that this method is not well adapted to the study of trypsin because egg albumin, even when coagulated, is a relatively resistant substrate for this enzyme.

#### Casein Substrate for all Following Methods.

In all of the experiments hereinafter described, casein<sup>1</sup> was used as substrate. For pepsin digestions the casein was suspended in 0.05 *M* HCl. For trypsin digestions solutions of sodium caseinate, of the slight alkalinity best suited to tryptic activity, were prepared as follows:

Ten grams of casein were dissolved in a mixture of about 200 cc. of distilled water and 8 cc. of molar sodium hydroxide. The mixture was slowly heated to 40° to aid solution and then rapidly heated to 85–90° to destroy any traces of proteolytic enzyme which might be contained in the casein. The solution was cooled and made up to 500 cc. For each determination, 50 cc. of this solution were placed in a 100 cc. flask, diluted to about 90 cc., warmed to 40° in a thermostat, constant to 0.01°, the enzyme added, and the volume made up to 100 cc. During the digestion the flasks were protected from the rays of light from the lamps in the thermostat. The enzyme action was stopped at stated intervals by pouring the digestion mixture (100 cc.) into 25 cc. of 20% sodium sulfate solution and then adding 5 cc. of half-molar hydrochloric acid. After standing for an hour, the undigested casein was filtered off and aliquot portions of the filtrate used for the measurement of proteolysis by the various methods already mentioned, such as titration, amino nitrogen, total nitrogen, etc.

In the pepsin experiments, 1 g. of casein was weighed out for each flask and dissolved in 0.05 *M* hydrochloric acid, the solution warmed, enzyme added and the volume made up to 100 cc. At the end of the digestion period, the undigested casein was precipitated by pouring the digestion mixture into 25 cc. of 20% sodium sulfate solution. After standing one hour, the casein was filtered out and portions of the filtrate analyzed as in the case of trypsin.

#### Total Nitrogen of Digestion Products.

In the filtrate obtained after precipitation of undigested casein by sodium sulfate and hydrochloric acid as described above, nitrogen can readily be determined by the Kjeldahl method and thus a measure obtained of the total of digestion products which have passed the early proteose stage. In using this as a method of studying proteolytic action of enzymes, "blank tests," in which all conditions and manipulations are the same except for the addition of the enzyme, must always be made and the nitro-

<sup>1</sup> Kahlbaum's "Casein nach Hammarsten."

gen thus found deducted. When relatively large amounts of enzyme preparation are used the soluble nitrogen thus introduced must also be allowed for. The figures given in the tables which follow are in all cases for the nitrogen found in the filtrates *in excess* of that found in the "blank." Table II shows the amounts of nitrogen digested by different weights of commercial pepsins and trypsins acting for a fixed length of time. Table III shows the results of a fixed weight of enzyme acting for different lengths of time.

TABLE II.—TOTAL NITROGEN OF DIGESTION PRODUCTS FORMED BY DIFFERENT WEIGHTS OF ENZYMES ACTING UPON 1 G. OF CASEIN IN A DIGESTION MIXTURE OF 100 CC. AT 40°.

TABLE III.—TOTAL NITROGEN OF DIGESTION PRODUCTS.

Amounts Formed in Different Times by 1 Milligram of Enzyme Acting on 1 Gram of Casein at 40°.

Time of digestion. Hours.	Pepsin I. Mg.	Trypsin I. Mg.	Trypsin II. Mg.	Apparent value of Trypsin I in percentage of that of Trypsin II as affected by time of digestion.
1/2	19.8	36.1	16.6	217
1	31.2	61.4	32.0	192
2	44.4	98.4	59.5	165
3	55.6	119.1	81.9	145
4	62.3	128.4	100.3	128
6	73.9	133.4	120.2	111
8	79.8	135.8	128.4	106
21	97.4	138.4	136.5	101
48	107.4	138.0	136.4	101

Comparing the delicacy of this method as shown by the data of Table II with that of the Mett method as shown in Table I, we find that in 20-hour digestions with Pepsin I the smallest amount of this commercial enzyme which was demonstrable by the Mett method was about 0.04 mg., while by the present method 0.001 mg. could be demonstrated with an equal degree of certainty and 0.01 mg. gave a yield of digestion products

sufficient for fairly accurate quantitative measurement. With trypsin, to which the Mett method has been seen to be poorly adapted, the present method gives excellent results. In the case of the commercial enzymes here used the present method permitted positive demonstration of trypsin at quite as great dilution as of pepsin and with increasing amounts of enzyme in the digestion mixtures the trypsin showed regularly higher proteolytic values than did equal weights of the pepsin obtained from the same manufacturer at the same time.<sup>1</sup>

The value of this method for quantitative comparisons is shown by the fact that, allowing for the probable errors of experiment, the amount of digested nitrogen increases in direct proportion to the amount of enzyme used up to about 20–25 mg. of nitrogen in the case of pepsin, or 40–60 mg. of nitrogen in the case of trypsin, quantities large enough to be determined by the Kjeldahl method with a high degree of accuracy.

A comparison of the data for Trypsins I and II in Table III illustrates the importance of avoiding too long a time (or too large a quantity of enzyme) in making comparisons of enzyme activities. Trypsin I has about twice the activity of Trypsin II, as may be seen by comparing the amounts of total digested nitrogen for 30 minutes or for 1 hour of digestion. But when the digestion is too prolonged the product of the weaker enzymes steadily approaches that of the stronger until at the end of 8 hours the enzyme which really has twice the activity appears but little more active. If, on the other hand, we compare the lengths of time required to digest a given amount of nitrogen, we find that, up to quite high amounts, the times required by Trypsin I and Trypsin II are approximately as 1 : 2. This may be seen by reference to the data of Table III, or (perhaps better), the curves in Fig. 4, from which it will be seen that the production of any given amount of total digested nitrogen (even up to 128 mg.) requires almost exactly twice as long with Trypsin II as with Trypsin I.

#### Amino Nitrogen of Digestion Products (Van Slyke Method).

In our experiments with this method, 2 cc. portions of the filtrates obtained as already described, which contained the digestion products formed by the action of pepsin or trypsin on casein, were analyzed for amino nitrogen by the Van Slyke method<sup>2</sup> in the "micro" apparatus, using the new 3 cc. gas buret recently described. Our experience leads us to emphasize the importance of frequent "reagent blank" determinations in order to

<sup>1</sup> It should, however, be noted in this connection that the commercial pepsin contained only 2.25% of nitrogen while the commercial trypsin contained 10.95% of nitrogen. Undoubtedly considerable amounts of inert material were present in both samples. It cannot be inferred that the digestive activities of pure pepsin and pure trypsin would bear the same quantitative relation to each other as do these commercial products. On the other hand, the commercial products used in our experiments have as high proteolytic activity as any which we have yet found in the market.

<sup>2</sup> *J. Biol. Chem.*, 9, 185 (1911); 12, 275 (1912); 16, 121 (1913); 23, 407 (1915).

detect deterioration of any of the substances used, especially the caprylic or heptyl alcohol which is introduced to prevent frothing. The determinations were carried out in all respects as described by Van Slyke, and the amounts of amino nitrogen found in the 2 cc. portions of filtrate were corrected for "blank" then multiplied by 62.5 or 65 to obtain the total amino nitrogen formed<sup>1</sup> by the action of the enzyme in each case. The data so obtained are given in Table IV.

TABLE IV.—AMINO NITROGEN (MEASURED BY VAN SLYKE METHOD) FORMED BY DIFFERENT WEIGHTS OF ENZYME ACTING UPON 1 GRAM OF CASEIN AT 40°.

Mg. of commercial enzyme.	Half-hour digestions.		20-hour digestions.	
	Pepsin I.	Trypsin I.	Pepsin I.	Trypsin I.
	Mg. of amino nitrogen.	Mg. of amino nitrogen.	Mg. of amino nitrogen.	Mg. of amino nitrogen.
0.001	0.0	0.0	0.0	0.5
0.002	0.0	0.0	0.2	0.7
0.01	0.0	0.0	0.3	1.3
0.05	0.0	0.0	1.7	4.6
0.1	0.2	0.7	3.3	8.1
0.5	0.7	2.0	5.5	21.0
1	1.5	3.3	7.0	26.7
2	3.0	5.4	9.4	31.3
5	4.6	11.0	11.9	36.1
25	8.9	27.1	14.8	44.9
50	11.2	35.1	15.8	50.2
100	14.1	41.0	17.8	58.2

If the data of Table IV, especially those for the very small amounts of enzyme, be compared in detail they appear somewhat irregular, probably because of the multiplication of unavoidable errors of observation by the large factor (62.5 or 65). The general trend of the results is, however, quite regular, as may be seen from Fig. 3, where the total and amino nitrogen of the products of half-hour digestions are shown together. The amino nitrogen formed in a given experiment is of course much smaller in amount than the total nitrogen of digestion products (unless the experiment be pushed far beyond the limits of those here considered) and after all of the casein has been converted into digestion products and the total nitrogen of digestion products can no longer increase, the amino nitrogen continues to rise as the proteoses, peptones and peptids are split to yield amino acids. Hence this method, in addition to measuring a change which is more definite in its chemical nature, has also the advantage of enabling one to follow the later stages of proteolysis. On the other hand, the very first stages of proteolysis are more readily detected by determining the total nitrogen of digestion products.

The amino nitrogen of digestion products was also determined in the

<sup>1</sup> The enzyme acts in a volume of 100 cc., but the sulfate solution and standard acid added at the end of the digestion period bring the total volume to 130 cc. in the case of trypsin experiments and 125 cc. in the case of pepsin.

Fig. 3.—Comparison of activity of Pepsin I and Trypsin I as shown by total nitrogen of digestion products (upper two curves), and by increase of amino nitrogen (lower two curves).

experiments (of which the total nitrogen of digestion products was shown in Table III) in which fixed amounts of enzyme were allowed to act for different lengths of time. The results thus obtained are shown in Table V, and those for the trypsins graphically in Fig. 4. As would be expected, the amino nitrogen of digestion products continues to increase long after the total nitrogen of digestion products has reached its maximum and is, therefore, applicable to the study of much later stages of the digestion. Comparing the two trypsins, I and II, we find them bearing the same relation to each other here as in Table III. The results of the determination of both total and amino nitrogen for digestion products of Trypsins I and II at different time intervals are shown together in Fig. 4.

TABLE V.—AMINO NITROGEN OF DIGESTION PRODUCTS (VAN SLYKE METHOD).  
Amounts Formed in Different Times by 1 Mg. of Enzyme Acting  
on 1 G. of Casein at 40°.

Time of digestion. Hours.	Pepsin I. Mg.	Trypsin I. Mg.	Trypsin II. Mg.	Time of digestion. Hours.	Pepsin I. Mg.	Trypsin I. Mg.	Trypsin II. Mg.
1/2	0.71	3.02	1.48	8	6.12	22.00	17.41
1	1.56	6.50	2.98	21	8.93	25.71	24.53
2	3.17	10.85	6.01	48	10.55	29.55	29.47

4	4.53	17.25	11.23	120	11.08 <sup>1</sup>	33.70	.....
6	5.23	19.63	14.34	168	12.31 <sup>1</sup>	35.61	.....

<sup>1</sup> These solutions contained thymol as antiseptic.

Here again we find striking evidence of the importance of reasonably short digestion periods in comparing the activities of two enzyme preparations. As already explained and as shown by the figures for 30 minutes' or for 1 hour's digestion as given in Table V, the activity of Trypsin I is about twice that of Trypsin II, but when the length of the digestion period is prolonged the difference between the two samples appears less

Fig. 4.—Comparison of activities of Trypsins I and II as measured by total nitrogen of digestion products (upper two curves) and by increase in amino nitrogen due to action of enzyme on substrate (lower two curves).

and less and by the end of about 20 hours they appear to be equally active. Thus in a comparison in which the time of digestion is too long a difference of 100% in the activity of two enzyme preparations may be entirely obscured. Unless the amount of protease present is exceedingly minute or the proteolytic activity very feeble the time of digestion should be preferably not be longer than 30 minutes or one hour.

If, instead of comparing the products obtained in a given length of time, one compares the length of time required for the formation of a given

amount of the product, the true relative values of the two trypsin can be traced through longer periods of time and to larger yields of product. Thus 14 mg. of amino acid nitrogen were formed by Trypsin I in three hours, by Trypsin II in six hours; 17 mg. of amino acid nitrogen required in the case of Trypsin I four hours, of Trypsin II eight hours. Even in this case, however, very long periods would be apt to give seriously misleading results, because when the reaction has become very slow the unavoidable errors in determining the total product would necessarily be large as compared with the small hourly increment.

#### Titration of Acid Cleavage Products (Volhard-Löhlein Method).

Thomas and Weber<sup>1</sup> estimated the activity of trypsin by allowing it to act upon casein as in the general procedure above described and weighing the undigested casein precipitated at the end of the digestion period. Volhard<sup>2</sup> tested pepsin, and Löhlein<sup>3</sup> trypsin, by titrating the filtrate. In 1912, Miss Ruth, working with one of us, obtained promising results from this method and we have therefore included it in the present comparison.

In most of the above experiments for which the total nitrogen or amino nitrogen of the filtrate has been determined, a portion of the filtrate (usually 50 cc.) has been titrated with tenth-molar sodium hydroxide with thymolphthalein as indicator. The amount of alkali thus required, above that required in the "blank," depends upon the carboxyl groups of the digestion products plus a little of the hydrochloric acid used in the digestion or added with the sulfate solution to precipitate the undigested casein; for the acidity of the "blank" filtrate does not account for all of the hydrochloric acid which was added, indicating that some of it is held by the undigested casein. In the pepsin tests this hydrochloric acid is liberated as the digestion proceeds. In the trypsin tests the more complete the digestion of the casein, the less hydrochloric acid will it hold when precipitated at the end of the digestion period. The fact that this method measures something more than the liberation of amino acids suggested that it might yield information somewhat different from that obtained from the Van Slyke and Sørensen methods.<sup>4</sup> In so far as it depends upon the titration of carboxyl groups, it is particularly appropriate that this method should accompany the use of casein as substrate on account of the high proportion of dibasic monoamino acid shown by Osborne and others to result from the hydrolysis of casein.<sup>5</sup>

<sup>1</sup> *Centrbl. f. Stoffw.-u. Verd.-Krankh.*, 2, 365 (1901).

<sup>2</sup> *Biochem. Z.*, 2, 231 (1903).

<sup>3</sup> *Beitr. Chem. Physiol.-Path.*, 7, 120 (1905).

<sup>4</sup> We have accepted the results of Harding and MacLean (*Loc. cit.*) as sufficiently indicative that the results of the Sørensen method run parallel with those of the Van Slyke and so have not included the Sørensen method in our comparative experiments.

<sup>5</sup> Osborne and Guest, *J. Biol. Chem.*, 9, 352 (1911).

The results obtained by this method are shown in Tables VI and VII, where (as in the preceding tables) the figures given are in all cases calculated for the total solution so as to indicate the work done by the amount of enzyme stated. Some of the filtrates were opalescent, making the end point of the titration somewhat uncertain. This method appears somewhat less delicate than the determination of total nitrogen; about as delicate but not so regular in its results as the determination of amino nitrogen in the filtrate. It is about equally delicate for pepsin and trypsin (referring of course to the commercial preparations here used), so that in 20-hour digestions both can be detected with certainty when present in quantities of 0.01 mg. and usually when as little as 0.002 mg. is present.

TABLE VI.—ACIDITY OF CLEAVAGE PRODUCTS (VOLHARD-LÖHLEIN METHOD) FORMED BY ACTION OF DIFFERENT WEIGHTS OF COMMERCIAL ENZYMES UPON 1 G. OF CASEIN AT 40°.

Mg. of commercial enzyme.	Half-hour digestions.		20-hour digestions.	
	Pepsin I.	Trypsin I.	Pepsin I.	Trypsin I.
	Acidity over that of "blank,"		in terms of cc. 0.1 M NaOH.	
0.001	0.0	0.0	0.0	0.2
0.002	0.1	0.0	0.1	0.2
0.01	0.1	0.0	0.6	1.2
0.05	0.2	0.0	2.4	5.8
0.1	0.3	0.6	4.2	11.0
0.5	0.9	1.3	8.5	22.5
1	1.9	3.0	12.1	26.0
2	3.3	6.1	13.1	27.7
5	6.1	12.1	15.3	30.1
25	12.3	25.6	18.5	33.9
50	12.4	28.6	18.7	35.6
100	16.0	30.6	21.1	37.8

TABLE VII.—ACIDITY OF DIGESTION PRODUCTS RESULTING FROM ACTION OF 1 MG. OF COMMERCIAL ENZYME UPON 1 G. OF CASEIN FOR DIFFERENT LENGTHS OF TIME AT 40°.

Time of digestion. Hours.	Acidity over that of "blank"—cc. of 0.1 M NaOH.		
	Pepsin I.	Trypsin I.	Trypsin II.
1/2	1.75	4.43	2.02
1	2.83	8.18	4.10
2	4.50	13.58	7.81
3	5.83	18.00	10.83
4	6.75	19.56	14.37
6	8.58	22.81	18.40
8	9.33	23.98	21.52
21	12.25	26.20	25.80

The general trend of these results (Tables VI and VII) is very nearly parallel with that for the total nitrogen of digestion products (Tables II and III). While the determination either of total, or of amino, nitrogen of digestion products is preferable both in delicacy and on theoretical

grounds, the convenience of this titration method makes it worthy of further study as a rapid approximate method for the measurement of proteolytic action.

### The Increase of Electrical Conductivity.

In view of the prominence given by Bayliss<sup>1</sup> to the conductivity method in his study of tryptic action, we have determined the increase of electrical conductivity resulting from the action of different amounts of trypsin upon casein substrates prepared in the manner already described. In this work the spiral Kohlrausch bridge of Leeds and Northrup was used with telephone buzzer. The solutions were contained in Freas conductivity cells having electrodes about 1 cm. square and about 1 cm. apart. The results of typical experiments are shown in Table VIII. Experiments were also made in which the enzyme was allowed to act upon the substrate in a conductivity cell, so arranged that determinations of conductivity could be made from time to time without interruption of the digestion. Table IX shows the results of a typical experiment of this type.

TABLE VIII.—INCREASE IN ELECTRICAL CONDUCTIVITY RESULTING FROM ACTION OF DIFFERENT WEIGHTS OF COMMERCIAL TRYPSIN UPON CASEIN SUBSTRATE AT 40°.

Mg. of commercial enzyme.	Increase in reciprocal ohms.			
	Half-hour digestions.		20-hour digestions.	
	Trypsin I. (1) <sup>2</sup>	Trypsin II. (2) <sup>2</sup>	Trypsin I. (3) <sup>2</sup>	Trypsin II. (4) <sup>2</sup>
0.002	0.00	0.00	0.00	0.00
0.01	0.00	0.00	0.16 × 10 <sup>-4</sup>	0.00
0.05	0.04 × 10 <sup>-4</sup>	0.00	0.47 × 10 <sup>-4</sup>	0.10 × 10 <sup>-4</sup>
0.1	0.07 × 10 <sup>-4</sup>	0.12 × 10 <sup>-4</sup>	0.81 × 10 <sup>-4</sup>	0.29 × 10 <sup>-4</sup>
0.5	0.21 × 10 <sup>-4</sup>	0.18 × 10 <sup>-4</sup>	2.26 × 10 <sup>-4</sup>	1.24 × 10 <sup>-4</sup>
1	0.37 × 10 <sup>-4</sup>	0.25 × 10 <sup>-4</sup>	3.03 × 10 <sup>-4</sup>	1.62 × 10 <sup>-4</sup>
2	0.66 × 10 <sup>-4</sup>	0.40 × 10 <sup>-4</sup>	3.44 × 10 <sup>-4</sup>	2.37 × 10 <sup>-4</sup>
5	1.26 × 10 <sup>-4</sup>	0.84 × 10 <sup>-4</sup>	3.99 × 10 <sup>-4</sup>	3.91 × 10 <sup>-4</sup>
100	5.58 × 10 <sup>-4</sup>	....	11.62 × 10 <sup>-4</sup>	....
250	8.82 × 10 <sup>-4</sup>	....	15.65 × 10 <sup>-4</sup>	....

This method is very convenient (as Bayliss has previously shown) for following the time curve of tryptic digestions, but offers no special advantage in comparing the effects of different amounts of enzyme. For the purposes of our investigations it has seemed preferable on theoretical grounds to depend chiefly upon those methods in which the effect measured can be expressed in definite chemical terms, *viz.*, as total nitrogen or as amino nitrogen of digestion products formed by the action of the enzyme.

4	$1.36 \times 10^{-4}$	$1.21 \times 10^{-4}$
5	$1.51 \times 10^{-4}$	$1.33 \times 10^{-4}$
6	$1.61 \times 10^{-4}$	$1.46 \times 10^{-4}$
7	$1.75 \times 10^{-4}$	$1.56 \times 10^{-4}$
9	$2.06 \times 10^{-4}$	$1.76 \times 10^{-4}$
24	$3.22 \times 10^{-4}$	$2.95 \times 10^{-4}$

### The Polariscopic Method.

Most investigators who have employed the optical method for the study of proteolysis have made use of an optically active di-, tri-, or poly-peptid as substrate. Abderhalden<sup>2</sup> tests for proteolytic action by polariscopic observations upon mixtures of blood serum and peptone prepared from tissue protein. In order to test the usefulness of this method for studies of the action of enzymes on typical protein, we have examined portions of the digestion filtrates obtained as described in connection with the four preceding methods, in comparison with those of the "blank" tests to determine what, if any, change had occurred in the optical rotatory effect of the substrate solution as the result of the action of the enzyme. A very delicate polariscope,<sup>3</sup> reading to hundredths of an angular degree, was employed. Readings were usually made in a 220 mm. tube and when made in shorter tubes are calculated to this basis for comparison. The "blank" filtrate solutions were always levorotatory and the result on slight or moderate proteolysis was to increase this levorotation; but with further digestive hydrolysis the levorotation was diminished. The results as shown in Table X are always averages of at least 3 or 4 readings.

The optical method shares with the titration and conductivity methods the advantage of rapidity, the relative convenience of these three methods depending upon the nature of the investigation and the equipment and arrangement of the laboratory. It also affords a delicate means of detecting the action of very small amounts of proteolytic enzyme; but the fact that the change in rotation does not proceed progressively with the amount of enzyme or the time during which a given amount of enzyme

<sup>1</sup> Initial conductivity, (1)  $6.56 \times 10^{-4}$ ; (2)  $6.56 \times 10^{-4}$ .

### The Biuret Reaction.

The biuret test was applied to the filtrates obtained from the peptic and tryptic digestions of casein and the colors obtained were found to pass gradually from a faint violet to a rose-red according to the extent of the digestion, showing that the test may serve for rough comparisons of proteolytic power within the range covered by these color changes.

Five cc. portions of the filtrates were placed in small porcelain dishes and to each portion one cc. of a nearly saturated solution of sodium hydroxide, and 0.15 cc. (three drops) of a 1% solution of copper sulfate were added. The solutions were stirred and allowed to stand at least fifteen minutes in order to obtain a full development of color.

The readings are expressed as nearly as possible according to the Milton Bradley Standard Color Charts, as given by Mulliken in his *Identification of Pure Organic Compounds*. In the cases of the strongest digestions, the color is better described as rose-red, than as any shade on the color charts.

The results of these tests are shown in Table XI.

By comparison of these data with those given in previous tables, it will be seen that the application of the biuret reaction, while superior to the Mett method, is a less delicate means of detecting proteolysis than most of the quantitative measurements already described and is capable of showing differences only in a much narrower range of enzyme concentrations. For the purposes of our investigations the method did not seem sufficiently promising to warrant further study.

TABLE XI.—COLORS OBTAINED ON APPLYING BIURET REACTIONS TO FILTRATES FROM DIGESTIONS OF CASEIN WITH DIFFERENT AMOUNTS OF COMMERCIAL ENZYMES.

### The Triketohydrindene Hydrate (Ninhydrin) Reaction.

The filtrates from several of the experiments with casein substrate above described have been subjected to the ninhydrin reaction of Abderhalden and to Herzfeld's modification of this test. As this part of our work was done before the results of the investigations of Harding and MacLean<sup>2</sup> became available we did not have the opportunity to include their colorimetric method based on this reaction in our comparison; but from the striking agreement of their results with those which they obtained by the Van Slyke method it would seem that these methods may be regarded as giving practically identical information in the study of proteolysis induced by pancreatic enzymes.

In our experiments the ninhydrin tests were performed as follows: 5 cc. portions of the filtrates to be tested were dialyzed against 15 cc. of water for 16 hours at 37°, through the specially prepared "Abderhalden" parchment thimbles (No. 579A) of Schleicher and Schüll; the dialysates were then neutralized with sodium hydroxide and 10 cc. portions tested with 0.2 cc. of a 1% solution of ninhydrin: (1) According to Abderhalden, by adding the reagent to the aqueous dialysate and boiling for one minute; (2) according to Herzfeld,<sup>3</sup> by evaporating the dialysate and reagent to dryness and taking up the residue with 10 cc. of absolute alcohol.

Typical results are shown in Table XII.

The Herzfeld modification is plainly much more delicate than the test as described by Abderhalden—perhaps too delicate for the clinical purpose which the latter chiefly emphasizes. Thus Abderhalden<sup>4</sup> says:

"Schwierigkeiten machen einzig und allein rötliche und braungelbe Farbtöne. Sie haben nichts mit der eigentlichen Ninhydrinreaktion zu tun."

<sup>1</sup> In these cases the color was of only slight intensity approximating the "Tint 2" of the Standard Color Chart.

				Violet-red <sup>3</sup> to Violet-red <sup>4</sup>	Violet-red <sup>3</sup> to Violet-red <sup>4</sup>	
				Violet-red to Red-violet <sup>3</sup>	Violet-red to Red-violet <sup>3</sup>	
				Violet <sup>3</sup>	Violet <sup>4</sup>	
				Violet <sup>4</sup> to Red-violet <sup>3</sup>	Violet <sup>4</sup> to Red-violet <sup>3</sup>	
				Violet <sup>4</sup> to Red-violet <sup>3</sup>	Violet <sup>4</sup> to Red-violet <sup>3</sup>	
				Violet <sup>4</sup> to Red-violet <sup>3</sup>	Violet <sup>4</sup> to Red-violet <sup>3</sup>	

<sup>1</sup> These colors were pale, approximating "Tint 2" of the Standard Color Chart; <sup>2</sup> "Tint 1;" <sup>3</sup> "Normal Tone;" <sup>4</sup> "Shade 1;" <sup>5</sup> "Shade 2;" <sup>6</sup> "Broken Tone (Medium)."

However, this may be from a clinical point of view, our experiments show that the solutions which gave an orange color in aqueous solution, contained a substance capable of reacting with ninhydrin because they gave a violet color when Herzfeld's conditions were used to make the test more sensitive. For example, the digestion containing 0.1 mg. of Trypsin I gave the color Orange, Tint 2, when the test was carried out in aqueous solution, and a color between Violet-red and Red-violet, Normal Tones, in alcoholic solution. Many other examples could be cited to the same effect.

But even with the increased delicacy given by the Herzfeld modification the ninhydrin test is, in our hands, a less delicate, and certainly a much less definite, means of demonstrating slight proteolytic action than is the determination of total nitrogen of digestion products or of amino nitrogen by the method of Van Slyke.

### Summary.

Eight methods for the study of proteolytic action have been examined: The Mett method, the determination of total nitrogen of digestion products, the measurement of increase of amino nitrogen by the Van Slyke method, the titration of acidity of digestion products, the increase of electrical conductivity, the polariscopic method, and the biuret and ninhydrin reactions.

The results obtained in comparable experiments upon typical commercial pepsin and trypsin are so tabulated as to permit detailed comparisons of the delicacy, accuracy and applicability of these methods. (The comparisons thus made possible are too numerous to be concisely summarized.)

In general it may be said that the quantitative determination of the total nitrogen or the amino nitrogen of the digestion products (or both) appears to be more delicate as a means of detecting proteolysis than either the biuret or the ninhydrin reaction and more delicate, accurate, and generally applicable as a means for its measurement than any of the other quantitative methods here studied.

The results emphasize the importance, in quantitative comparisons, of so limiting the amount of enzyme preparation and the time of its action as to keep within the region in which the velocity of hydrolysis is directly proportional to the enzyme concentration (Fig. 4.).

We are greatly indebted to the Carnegie Institution of Washington for grants in aid of this investigation.

### CORRECTION.

In the article by C. S. Hudson and J. K. Dale in the July number of THIS JOURNAL (p. 1434, line 3 from bottom), entitled "The Isomeric

Pentacetates of Glucosamine and of Chondrosamine," the melting point of  $\beta$ -pentacetyl glucosamine recorded as 118–189° should be 188–189°.

### NEW BOOK.

**A System of Physical Chemistry.** Vol. I. Kinetic Theory. Vol. II. Thermodynamics and Statistical Mechanics. By WILLIAM C. MCC. LEWIS, Professor of Physical Chemistry in the University of Liverpool. Text-Books of Physical Chemistry, edited by Sir William Ramsay. New York and London: Longmans, Green and Co., 1916. Pp. xiv + 523, vii + 522. Price \$2.50 each volume.

In the preface the author states that "this book is intended to be used as a general text-book of physical chemistry by those who already possess some knowledge of both physics and chemistry," and "suggests to the reader the advisability of first familiarizing himself with the broad outlines" of physical chemistry. The "System" referred to in the title "consists in regarding all physico-chemical phenomena as being capable of separation into two classes: first, phenomena exhibited by material systems when *in* a state of equilibrium; and secondly, phenomena exhibited by material systems which have *not* reached a state of equilibrium." The book is divided "into three parts, in which the phenomena exhibited by systems in equilibrium and not in equilibrium are treated, first, from the 'classical' kinetic standpoint only (Vol. I); then independently from the thermodynamics; and finally from the standpoint of thermodynamics and the new or 'modified' principles of statistical mechanics (Vol. II)." This division into parts is not an essential feature of the System and is "introduced for the purpose of making the book as readable as possible from the students' point of view."

On account of the novel arrangement of the material the principal subjects considered are listed below:

Volume I, Part I. Chapters I and II, kinetic theory, evidence for the real existence of molecules (Perrin's work is discussed in detail), electron theory of matter, transmutation of the elements (radioactivity), continuity of the liquid and gaseous states, molecular association; Chapters III to VI, chemical equilibrium in homogeneous systems, law of mass action, gaseous systems, liquid mixtures, osmotic pressure, theory of electrolytic dissociation, solid solutions; Chapters VII and VIII, chemical equilibrium in heterogeneous systems, first in the absence of effects due to capillarity, radiation, etc., and second as modified by capillary and electro-capillary effects (colloidal solutions); Chapter IX, homogeneous systems not in equilibrium, diffusion, reaction velocity, catalysis; Chapter X, heterogeneous systems not in equilibrium, reaction velocity, catalysis.

Volume II, Part II. Chapters I and II, principles of thermodynamics; Chapter III, continuity of the liquid and gaseous states; Chapter IV, thermodynamic criteria of equilibrium; Chapters V to VIII, chemical

equilibrium in homogeneous systems, law of mass action, gaseous systems, dilute solutions, osmotic pressure, electrochemistry of dilute solutions, osmotic pressure of concentrated solutions; Chapters IX and X, parallel to VII and VIII above, phase rule, adsorption; Chapters XI and XII, parallel with IX and X above, affinity and its measurement, Nernst Heat Theorem.

Volume II, Part III. Chapter I, photochemistry; Chapter II, applications of the Quantum Theory.

Physical chemists will be especially interested in the excellent discussions of important recent investigations, such as the work on molecular reality, electron theory of matter, radioactive transformations, colloids, Nernst heat theorem, photochemistry, quantum theory and the calculation of the specific heats of solids. The date on the title page is 1916 but only a few brief references to work done since 1912 are given. The work on X-ray spectra and atomic numbers is entirely omitted.

An unusual and commendable feature of this book is the introduction of direct quotations from a number of original papers. The author has made it a point to present the principles of experimental methods and to give experimental results in some detail. These features, together with the large number of references to original papers and the excellence of the subject and author indexes for each volume make the book a valuable reference book for all chemists.

ANNUAL REPORT OF THE INTERNATIONAL COMMITTEE ON  
ATOMIC WEIGHTS, 1917.

The following new determinations of Atomic Weights have been published since the issue of the last Annual Report:

**Hydrogen.**—Burt and Edgar<sup>1</sup> conclude from a long series of experiments that the ratio of the combining volumes of hydrogen and oxygen is represented with a high degree of probability by the figure 2.00288 at 0° and 760 mm. pressure. Assuming Morley's values for the densities of hydrogen and oxygen, namely 0.089873 and 1.42900, respectively, the atomic weight of hydrogen is found to be 1.00772. This new value for H is very nearly the arithmetic mean of the independent values obtained by Morley and Noyes. It may be taken, therefore, that the true value for H lies very close to 1.0077.

**Zinc.**—Baxter and Grose,<sup>2</sup> by the electrolysis of zinc bromide, find  $Zn = 65.388$ .

**Cadmium.**—Baxter, Grose and Hartmann,<sup>3</sup> by the electrolysis of cadmium bromide, find  $Cd = 112.407$ . Similar analyses of the chloride gave  $Cd = 112.413$ . Oechsner de Coninck and Gérard,<sup>4</sup> by reducing cadmium carbonate to metal, found  $Cd = 112.32$ .

<sup>1</sup> *Phil. Trans.*, 216, 393 (1916).

<sup>2</sup> *THIS JOURNAL*, 38, 868 (1916).

<sup>3</sup> *Ibid.*, 38, 857 (1916).

<sup>4</sup> *Compt. rend.*, 161, 676 (1915).

**Lead.**—Hönigschmid and Horovitz,<sup>1</sup> by analyses of the chloride, found for common lead the value  $Pb = 207.180$ . Similar analyses of radioactive lead chloride from various sources gave atomic weight values ranging from 206.050 to 206.084.

## THE CONSTITUTION AND FUNDAMENTAL PROPERTIES OF SOLIDS AND LIQUIDS.

### PART I. SOLIDS.

BY IRVING LANGMUIR.

Received September 5, 1916.

The importance of the work of W. H. Bragg and W. L. Bragg in its bearing on chemistry has not, as yet, been generally recognized. In hearing two of W. H. Bragg's lectures in this country a few years ago, the writer was impressed with the very great significance of this work in the field of chemistry. The structure of crystals as found by the Braggs leads to new and more definite conceptions as to the nature of chemical forces.

The writer has constantly endeavored to apply this new conception in his work on heterogeneous reactions and particularly in connection with a study of the phenomena of adsorption and surface tension. In this way he has gradually been led to form more or less definite theories of the mechanism of evaporation, condensation, liquefaction, adsorption, and capillary phenomena. According to this theory, both solids and liquids

<sup>2</sup> THIS JOURNAL, 37, 2046 (1915).

<sup>3</sup> *Ibid.*, 38, 302 (1916).

<sup>4</sup> *Ibid.*, 38, 1783 (1916).

<sup>5</sup> *Ann. Physik*, [iv] 48, 269 (1915).

consist of atoms held together entirely by *chemical forces*. The conception of the molecule thus almost entirely loses its significance except in the case of gases. In fact, we may well look upon any solid or liquid body as constituting a single large molecule. Any change of phase, such as the melting of a solid, is thus a typical chemical reaction. The mobility of liquids, according to this viewpoint, is due to a kind of tautomerism.

The present paper is merely an outline of this theory. The more detailed description of the experimental work upon which it is largely based, will be reserved for future papers.

### STRUCTURE OF CRYSTALS.

The idea that a crystal should constitute an effective diffraction grating for X-rays originated with Laue,<sup>1</sup> who also saw that by means of such a grating not only could the wave length of the X-rays be determined, but also a powerful method for studying the structure of crystals was made available. The detailed theory developed by Laue proved incorrect in certain important respects. W. L. Bragg<sup>2</sup> called attention to these errors and gave a theory by which the true structure could be determined from the diffraction pattern. Since then the method has been greatly simplified, so that at present it is usually a matter of no great difficulty to find the exact arrangement of the atoms in a crystal. In this way the structures of some 30 or more kinds of crystals have been determined.

The alkali halides NaCl, KCl, KBr, and KI all have a similar structure in which the *atoms* are arranged according to a simple cubic lattice. Thus, in the case of sodium chloride crystals, sodium and chlorine atoms alternate along three sets of lines at right angles to each other. Each sodium atom is surrounded by six equidistant chlorine atoms arranged around it, as the corners of an octahedron are arranged around its center. Similarly, each chlorine atom is surrounded by six equidistant sodium atoms.

Up to this time it had been taken for granted that crystals were built up of molecules. But from this work of the Braggs it is clear that in crystals of this type the identity of the molecules is wholly lost, except in so far as we may look upon the whole crystal as composing a single molecule. From the arrangement of the atoms we must conclude that the forces holding the crystal together (cohesion) are forces which exist directly between sodium and chlorine atoms. Every chemist looks upon such forces as chemical in nature.<sup>3</sup>

<sup>1</sup> *Sitzb. d. Bayer. Akad. d. Wiss.*, June, 1912.

<sup>2</sup> *Proc. Camb. Phil. Soc.*, 17, 43 (1912). The subsequent papers of W. H. and W. L. Bragg were published in 1913 and 1914 in the *Proc. Camb. Phil. Soc.*, the *Proc. Roy. Soc.*, and the *Phil. Mag.* All of these papers were translated into German and were published together in one volume of the *Z. anorg. Chem.*, 90 (1914).

<sup>3</sup> Of course all chemical forces are probably of electromagnetic origin, but for this reason we do not need to call the forces in crystals by the vague term "physical forces" (and thus distinguish them from chemical force).

But the significance of this structure for the chemist extends further. Sodium is invariably regarded as a monovalent element, yet in the sodium chloride crystals we see a structure which in no wise suggests the monovalent character of the atom. The sodium atom is held by chemical forces to six chlorine atoms. If we retain the conception of valency in such a case, we must clearly admit that the valency of the sodium is divided equally between the six chlorine atoms.

If a sodium chloride crystal evaporates at high temperature, the atoms leave the surface in pairs in the form of sodium chloride molecules. These molecules are formed in the process of evaporation, since they do not exist as such in the crystal. The process of evaporation is thus a chemical process.

In the diamond, each carbon atom is surrounded by four others equidistant from it. These are arranged around the central one in the same way as the four corners of a regular tetrahedron are arranged around its center. In this case the tetravalent character of the carbon atom manifests itself clearly. When a model of a diamond crystal is examined, it is seen that the atoms appear to be arranged in rings of six, corresponding to the benzene ring. The remarkable strength of the carbon chain and especially the stability of the benzene ring, so familiar to chemists, is thus seen to be the cause of the hardness, the high melting point and the low vapor pressure of the diamond.

It is interesting to note that the structure of zinc blend,  $\text{ZnS}$ , is very similar to that of the diamond, the zinc and sulfur being alternately substituted for adjacent carbon atoms. Thus each zinc atom is surrounded by four symmetrically placed sulfur atoms, while each sulfur atom is surrounded by four zinc atoms. The valency is thus again divided.

With fluorite,  $\text{CaF}_2$ , each fluorine atom is surrounded by four symmetrically placed calcium atoms, while each calcium atom has eight fluorine atoms arranged around it like the eight corners of a cube about the center of the cube.

The structure of pyrites,  $\text{FeS}_2$ , is much more complicated. Each iron atom has four equidistant sulfur atoms around it, but there are other sulfur atoms at distances only slightly greater. Similarly, each sulfur atom has three equidistant iron atoms forming a triangle around it, but above and below the plane of this triangle there are other iron atoms whose distance is only slightly greater.

Hauerite,  $\text{MnS}_2$ , has a similar structure to that of pyrites.

In the case of calcite,  $\text{CaCO}_3$ , the carbon and oxygen atoms lie in planes perpendicular to the crystal axis. Three oxygen atoms are arranged in groups around each carbon atom, forming an equilateral triangle. The calcium atoms lie in planes just above and just below the carbon-oxygen planes. Each calcium atom has six equidistant oxygen atoms around it.

The distance between the calcium and the carbon atoms is considerably more than either the distance between oxygen and carbon, or between oxygen and calcium. Thus the crystal is evidently held together by forces acting between carbon and oxygen and between oxygen and calcium. The group  $\text{CO}_3$  appears as a unit, since each carbon atom is associated with three oxygen atoms while these are associated with only the one carbon atom. But each  $\text{CO}_3$  group is equidistant from six calcium atoms, so that it is impossible to pick out any one of these as forming a molecule with the  $\text{CO}_3$ . If we are to retain the idea of a molecule at all, we must consider that the entire crystal is a single molecule.

In dolomite,  $\text{CaMgCO}_3$ , the structure is exactly similar except that calcium and magnesium planes alternate. The structures of rhodochrosite,  $\text{MnCO}_3$ , siderite,  $\text{FeCO}_3$ , and sodium nitrate,  $\text{NaNO}_3$ , are like that of calcite. This last case is of special interest to the chemist, since a monovalent atom replaces a divalent, and a pentavalent (?) atom replaces a tetravalent one without causing a change in the arrangement of the atoms.

The crystals of magnetite afford an illustration of a structure in which different atoms of the same element have different functions. Two-thirds of the iron atoms occur in positions in which each is surrounded by four oxygen atoms (tetrahedral arrangement), while the other third of the iron atoms are each surrounded by six oxygen atoms. The iron atoms have thus a divalent and trivalent character, but each unit of valence is divided between two oxygen atoms. Spinel,  $\text{MgAl}_2\text{O}_4$ , has an exactly similar structure in which the Mg atoms take the place of the divalent iron atoms, while the Al atoms replace the trivalent iron atoms.

Crystals of metallic copper and metallic silver have been found to have their atoms arranged according to the face-centered cubic lattice. This arrangement is the same as the familiar one obtained when round shot are piled in layers as regularly and compactly as possible. In this structure each atom is equidistant from the twelve adjacent atoms.

The structures of crystals of rhombic sulfur and quartz have been partly worked out. In the sulfur crystals the atoms are found to be arranged in a lattice structure in groups of eight. The particular arrangement of the atoms within these groups is not yet known. To the chemist it is of significance that these groups of eight contain the same number of atoms as are found in molecules of sulfur vapor. Here, then, for the first time, the crystal has a structure in which the identity of the molecules (as found in the gas phase) is apparently not wholly lost.

In a recent article<sup>1</sup> L. Vegard shows that the structures of gold and lead crystals are the same as those of silver and copper. He also describes the structure of the zircon group of minerals represented by zircon,  $\text{ZrSiO}_4$ ,

<sup>1</sup> *Phil. Mag.*, 32, 65 (1916).

rutile,  $\text{TiO}_2$ , and cassiterite,  $\text{SnO}_2$ . The structure of zircon proves to be especially interesting, for it is found "that each of the Zr or Si atoms is associated with two oxygen atoms; thus the groups  $\text{SiO}_2$  and  $\text{ZrO}_2$  form a kind of 'molecular elements' of the lattice. This is not merely a way of regarding the geometrical arrangement of the atoms; but we have reason to believe that the groups  $\text{SiO}_2$  and  $\text{ZrO}_2$  form chemically saturated compounds" within the crystal.

Two facts stand out clearly as a result of the consideration of these crystal structures. In the first place, it is evident that crystals are built up of atoms in such a way that each atom is chemically combined to all the adjacent atoms, while these in turn are combined to those beyond.

Secondly, we see that the arrangement of the atoms in general does not follow the usual rules of valency, but that each atom is combined with a much larger number of atoms than corresponds to its normal valence.

In the past it has been customary to consider that solids and liquids are held together by the "forces of cohesion" and to call these "physical forces" as distinguished from chemical forces. Often these distinctions are known to be rather vague, but in the more recent years, with growing confidence in the atomic theory, we have been accustomed to consider that chemical phenomena are those involving an alteration of the structure of molecules, while physical phenomena are those in which only the molecule as a whole is concerned. This distinction throws the whole difficulty back on to the definition of the molecule. In gases there is usually no uncertainty as to the size of the molecules, but in liquids and solids no really satisfactory methods have been found for determining molecular weights. As long as we cannot definitely determine the molecular weights, it thus remains impossible to distinguish sharply between chemical and physical phenomena. Nevertheless, much discussion has arisen of late years over such questions as whether adsorption and surface tension are chemical or physical phenomena. The overwhelming consensus of opinion seems to be that these are both physical phenomena.

In the following pages the writer hopes to show that there is no present justification for this distinction between chemical and physical forces. Cohesion, adsorption and surface tension are all manifestations of forces similar in their nature to those acting between the atoms of solid bodies. It is therefore advantageous to look upon these forces as direct results of chemical affinity. In this way it becomes possible to correlate these so-called physical phenomena with the known chemical characteristics of the atoms and groups of atoms forming the bodies.

**Theories of Chemical Constitution.**—The fact that each atom in a crystal is usually combined with a larger number of adjacent atoms than corresponds to its valence, is not in conflict with recent theories of the constitution of chemical substances.

A. Werner<sup>1</sup> has made a very extensive study of complex inorganic compounds, and as a result has established a theory of residual or secondary valence.

In accordance with the ordinary theory of valency which has proved so invaluable in organic chemistry, it has been customary to assign structural formulas of similar type to inorganic compounds. Thus the graphic formula for sulfuric acid is often written

Whereas among organic compounds the structural formulas can be determined with certainty and undoubtedly correspond to the actual arrangement of the atoms in the molecules, no such certainty is ever found in the case of complex inorganic compounds. As a result, such formulas have served no useful purpose in the development of inorganic chemistry. In fact, Werner claims that the common acceptance of such conceptions was responsible for the fact that our knowledge of the constitution of inorganic compounds failed to progress for so many years.

Werner<sup>2</sup> then shows clearly that such formulas are untenable. In the first place, the formula would lead to a sharp distinction between the combination of oxides and halides, whereas such a distinction does not actually exist. A proper theory should show a close relationship between such reactions as

and

The same kind of relations exist with complex cyanides, nitrites, etc., and these cannot be accounted for by the ordinary theory of valency.

Secondly, the ordinary theory would indicate that oxides such as  $\text{OsO}_4$ ,  $\text{RuO}_4$ , etc., should easily form acids by combination with water. Actually, it is found that the number of molecules of water which can be taken up by an oxide does not bear any definite relation to the number of doubly bound oxygen atoms.

Several other good reasons are given against the ordinary graphic formula for such compounds.

Werner then proceeds to show that the ordinary conception of (primary) valence applies (except in organic compounds) practically only to compounds of the first order; that is, to simple compounds containing not more than two elements, such as  $\text{H}_2\text{O}$ ,  $\text{NaCl}$ ,  $\text{SO}_3$ , etc.

Compounds of higher order are formed when compounds of the first

<sup>1</sup> *Neuere Anschauungen auf dem Gebiete der Anorganischen Chemie*, Braunschweig (1905).

<sup>2</sup> *Loc. cit.*, p. 42.

order combine together. Thus Werner draws no sharp distinction between the combination of  $P_2O_5$  and  $Na_2O$  to form  $Na_3PO_4$ , and such a process as the taking up of "water crystallization" by a salt such as  $BaCl_2$  to form  $BaCl_2 \cdot 2H_2O$ .

When two elements combine to form a compound of the first order, their primary valences become saturated. But there is still a field of force around the molecule which enables it to combine with other molecules to form compounds having almost any degree of stability. The molecules are then said to be held together by residual or secondary valence.

Werner gives the following definitions of primary and residual valency:

(a) "Primary valence serves to unite those simple or complex radicals which can exist as separate ions or whose chemical combining power is equivalent to an ionizable radical."

(b) "Residual valence represents the affinity that binds together radicals which can neither act like nor be equivalent to separate univalent ions."

As illustrations of primary valence, he gives  $-Cl$ ,  $-Na$ ,  $-NO_2$ ,  $-CH_3$ , and for residual valence :  $OH_2$ , :  $NH_3$ , :  $ClK$ , and :  $CrCl_3$ .

R. Abegg<sup>1</sup> advanced a somewhat similar theory of the constitution of inorganic compounds. He looks upon salts of oxygen acids, for example, as consisting of basic and acid oxides held together by secondary valence. He considers Berzelius' idea of the structure of such compounds ( $K_2O \cdot SO_3$ , for instance) to be much preferable to the structural or graphic formula

and gives many good reasons to support his contention.

Stark<sup>2</sup> has developed a theory of the mechanism of chemical valency based on the electron theory. This electroatomic theory gives symbolically a very satisfactory picture of the different types of valence. According to Stark, portions of the surfaces of atoms contain an excess of positive electricity. In the neutral atom one or more electrons are held close to the surface of the atom by this positive charge. Compounds are formed when the lines of force from one of these "valence electrons" reach out and end on the positive areas of other atoms. In the case of strongly polar compounds, an electron is almost wholly drawn over to the atom which it holds in combination. Primary valences are due to a pair of valence

<sup>1</sup> *Z. anorg. Chem.*, **39**, 330 (1904); **50**, 309 (1906), and *Z. physik. Chem.*, **69**, 1 (1909).

<sup>2</sup> *Jahr. d. Radioakt. und Elek.*, **5**, 125 (1908); *Prinzipien der Atomdynamik*, Vol. 3; "Die Elektrizität im chemischen Atom," Leipzig, 1915. A short description of Stark's theory of valence was given by Misses Hahn and Holmes in *THIS JOURNAL*, **37**, 2611 (1915). This article is essentially an abstract of Paul Ruggli's book, "Die Valenzhypothese von J. Stark vom Chemischen Standpunkt," Stuttgart, 1912.

electrons whose field binds two atoms together. The stray electric field in the space around the resultant molecule is the cause of the residual valence. This theory accounts particularly well for the gradations between primary and secondary valence.

Thus when two atoms combine chemically, they are held together by certain electrons which are common to both atoms. Bohr's model of the hydrogen molecule assumes a similar function of the electrons. According to Bohr's theory, a hydrogen atom consists of a positive nucleus around which (at a distance of  $0.55 \times 10^{-8}$  cm.) an electron revolves with very high speed. The hydrogen molecule, on the other hand, consists of two hydrogen nuclei (at a distance apart of  $0.60 \times 10^{-8}$  cm.) and two electrons which revolve in an orbit in a plane perpendicular to the line joining the nuclei. The radius of the orbit of the electrons is  $0.52 \times 10^{-8}$  cm. In the hydrogen atom the electron forms part of the atom. When two atoms combine the two nuclei share the two electrons equally. If the two atoms separate again, there is an even chance that they will have exchanged electrons. The two electrons held in common by the two nuclei hold the molecule together and are thus equivalent to the bond by which we ordinarily imagine two univalent atoms to be joined. This model of the univalent bond is remarkably similar to that proposed by Stark.

J. J. Thomson<sup>1</sup> has also developed a theory of the mechanism of chemical affinity. On the whole, his theory is very much like that of Stark. Thomson considers that the electrons near the surface of an atom, together with the positive charge in the core of the atom, constitute one or more electric doublets which exert forces not only on free electrons or ions in their neighborhood, but also on other electric doublets. The force of attraction between such doublets varies much more rapidly with the distance than the inverse square. Thomson uses the dielectric constant of the substance in the gaseous condition as a measure of the moment of the electric doublets. In this way he concludes that there has been an actual transfer of an electron from one atom to another in such compounds as  $\text{H}_2\text{O}$ ,  $\text{NH}_3$ ,  $\text{SO}_2$ ,  $\text{HCl}$ ,  $\text{CH}_3\text{OH}$ ,  $\text{C}_2\text{H}_5\text{OH}$  and  $\text{CH}_3\text{Cl}$ , even when these are in the gaseous condition. This "intra-molecular ionization" greatly increases the moment of the doublet by increasing the distance between the charges. In other types of compounds, however, Thomson believes that the atoms are electrically neutral and are held together by one or more doublets on each atom. As compounds of this type he cites  $\text{H}_2$ ,  $\text{O}_2$ ,  $\text{N}_2$ ,  $\text{Cl}_2$ ,  $\text{CO}$ ,  $\text{CO}_2$ ,  $\text{CS}_2$ ,  $\text{CCl}_4$ ,  $\text{C}_6\text{H}_6$ ,  $\text{CH}_4$ ,  $\text{N}_2\text{O}$ .

It should be noted that Stark's theory recognizes both these types and indicates how there may be all possible gradations between these extremes.

<sup>1</sup> *Phil. Mag.*, 27, 757 (1914).

Thomson also believes that the more complex compounds are "molecular compounds" in which simple molecules are held together by the stray field around the molecules. In the first paragraph of his paper he says: "These forces will be exerted by the atom not merely on the atoms which are associated with it in the molecule of a chemical compound, but also on the atoms in other molecules, giving rise to forces between the molecules and producing thereby the intrinsic pressure and surface tension of liquids, latent heat of evaporation, cohesion of solids and liquids, the rigidity of solids and so on. These physical phenomena are the effects of forces between different molecules, whereas chemical affinity and chemical phenomena in general are the effects of forces having the same origin, but acting between the atoms of the same molecule."

We shall see that this division of solids and liquids into molecules is very arbitrary and that the same kind of chemical relationships exist between these forces, which Thomson calls physical, as exist among the forces which cause the formation of molecular compounds.

In regard to saturated valence, Thomson considers that two electrons are involved in holding two univalent uncharged atoms together. In this respect his theory is like those of Stark and Bohr. He points out, however (as Stark has also done), that by this theory three univalent atoms may be held together in the form of a ring, one electron being located between each pair of adjacent atoms. He says: "The difference between the theory we are considering and the accepted theory of valency may be expressed by saying that not only is every possible valency compound on the old theory a valency compound on this theory, but every compound which would be a valency one on the old theory if the valency of every element was doubled, would be a valency compound on the new, with the atoms retaining their original valency. This only applies to the compounds when the atoms are uncharged; when the atoms are charged the valency conditions are the same as on the old theory."

This theory would seem to fit in badly with the facts of organic chemistry, for we find no evidence of organic compounds in which carbon acts as if it had a valency of eight or hydrogen a valency of two. But in the formation of crystals this theory suggests an explanation of the divided valence observed in crystals of the spinel group. For instance, it was found in magnetite that the *divalent* iron atoms were surrounded by *four* symmetrically placed oxygen atoms, while the *trivalent* iron atoms were surrounded by *six* oxygens.

An extremely important theory of the "Atom and Molecule" is that recently described by G. N. Lewis.<sup>1</sup> Substances are classified into two general groups: polar and nonpolar. The polar type, represented by  $\text{H}_2\text{O}$ ,  $\text{NH}_3$ ,  $\text{NaCl}$ , etc., is characterized by reactivity, high dielectric constant,

<sup>1</sup> THIS JOURNAL, 38, 762 (1916).

tendency to form molecular complexes, etc. Tautomerism is a "predominant trait of most inorganic substances (polar type), which behave as if a great variety of forms were existing together in extremely mobile equilibrium."

For this reason Lewis<sup>1</sup> believes that the constitution of the more complex inorganic compounds cannot be represented by any single structural formula.

We shall see that these ideas on tautomerism will prove of value in connection with a study of the constitution of liquids.

**Crystal Structure from the View Point of Chemical Theory.**—The work that has been done so far on crystal structure testifies to the general applicability of such theories of chemical constitution as that of Werner.

Except in the case of diamond crystals, no structural formula can be written consistent with our ordinary ideas of (primary) valence, which adequately represents the constitution of the crystal. We see, however, that the arrangement of the atoms in crystals is just what we should expect if the forces binding the atoms together are similar to those forces which, by Werner's theory must hold together the *molecules* in molecular compounds (compounds of higher orders).

Werner's theory, however, needs to be modified in some respects, to fit in with the new work. According to Werner, compounds of the first order are held together by primary valence, and only when these simple compounds form compounds of higher orders are the residual valences called into play. But when we consider the structure of the halide salts of the alkalis and the structure of such crystals as fluorite, we must conclude that even in the case of these first order compounds the ordinary rules of valence do not always apply.

It thus seems that secondary, or residual valence is active, not only in the higher order compounds, but that a valency of the secondary type may also characterize single atoms when these are combined with others in crystals.

It is evident that solid bodies could not be built up of atoms held together exclusively by primary valences except in the case of atoms having valences of four or more. Thus, when two monovalent atoms combine to form a gas molecule, they are held together by primary valence. If there were no residual valence, these molecules could not condense either as a solid or liquid. Divalent atoms could combine together in long chains, but these chains could not be linked together except by secondary valence. With trivalent atoms branching chains could be formed which could interlock so as to cover a plane surface, but except by secondary valence no atoms could be held outside of this plane. With tetravalent

<sup>1</sup> THIS JOURNAL, 35, 1448 (1913).

atoms, on the other hand, the atoms can be linked together by their primary valences, as in the diamond crystal, so as to fill a volume.

We thus see that primary valences cannot play an important part in crystal structure in the case of atoms with a valency of less than four. Most of the crystals containing tetravalent atoms which have been studied so far, have shown that the primary valences of the tetravalent atoms seem to exert their influence. This is shown not only in the case of the diamond, but in zircon, cassiterite and rutile, in which each atom of Zr, Si, Ti or Sn is clearly associated with two atoms of oxygen.

From these considerations it seems that in general there is a strong tendency for every atom to form compounds by means of its primary valence, but where the conditions are such that combination by primary valence is no longer possible, then secondary valence is called into play and may entirely supersede the primary valence.

Thus, when sodium atoms and chlorine atoms combine at high temperatures to form gaseous NaCl, the primary valence holds the atoms together. But when the pressure is raised or the temperature is lowered, the secondary valence is enabled to completely supersede the primary valence, since the primary valence cannot cause the combination of the molecules necessary to form a solid body.

With divalent and trivalent atoms a sort of divided valence like that suggested by J. J. Thomson, is apparently often manifest and is probably a sort of transition between primary and secondary valence. This is seen particularly in crystals of the spinel group, in which the divalent atoms have assumed a tetravalent character and the trivalent atoms a hexavalent character.

By this division of each of the valence units into two parts, the apparent valency is raised to four or more, so that the solid body can then be held together by this means. According to Stark and J. J. Thomson's theories, we should never expect the subdivision of a primary valence unit into more than two parts. Furthermore, we should not expect that a monovalent element would often exhibit this divided valence in solid bodies, because, even if its apparent valence was doubled by this means, it still would not be able to make use of this valence in forming a crystal.

The compounds whose crystal structures have been studied thus far, are all more or less of the polar type. It is not safe to conclude that the structures of nonpolar compounds will be similar to those already found.

For example, when an organic compound such as methane, is crystallized as a solid and is then converted again into a gas, it is certain, from chemical considerations, that none of the hydrogen atoms have been separated from the carbon atoms to which they were originally attached. The identity of the original molecules must, in a sense, have been preserved even when the methane was in the solid condition.

On the other hand, with crystals of the types studied so far, the substance could not be condensed from the gaseous condition and be re-evaporated again without most of the atoms having exchanged partners. Thus, when a crystal of sodium chloride evaporates, a sodium atom on the surface may escape with any one of the four adjacent chlorine atoms as a molecule of salt vapor. There is only a small chance that the particular chlorine atom with which it escapes will be the same one as that with which the sodium atom was combined before it formed part of the crystal.

From these considerations we are forced to conclude that in crystals of methane each carbon atom is surrounded by four hydrogen atoms held to it by primary valences. The crystal is then held together by residual valences. Since the methane is so thoroughly saturated chemically, these residual forces are very weak and, therefore, methane melts and boils at a very low temperature. But there is absolutely no reason for assuming that these residual forces are any less chemical in nature than those which cause the combination of  $K_2O$  and  $SO_3$  to form  $K_2SO_4$ . We certainly cannot limit chemistry to a study of only those substances whose atoms are held together by primary valence.

Determination of the crystal structure of organic compounds should prove of very great value in clearing up the true distinctions between primary and secondary valence. Unfortunately, the very low absorption of X-rays by the hydrogen makes it difficult to determine the positions of the atoms of this element by the present methods. This difficulty can be avoided by choosing such substances as  $C_2Cl_6$  and  $C_6Cl_6$ .

Similar considerations to those used with methane apply to such substances as  $H_2$ ,  $N_2$ ,  $O_2$ , etc., and nearly all typical organic substances. That the crystal structure, even with these substances, depends on the space arrangement of the atoms, is clear from the work of W. Wahl<sup>1</sup> on the crystal forms of the lower members of the aliphatic hydrocarbon series. He finds methane crystallizes in the isometric system, ethane in the hexagonal, propane apparently rhombic, trimethyl methane probably rhombic. Tetramethyl methane occurs in two modifications, one isometric and one tetragonal. Normal butane also has two forms, hexagonal and rhombic. Normal pentane is rhombic, while normal hexane, heptane and octane are monoclinic or triclinic.

The lower members of this series show a remarkable agreement between the chemical constitution and the crystal form. Thus the symmetry of the methane molecule requires a crystal of the isometric form, probably with an arrangement rather similar to that of the diamond. If we look upon the carbon atom as having its bonds arranged symmetrically after the pattern of the tetrahedron, then the ethane molecule would con-

<sup>1</sup> *Proc. Roy. Soc., (A)* **88**, 354 (1913).

sist of two carbon atoms each with three hydrogen atoms (in planes  $120^\circ$  apart) arranged around them. This leads naturally to the hexagonal form.

The definiteness of this dependence of the crystalline form upon the arrangement of the atoms indicates that even with these nonpolar compounds the forces holding the *molecules* together in the crystals are of the same nature as those holding the *atoms* together in the polar types of crystals.

Since the forces acting between the molecules in these crystals are then quite similar to those acting in the more complex inorganic compounds we would still be justified in regarding a crystal of methane as one large molecule. We thus have molecules within the molecule.

This leads us to consider whether it is not desirable to revise our conception of the molecule. There is an advantage in looking upon every crystal (and in fact every mass of liquid) as a single large molecule, in that this viewpoint brings out strongly the *chemical* nature of the forces holding the crystal together, and thus encourages us to apply to the study of these forces the knowledge already available from other fields of chemistry.

On the other hand there is a real need for a term to denote a group of atoms which can pass from the gas phase to the solid (or liquid) and back again without the exchange of any atoms. If, however, we should limit the word molecule (in liquids and solids) to this narrow definition, we would have to say that there are no molecules at all in the great majority of inorganic substances.

On the whole, it seems best to define a molecule as *a group of atoms held together by atomic forces*. We must then distinguish between various kinds of molecules.

The *gas molecule* may be defined in terms of Avogadro's Law, and is thus only sharply definable in so far as the gas follows the laws of ideal gases. We may define a *fixed molecule* as the largest aggregate of atoms which may pass from the gaseous phase to the solid (or liquid phase) and back again to the gaseous phase without exchange of atoms with other aggregates. With substances which are wholly nonpolar, such as the saturated hydrocarbons, this definition of fixed molecule is probably never ambiguous. But with molecules which are partly polar, as for example acetic acid, this definition may lack sharpness. Thus when  $\text{CH}_3\text{COOH}$  vapor dissolves in water (or condenses as a solid), it is probable that the replaceable hydrogen atom will be exchanged with that of the other  $\text{CH}_3\text{COO}$  groups. According to our definition of fixed molecule we must, therefore, consider that the *fixed molecules* in liquid or solid acetic acid consist of  $\text{CH}_3\text{COOH}$  groups. Cases will frequently arise, as for example in the alcohols, where the rate of exchange of the hydrogen atoms is so

slow as to be almost negligible, so that it will be impossible to limit sharply the extent of the fixed molecule. This difficulty, however, seems an inherent one, for it depends upon the fact that all possible degrees of tautomerism may actually exist in the large molecule forming the whole mass of the solid or liquid.

It will also be convenient to distinguish another type of molecule which we may call the *group molecule*. This may be defined as an aggregate of atoms which are interrelated in such a way (by position or mobility) that the atoms in the group may be distinguished from atoms outside the group. Thus in solid methane each hydrogen atom is associated with a particular carbon atom, while the carbon atom is associated with four hydrogen atoms. All other hydrogen atoms beside these four may be distinguished from these by their being combined with a different carbon atom.

If we represent a methane crystal diagrammatically as follows:

it is evident that we might also look upon the crystal as consisting of group molecules of hydrogen ( $\text{H}_2$ ) held together by carbon atoms. Chemical considerations, however, would lead us to choose  $\text{CH}_4$  as the group molecule.

In liquid methane we could distinguish the group molecule either by the fact that four atoms of hydrogen must be geometrically associated with a single carbon atom, or by the fact that four hydrogen atoms always move with a particular carbon atom, whereas all other neighboring hydrogen atoms in the course of time gradually (by diffusion) become separated more and more from the given carbon atom.

A crystal of zircon would thus be a compound consisting of group molecules of  $\text{ZrO}_2$  and group molecules of  $\text{SiO}_2$ .

In inorganic compounds in the solid or liquid state there are usually no fixed or group molecules. It is probable, however, that an ion of the type  $\text{CO}_3^-$  in solution constitutes a group molecule, since the structure of the calcite crystal suggests the carbon atom may be more or less permanently associated with three particular oxygen atoms. An ion of the type  $\text{OH}^-$ , however, can probably not be properly looked upon as a group molecule since the high mobility of the  $\text{OH}^-$  ion and other factors indicate that this ion is continually exchanging its atoms with the surrounding mass of water.

Besides these types of molecules, there are the large molecules which constitute colloid particles. These may be called *colloid molecules*. They probably usually consist of large aggregates of atoms or group molecules

combined together by means of secondary valence. In the second part of this paper the probable structure of these colloid molecules will be discussed in more detail.

Finally, every continuous solid or liquid mass whether homogeneous or not may be looked upon as consisting of one large molecule. We may speak of molecules of this type as *solid* or *liquid molecules*.

**Forces between Atoms in Crystals.**—From our knowledge of the structure of crystals and from such properties as specific heat, compressibility, thermal coefficient of expansion, elasticity in different directions, melting point, vapor pressure, and latent heat of evaporation, it should be possible to determine the laws governing the forces around the atoms. Such a study would give us the clearest kind of insight into the nature of chemical affinity.

In view of the marked influence of temperature on the properties of liquids and solids, it is evident that the motions of the atoms in solids are of great importance. A study of specific heats gives us considerable information regarding the kinetic energy of the atoms. According to the Principle of the Equipartition of Energy<sup>1</sup> the average kinetic energy of any particle is  $\frac{1}{2} kT$  for each degree of freedom, where  $k$  is the Boltzmann gas constant and is equal to  $1.372 \times 10^{-16}$  ergs per degree. In other words, each particle should contribute the amount  $\frac{1}{2} k$  to the specific heat for each degree of freedom which it possesses. Thus for a gram molecule of particles ( $6.06 \times 10^{23}$ ) we find a specific heat of  $\frac{1}{2} R$  for each degree of freedom. Here  $R$  is the gas constant ( $6.06 \times 10^{23} \times 1.372 \times 10^{-16} = 83.1 \times 10^6$  ergs/deg.). Expressed in calories this gives 0.993 calorie per degree per gram atom for each degree of freedom. We thus have the simple rule that the atomic or molecular heat should be numerically equal to 0.993 times the number of degrees of freedom ( $n$ ) of the atoms or molecules.

Each atom of a monatomic gas has three (translational) degrees of freedom and we should thus expect the atomic heat to be  $C_v = 3 \times 0.9935 = 2.98$ . Actually for all the monatomic gases we find exactly this value with the single exception of helium, which gives a slightly lower value.

The specific heats of most diatomic gases is approximately  $C_v = 5$ , from which we may conclude that there are five degrees of freedom (three translational and two rotational). The possible motion of the two atoms along the line joining them, evidently does not represent a degree of freedom. However, the diatomic gases like chlorine, bromine and iodine which are easily dissociated into atoms, have specific heats considerably greater than 5. There is thus evidence that with very strong chemical forces between atoms the number of degrees of freedom is less than with weaker forces.

<sup>1</sup> For a short description of this principle and its present significance, see Dushman, *General Electric Review*, Sept., 1914.

The atoms of copper, silver, gold and lead are arranged according to a simple face-centered lattice with single atoms at each point of the lattice. It is evident that there are no group molecules. Each atom must possess (at high temperatures) three degrees of freedom corresponding to the directions in which it may move.

We know, however, in accordance with Dulong and Petit's law that the atomic heat of these metals is approximately 6.0,<sup>1</sup> and this is usually explained by assuming that the atoms vibrate in such a way that their energy is equally divided between kinetic and potential energy. When a body such as a pendulum describes *harmonic* vibrations, the time average of its kinetic energy is equal to the time average of its potential energy, if we assume that its potential energy is zero when it passes through its equilibrium position. The equipartition principle is concerned directly only with kinetic energy, but if the average potential energy is equal to the average kinetic energy it is evident that it will contribute as much as the latter to the specific heat. Thus if the atoms of the solid body describe harmonic oscillations about their equilibrium positions, the atomic heat should be double that corresponding to the three degrees of freedom, in other words it should be  $6 \times 0.9935 = 5.96$ .

It is often said that in this case there are three kinetic and three potential degrees of freedom. This statement is open to serious objection, for it implies that the Equipartition Principle is applicable to potential energy. As a matter of fact, if the forces around the atoms are such as to lead to oscillations that are not harmonic in character there will in general be no equality between the time averages of the kinetic and potential energies. For example, let us consider a ball rolling on a surface, such as that represented in Fig. 1. If the ball is displaced from its lowest position and released, it will oscillate about this position. If the displacements are small the motion will be approximately

Fig. 1

harmonic in character. But with oscillations so large that the ball frequently mounts up on to the comparatively level parts of the surface, it is evident that the oscillations will be far from harmonic. In this case, the motion of the ball on the flatter parts of the surface will be

<sup>1</sup> According to Dulong and Petit's Law, the atomic heats of the elements at *constant pressure* are about 6.3. The specific heat of  $6 \times 0.993$  calculated by the Equipartition Principle is the atomic heat at constant volume. Lewis, Nernst, Lindemann and others have shown that the atomic heats of metals at *constant volume* gradually approach the above value asymptotically at higher temperatures, but at lower temperatures the atomic heat is considerably less. Elements with atomic weight less than about 20 form an exception to this rule in that their atomic heats are less than  $6 \times 0.993$  even at room temperature.

so slow that the length of time it remains in these positions will be much larger than it would be if the slope of the surface increased steadily from the center outwards. Thus with such a surface the time average of the potential energy may be much greater than the time average of the kinetic energy.

The same considerations apply to the oscillations of atoms. If the restoring force acting on an atom is proportional to the displacement from the equilibrium position (condition for harmonic motion) then the average kinetic and potential energies will be equal and the atomic heat will be  $6 \times 0.993$ . But if the restoring force increases more slowly than proportional to the distance (as in the case cited above), then the potential energy will be greater than kinetic energy so that by the Equipartition Principle the atomic heat will be greater than  $6 \times 0.993$ . On the other hand, if the restoring force increases more rapidly than the displacement, then the atomic heat will be less than  $6 \times 0.993$ .

The remarkable closeness with which the atomic heats at constant volume approach the value  $6 \times 0.993$  at the higher temperatures, may be taken as proof that the forces to which the atoms in solids are subjected vary approximately in proportion to the displacement of the atoms from equilibrium positions. There must then be both attractive and repulsive forces acting between the atoms. On the average, these opposing forces must just balance each other. As one atom approaches another the repulsive force must *gradually* increase and the attractive force decrease until the repulsive force greatly predominates. We cannot consider that the repulsive forces in solids are exerted only during collisions between atoms, for under these conditions there would be no potential energy and the atomic heat would be  $3 \times 0.993$ .

No adequate explanation has been offered of the repulsive forces between atoms. If matter is built up of positive and negative electricity the ordinary electromagnetic theory would indicate that the two opposite charges would neutralize each other. Actually, however, this neutralization only occurs to the extent of destroying the electric field at a comparatively large distance from the electrons. The positive and negative electrons are never able to destroy one another. Some cause, at present unknown, must operate to keep the positive and negative charges from approaching with less than a certain distance. It is evident that the laws governing the forces and motions of electric charges separated by distances comparable with the dimensions of atoms are in some respects radically different from the laws with which we are familiar. G. N. Lewis<sup>1</sup> believes that such considerations lead "irresistably to the conclusion that Coulomb's law of inverse squares must fail at small distances," and that it may be necessary to modify the law "even to the

<sup>1</sup> THIS JOURNAL, 38, 773 (1916).

extent of changing the sign of the force." This difficulty is undoubtedly connected in some way with those which have forced us to the quantum theory. Some more or less successful attempts have been made to apply this quantum theory to the structure of atoms and molecules. Bohr's theory of the hydrogen atom has been remarkably successful in that it enables one to calculate all the lines in the Balmer series of the hydrogen spectrum, but his theory of the hydrogen molecule is apparently not complete, for it leads to a value of 63000 calories for the heat of formation of  $H_2$  from atoms, while direct measurement<sup>1</sup> gives 84000 calories.

A very suggestive theory has been worked out by A. L. Parson<sup>2</sup> in which he assumes that the electron itself is not merely an electric charge but is also a magnet. Crehore<sup>3</sup> has developed a theory in which the magnetic field produced by the rotation of electrons in extremely small orbits ( $10^{-12}$  cm.) is assumed to play an essential part in the structure of molecules. By means of the magnetic fields, it is possible to account for both attractive and repulsive forces. Both of these theories assume that the positive electricity of the atom is distributed uniformly throughout a sphere of definite size, inside of which the electrons are located (Thomson's theory). Rutherford's work on the scattering of alpha particles, Moseley's work on X-ray spectra, and considerations based on the disintegration of the radioactive elements, all seem to compel us, however, to adopt Rutherford's theory of the atom in which the positive electricity is concentrated in the center of the atom and the electrons revolve in one or more orbits of diameters of the order of magnitude of  $10^{-8}$  cm. The strength of this evidence in favor of Rutherford's theory is such that it seems to the writer impossible to accept either Parson's or Crehore's theory in their present forms.

These questions will probably be satisfactorily answered only when we understand the mechanism underlying the quantum theory and know the true relationship between positive and negative electricity. We must have an explanation of the remarkable fact that the charge on an electron is *exactly* equivalent (although opposite in sign) to the unit of positive electricity (for example the nucleus of the hydrogen atom).

At present, therefore, in an analysis of the forces between atoms, we must recognize both attractive and repulsive forces, although we cannot satisfactorily explain the mechanism of the repulsive forces. Thus by admitting the existence of forces which prevent electrons from approaching too closely to positive charges we may accept Stark's and J. J. Thomson's theories of the general character of the forces between atoms.

<sup>1</sup> Langmuir, *THIS JOURNAL*, 37, 417 (1915).

<sup>2</sup> "A Magnetron Theory of the Structure of the Atom," *Smithsonian Publication* 2371, Washington, 1915.

<sup>3</sup> *Phil. Mag.*, 20, 310 (1915).

There are many other properties of solids which indicate that repulsive as well as attractive forces exist between atoms, and that the repulsive forces act over distances comparable with the dimensions of atoms and not merely during collisions between atoms.

The compressibility and coefficient of thermal expansion are two such properties. In the case of ideal gases, these quantities vary with the pressure and temperature in a way that indicates that the volume would be zero if the atoms or molecules were brought into contact.

From the smallness of the coefficient of expansion of solids we must conclude that even at the absolute zero of temperature, the volume of crystals would not be so very much less than at room temperature. Furthermore, there are no indications that the compressibility would become zero even at the absolute zero. These facts are further evidence that the atoms of solids tend to be held in definite equilibrium positions by forces which vary approximately proportionally to the displacements of the atoms from these positions.

Nernst, Einstein and Lindemann have shown that the natural frequency of vibration of the atoms of elements may be calculated by three independent methods based, respectively, on measurements of the specific heat at low temperatures, the compressibility and the melting point. The fairly good agreement between these methods lends further support to the belief that the atoms vibrate about equilibrium positions.

The intensity of the higher orders in the X-ray spectrum of crystals, increases as the temperature of the crystal is lowered. This effect, known as the Debye effect, constitutes striking proof of the heat vibrations of the atoms and should lead to quantitative measurements of these vibrations.

The magnitude of the heat conductivity of solids, especially metals, throws some interesting light on the character of atomic vibrations. Let us imagine all the atoms in the surface layer of a solid to have their temperature suddenly raised by a given amount. This layer will then rapidly cool and will approach the temperature of the underlying layers. The rapidity with which this temperature equalization takes place will measure the rate at which a motion of one atom affects the adjacent ones. A simple approximate calculation<sup>1</sup> gives for the time necessary for the temperature increment of the surface layer to fall to 37% of its initial value.

$$t_r = \frac{3k}{h\sigma} \quad (1)$$

Here  $k$  is the Boltzmann gas constant  $1.372 \times 10^{-16}$ ,  $h$  is the heat conductivity of the solid and  $\sigma$  is the distance between adjacent atoms. The quantity  $t_r$  is exactly analogous to Maxwell's "time of relaxation" in a gas which is the time needed for any abnormal distribution of kinetic energy among gas molecules to subside to  $1/e^{th}$  of its original value.

<sup>1</sup> See Langmuir, *Phys. Rev.*, 8, 149 (1916).

For copper we thus find  $t_r = 4.6 \times 10^{-16}$  seconds. This has been calculated on the assumption that each atom can receive heat from one direction only. When we consider that a single atom in the interior may receive energy from six different directions, it seems probable that the real time of relaxation of a single copper atom is about  $10^{-16}$  seconds. Now the atomic frequency calculated from the compressibility by Einstein's method is  $5.6 \times 10^{12}$ , or the time necessary for an atom to complete a single oscillation, the reciprocal of this or  $1.8 \times 10^{-13}$  seconds. Thus the time required for an atom nearly to reach equilibrium with its neighbors is only 1/1800th of the time of a single oscillation.<sup>1</sup>

Even for nonmetallic substances, such as sodium chloride, the time of relaxation is always very small compared to the natural period of the atoms. This indicates that motions of a single atom must always be very highly damped. In other words, the atoms behave towards each other as though they were almost completely inelastic. However, if all the atoms are stimulated simultaneously by a periodic disturbance having a frequency corresponding to the natural frequency of the atoms, then the oscillations will be practically undamped, for there are then no adjacent atoms to which the oscillating ones can give up their energy.

We shall see that this apparent inelasticity of the atoms of solids is of great importance in the theory of evaporation, adsorption and surface tension.

The principle of the Equipartition of Energy has been found to apply at higher temperatures to the specific heats of monatomic gases, most diatomic gases and most elementary solids. But at low temperatures the specific heats always fall below that calculated by this principle. According to Einstein's theory this is due to the inability of oscillators to take up energy in quantities less than  $h\nu$ , where  $h$  is Planck's quantum  $6.58 \times 10^{-27}$  erg deg. Whether this is the correct explanation or not, it is a fact that degrees of freedom tend to disappear at lower temperatures. Eucken has shown that at temperatures as low as  $58^\circ$  absolute, hydrogen molecules have only three degrees of freedom, whereas they have five at ordinary temperatures. Similarly the specific heat of helium at the lowest temperatures falls even below 2.98. Evidently, therefore, it is possible that a single atom may have less than three degrees of freedom, although it is hard for us to conceive of such a possibility.

<sup>1</sup> A. H. Compton, *Phys. Rev.*, 7, 341 (1916) in a "Physical Study of the Thermal Conductivity of Solids" reached the conclusion "that the average distance through which the energy of an atomic collision in a crystal is transmitted is approximately inversely proportional to the temperature and is many times the distance between atoms." In many ways this is equivalent to our conclusion that the time of relaxation is small compared to the natural period of oscillation. From what has been said above, Compton's statement is open to serious objection, since we cannot look upon the repulsive forces in solids as being due to collisions.

The smaller the atomic weight of an element and the greater the strength of the union between the atoms, the higher is the temperature at which the atomic heat begins to be normal (5.96). Thus there seems to be a relation between the natural frequency of the atoms and the deviations from the equipartition principle.

However, Trautz<sup>1</sup> attempts to explain the decrease in the specific heat of hydrogen at low temperatures by assuming that for each temperature a certain fraction of the hydrogen molecules are transferred into another modification of hydrogen which has the properties of a monoatomic gas. A. H. Compton<sup>2</sup> makes a somewhat similar assumption regarding solids, namely, that at low temperatures the atoms are agglomerated into larger aggregates in which the individual atoms lose one or more of their degree of freedom.

The specific heat of solids at ordinary temperatures is a distinctly additive property (Kopp's rule), a fact which is in itself an indication that solids are not built up of molecules. With compounds of the heavier elements, each atom contributes an equal amount (about 6.3 calories per gram atom at constant pressure) to the specific heat. In the case of the lighter elements, such as those forming organic compounds, the additive relations still hold fairly well, but the atomic heats of these elements must be taken to be less than 6.4. According to Kopp's rule,<sup>3</sup> the following atomic heats should be taken: C = 1.8, H = 2.3, B = 2.7, Be = 3.7, Si = 3.8, O = 4.0, P = 5.4, S = 5.4 and all elements of higher atomic weights about 6.4.

Accurate determinations of the specific heats of organic compounds in the solid, liquid and gaseous condition and at various temperatures will undoubtedly be of great service in establishing the character of the vibrations of the atoms and the nature of the forces controlling them. The available data at present are very meagre and unreliable.

**Chemical Compounds Existing Only in the Solid State.**—From what has been said regarding the relation between primary and secondary valences in solid bodies, it would follow that in general the composition of a solid body should give us little or no information about the primary valences. Conversely, we should expect more compounds to exist in the solid state than we would be led to predict from the ordinary rules of valence.

When we consider that every atom (and every molecule for that matter) is surrounded by a field of electro-magnetic force, it appears probable that solids can be built up with almost any arrangement of atoms, provided the temperature is sufficiently low. If these arrangements of

<sup>1</sup> *Verh. deut. physik. Ges.*, 15, 969 (1913).

<sup>2</sup> *Phys. Rev.*, 6, 377 (1915).

<sup>3</sup> Nernst, *Theoretische Chemie*, 1903, p. 180.

atoms are regular so as to constitute a space lattice, the resulting solid will have a definite and invariable chemical composition which can be represented by a chemical formula, and would, therefore, be recognized as a chemical compound. The arrangement of the atoms in such compounds would bear no more relationship to the primary valence of the atoms than does the arrangement of the carbon, oxygen and calcium atoms in a crystal of calcite. The formula representing a compound of this type would thus be totally unrelated to the valence of the atoms.

The reason that the composition of solid compounds is so often consistent with the ordinary valence rules, is probably that the compounds are formed from solutions or from gaseous phases. In liquids or gases there is naturally more opportunity for the primary valences to manifest themselves.

As a matter of fact there are vast numbers of chemical compounds which exist in the solid state only and among these compounds the absence of valence relations is very striking.

Tammann and his students have proven the existence of a hundred or more definite metallic compounds by their studies of alloys. Out of 100 such compounds only 26 have formulas which agree with the ordinary valence.<sup>1</sup> A few typical compounds are  $\text{AgMg}_3$ ,  $\text{AgMg}$ ,  $\text{AuZn}$ ,  $\text{Au}_3\text{Zn}_5$ ,  $\text{Cu}_3\text{Al}$ ,  $\text{CuAl}$ ,  $\text{CuAl}_2$ ,  $\text{Mg}_4\text{Al}_3$ ,  $\text{AlSb}$ ,  $\text{Zn}_7\text{Fe}$ ,  $\text{Zn}_3\text{Fe}$ ,  $\text{Al}_3\text{Fe}_2$ ,  $\text{NaZn}_{12}$ ,  $\text{NaCd}_5$ ,  $\text{NaHg}_4$ ,  $\text{NiCd}_5$ ,  $\text{AuSb}_2$ , etc. Tammann shows that definite compounds are never formed between metals which are closely related in the periodic system, such as Cu-Ag or Fe-Ni, although solid solutions or mixed crystals frequently form in these cases.

If we consider these metallic compounds from the viewpoint we have developed above, it is evident that the atoms are held together by secondary valence, as are for instance those in a copper crystal or a rock-salt crystal. The reason that they have a definite chemical composition is that the atoms are arranged in some form of regular lattice. For example, if, in a face centered cubic lattice such as that of a copper crystal, we should replace the corner atoms by atoms of an element A, and replace the atoms in the faces of the cubes by atoms B, then we should have a compound of the composition  $\text{AB}_3$ . Each atom A would be surrounded by twelve atoms B all equidistant. Each atom B, however, would have 4 atoms of A and 8 of B equidistant from it. Such a structure would reveal nothing as to the valency of the atoms. It is quite probable that the compound  $\text{AgMg}_3$  has a structure of this kind.

If the atoms of the copper crystal we have considered should be replaced by atoms of two elements A and B in an irregular manner, then the resulting crystal would not have a definite chemical composition and would, therefore, not be recognized as a chemical compound, but would be con-

<sup>1</sup> Tammann, *Z. anorg. Chem.*, **49**, 113 (1906) and **55**, 289 (1907).

sidered a solid solution or mixed crystal. Yet there is no reason to assume that the forces holding the crystal together in one case are any different from those in the other.

If the two elements have combined together to form a chemical compound in one case, why not assume that the elements are equally combined in the mixed crystal? In the crystal of a pure metal we should also consider the atoms chemically combined with one another.

In mixed crystals or solid solutions, the atoms are evidently arranged in a haphazard manner according to the laws of probability, many different arrangements of atoms occurring side by side in the crystal. If the atoms of the two elements differ sufficiently in size or in their fields of force, then certain of these arrangements will be more stable than others. Thus, although at low temperatures almost any conceivable arrangement of atoms might be stable, it may be impossible to form mixed crystals by cooling a molten mass, because the atoms during the process of solidification have ample opportunity to arrange themselves in the most stable arrangements.

Thus the limitation in the number of compounds actually found is probably due to the restrictions imposed by our present methods of preparing these alloys by solidification from a melt, and is not an indication that such chemical compounds (or solid solutions) are not capable of existence in the solid condition.

Mineralogy also affords us an abundance of compounds which exist in the solid condition only and whose composition is not in accordance with the ordinary valence rules. The complex silicates are apparently built up of compounds of the first order ( $\text{SiO}_2$ ,  $\text{K}_2\text{O}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{H}_2\text{O}$ , etc.) in much the same way that the metallic compounds are built up of the atoms of the metals. If we consider such typical compounds as  $(\text{K}_2\text{O})(\text{Al}_2\text{O}_3)(\text{SiO}_2)_6$ ;  $(\text{MgO})_3(\text{SiO}_2)_4(\text{H}_2\text{O})$ ;  $(\text{MgO})(\text{SiO}_2)(2\text{H}_2\text{O})_2$ , etc., it appears that the number of each of the groups ( $\text{K}_2\text{O}$ ), ( $\text{Al}_2\text{O}_3$ ), etc., which enter into the formula bears no relation to the valence of the elements. It is probable that in many cases each of the groups  $\text{K}_2\text{O}$ ,  $\text{Al}_2\text{O}_3$  really constitute group molecules and that these are held together in the crystal by secondary valence, just as the atoms of the metallic compounds are.

Solid solutions or mixed crystals are of even more frequent occurrence among minerals than among alloys, and similar considerations must apply in regard to their constitution.

In the field of inorganic chemistry, especially in that of complex salts so well covered by Werner and his students, the relative number of compounds that can exist in the gaseous condition is extremely small.

Practically all complex compounds decompose or dissociate when heated. Even sulfuric acid gives a vapor whose density indicates that it is completely dissociated into  $\text{H}_2\text{O}$  and  $\text{SO}_3$ . In fact the great majority of com-

plex compounds do not even show a molecular weight in solution which corresponds to their composition in the solid state. For example, when alum  $(K_2O)(Al_2O_3)(SO_3)_4(H_2O)_{24}$  is dissolved in water it shows a "molecular weight" very much less than that corresponding to its formula. Crystals containing water of crystallization cannot be made to evaporate and still retain the combined water.

The number of complex compounds that can be formed must be unlimited. If methods can be found for forming them at sufficiently low temperature, probably almost any conceivable arrangements of group molecules could be built up having definite chemical compositions. Or solid solutions consisting of almost any combination of atoms and molecules could theoretically be formed. We are only sharply restricted in the formation of compounds in the case of compounds of the first order. But there is no sharp limit to the compounds that may be formed by secondary valences.

So far we have considered only crystalline solid bodies. It is evident that atoms or group molecules could be arranged irregularly in space (not according to a regular space lattice). A solid body built up in this way would have the properties of an amorphous body or glass. There can be little reasonable doubt, but that the structure of glass is of this nature. Such a structure is naturally much more easily built up of group molecules than of atoms for the greater symmetry of the atom enables it to assume definite and regular positions with respect to its neighbors more readily than group molecules could do.

The nature of the forces acting between the atoms or group molecules in amorphous bodies cannot be essentially different from that in crystals. We should expect the union between adjacent atoms or molecules to be dependent upon exactly the same kind of chemical properties as those which determine the combination of the atoms or molecules to form complex compounds (secondary valence).

From the fact that glasses, when heated, change to the liquid state by a continuous process, we are led to conclude that the structure of a liquid does not differ from that of a glass in any essential respect except that in the liquid there is a certain mobility (entirely analogous to tautomerism). Therefore, even in a liquid we look upon every atom (or group molecule) as combined chemically (or adsorbed) to all the adjacent ones. The molecular weight is, therefore, a term that has very little significance in the case of a liquid. This theory of the structure of liquids will be developed in more detail in the second part of this paper.

#### STRUCTURE OF THE SURFACES OF SOLIDS.

Unfortunately the study of crystals by the X-ray spectrum has not yet given us any direct knowledge of the structure of the surfaces of solids. From the point of view of the chemist, the structure of the surface must be

of the utmost importance, for chemical reactions in which solids take part are practically always surface reactions.

Our knowledge of the surfaces of solids must, therefore, be derived from indirect sources.

Since the forces that hold the atoms of solids together are of the same kind as those that hold the atoms of complex chemical compounds, we have excellent reasons for believing that the forces decrease extremely rapidly as the distance between atoms increases. We may also draw this conclusion from the compressibility of solids.

The energy which must be expended in separating the atoms of a solid metal from each other is given by the latent heat of evaporation  $\lambda$  (per gram atom). We can also calculate the energy necessary to change the distance between atoms from the compressibility. By comparing this energy with the latent heat, we may estimate the distance through which atomic forces are effective.

Let  $K$  represent the coefficient of compressibility of an element having an atomic volume  $A/\rho$ . We have good reasons for believing that the atoms of a solid are subject to forces that vary in proportion to the displacement of the atoms from their equilibrium positions.<sup>1</sup>

If we compress a unit volume of a solid so as to decrease its volume by the amount  $\Delta V$  the work expended will be  $(\Delta V)^2/2K$ . If the body is subjected to tension in all directions (negative pressure) so as to *increase* its volume by the amount  $\Delta V$ , the work expended will also be  $(\Delta V)^2/2K$ . This relation will hold accurately only for such small negative pressures that  $K$  remains constant. It is evident that as the atoms are being separated from each other, the attractive forces will at first increase in proportion to the displacement, then gradually more slowly, until finally the attractive force reaches a maximum. Beyond this distance the force rapidly decreases (probably according to about the inverse 4th or 5th power) to negligible values. It will be very instructive, however, to calculate on the assumption that  $K$  is constant, how far we need to pull the atoms apart before the work expended will equal the known latent heat of evaporation.

We readily obtain

$$(\Delta V_0)^2 = \frac{2\lambda K}{A/\rho}.$$

<sup>1</sup> The specific heats and other properties of the heavier elements compel us to this view when the displacements are small. Richards has shown that the compressibility of the elements decreases gradually as the pressure is raised to very high values. This proves that the repulsive forces between atoms increase more rapidly than the displacement. It is well known that liquids can be subjected to negative pressures and have substantially the same coefficient of compressibility for negative as for positive pressures. Undoubtedly the coefficient  $K$  should increase considerably for very intense negative pressures. Nevertheless the assumption of a constant value of  $K$  could hardly affect to order of magnitude of the calculated range of atomic forces.

In this equation  $\Delta V_0$  represents the increase in volume which could cause an expenditure of energy equal to  $\lambda$  per gram atom. The volume is thus increased from 1 to  $1 + \Delta V_0$ . The relative increase in the distance between the atoms is given by  $\sqrt[3]{1 + \Delta V_0}$ . In Table I the data for several elements are given. According to Richards, tungsten is the least compressible and caesium the most compressible metal.

TABLE I.

Metal.	C. G. S. units.	$\lambda$ ergs.	$\lambda/p$	$\sqrt[3]{1 + \Delta V_0}$	$\bar{r}$ cm.	$\Delta \bar{r}$ cm.
W	$0.28 \times 10^{-12}$	$9.2 \times 10^{12}$	9.6	1.20	$2.8 \times 10^{-8}$	$0.57 \times 10^{-8}$
Pt	$0.38 \times 10^{-12}$	$5.4 \times 10^{12}$	9.1	1.19	$2.78 \times 10^{-8}$	$0.53 \times 10^{-8}$
Mo	$0.46 \times 10^{-12}$	$7.4 \times 10^{12}$	11.1	1.21	$2.96 \times 10^{-8}$	$0.62 \times 10^{-8}$
Hg	$3.95 \times 10^{-12}$	$0.58 \times 10^{12}$	14.8	1.16	$3.26 \times 10^{-8}$	$0.52 \times 10^{-8}$
Cs	$61.0 \times 10^{-12}$	$1.0 \times 10^{12}$	71.0	1.12	$5.50 \times 10^{-8}$	$0.66 \times 10^{-8}$

Thus, if the attractive forces between the atoms varied in proportion to the displacement, the expenditure of energy necessary to increase the distance between the atoms by 12% in case of caesium (or 21% in case of molybdenum) would be as great as that actually required to separate them to an infinite distance.

Actually, the attractive force can vary proportionally to the displacement only for displacements much less than 10% of the distance between atoms. However, the distance calculated by the above rough method is probably very close to that at which the *maximum attractive force* occurs. The work done in separating the atoms beyond this distance probably compensates for the decrease in attractive force before the maximum is reached.

From these considerations it seems safe to say that: *The attractive force between atoms reaches a maximum when the atoms are separated by distances 10-30% greater than the distance at which they are in stable equilibrium.*<sup>1</sup> Since the force varies with a high power of the distance, we may also conclude: *The attractive force becomes practically negligible when the distance between the centers of the atoms becomes twice as great as the distance at which the atoms are in equilibrium.*<sup>2</sup>

It is interesting to note in Table I that the values of  $\sqrt[3]{1 + \Delta V_0}$  are largest for the elements of smallest atomic volume. This suggests that the increase in actual distance at which the attractive force becomes a maximum may be approximately the same for all the elements. In the sixth column are given the distances between the centers of the atoms calculated from the atomic volume on the assumption that the atoms are arranged

<sup>1</sup> Grüneisen (*Ann. Physik*, 39, 298 (1912)) by a mathematical development of a theory of monoatomic solids concludes that the average *amplitude of vibration* of the atoms in a solid at its melting point is 8.5% of the distance between the atoms.

<sup>2</sup> Probably the best evidence of the very limited range of atomic forces is that afforded by surface tension phenomena. This will be discussed in the second part of the paper.

according to a face-centered cubic lattice. The next column gives  $\Delta\sigma$ , the increase in this distance corresponding to the increase in volume represented by  $1 + \Delta V_0$ . It is seen that the values of  $\Delta\sigma$  are substantially constant so that we may conclude that: *The attractive forces between atoms increase to a maximum when the distance between the atoms is about  $0.6 \times 10^{-8}$  cm. greater than the distance at which the attractive force is zero.*

We are now in a position to draw certain conclusions regarding the structure of the surfaces of crystals.

Let us consider a crystal such as calcite in which cleavage surfaces may be obtained. To break a crystal into two parts requires the expenditure of a certain amount of energy. Let  $\gamma$  be the *work or free energy* which must be expended in producing each square centimeter of cleavage surface. Thus if we have a crystal of one square centimeter in cross-section (parallel to a cleavage face),  $\gamma$  will be one-half of the work required to separate the crystal into two parts. In general  $\gamma$  will decrease as the temperature rises. If we consider the mechanism of the formation of a cleavage surface, it is evident that as the atoms are pulled away from each other a certain amount of work will be done by the thermal agitations of the atoms. The atoms moving towards the receding surface are repelled by a gradually decreasing force so that they return from the receding surface with a velocity lower (on the average) than that with which they started out. Thus there must be a certain cooling effect accompanying the formation of a cleavage surface and this heat energy must result in a corresponding decrease in the free energy required to produce the surface. This reasoning is entirely analogous to that in the case of the mechanism of the adiabatic expansion of a gas.

Simple thermodynamical reasoning (see first chapter of Nernst's *Theoretical Chemistry*) shows that in the production of a cleavage surface the amount of energy contributed by the thermal agitation is equal to  $-T d\gamma/dT$ . If we add to this the free energy expended, we obtain, for the total energy involved in the formation of a unit surface, the expression

$$\gamma_0 = \gamma - T \frac{d\gamma}{dT}. \quad (2)$$

This quantity  $\gamma_0$  represents the total potential energy of the surface. Since we look upon atomic forces as electromagnetic in nature, the quantity  $\gamma_0$  is a quantitative measure of the increase in the energy of the electromagnetic field surrounding the atoms, produced by the formation of the surface.

Just as we traced a relationship between the compressibility, the heat of vaporization and the range of atomic forces, we may derive a similar relationship between the elastic properties, surface energy and range of atomic forces. Unfortunately, however, few data on the surface energy of solids are available.

There is every reason for believing that the range of atomic forces is of the same order of magnitude in all the states of matter. In forming a cleavage surface, therefore, it is probable<sup>1</sup> that the atoms pull part when the distance between adjacent atoms has been increased by about  $0.6 \times 10^{-8}$  cm.

When electrically charged or magnetized bodies are brought into proximity, they tend to move in such a way that the total energy of the electric or magnetic field becomes a minimum. For example, if we imagine a number of small horseshoe magnets to be placed in a box and shaken, we should expect on opening the box to find that the magnets had become attached to each other in pairs in such a way that in each pair the north pole of one is in contact with the south pole of the other. This arrangement would be a very stable one and would require a maximum amount of energy to break it up.

In a similar manner the atoms in the surface of a crystal must tend to arrange themselves so that the total energy in the field surrounding them will be a minimum.<sup>2</sup> In general, this will involve a shifting of the positions of the atoms with respect to one another. However, from the fact that energy is always required to separate a solid body into two parts we must conclude that the field energy associated with the surface atoms is always greater than that associated with a like number of atoms in the interior of the solid, notwithstanding the shifting of the positions of the atoms in the surface layer.

The smallness of the range of the atomic forces, compels us to conclude

<sup>1</sup> Further evidence in support of this statement will be given in the second part of this paper.

<sup>2</sup> In the second part of this paper it will be shown that this principle is of great importance in connection with surface tension phenomena. The group molecules in liquids arrange themselves in the surface layer in such a way that the part of the molecule which has the weakest field around it actually forms the surface, while the more active parts of the molecule are drawn below the surface, and are then without effect on the surface tension except in so far as they crowd the surface atoms apart.

The above principle also seems to be related to the cleavage or crystal habits of solids. In a crystal built up of atoms arranged according to a face centered cubic lattice the number of atoms per sq. cm. of crystal face is  $5.56 \times 10^{15} \times V^{-\frac{3}{4}}$  for the 1:0:0 faces;  $4.02 \times 10^{15} \times V^{-\frac{3}{4}}$  for the 1:1:0 faces and  $6.57 \times 10^{15} V^{-\frac{3}{4}}$  for the 1:1:1 faces. Here  $V$  is the atomic volume. Thus the atoms are arranged more compactly in the octahedron faces than in any others.

For such faces the value of  $\gamma_0$  should be a minimum. When platinum is slowly sublimed at high temperatures as, for instance, in the winding of an electric furnace, it crystallizes in the form of beautiful octahedra. The writer has observed similar crystals of tungsten.

On the other hand, in the simple cubic lattice the most compact arrangement of the surface atoms occurs in the 1:0:0 faces. Crystals of the alkali halides have cubic cleavage and usually crystallize as cubes and the atoms in these crystals are spaced according to a simple cubic lattice.

that in general the distances through which the surface atoms are shifted from their original positions in the solid, are small compared to the average distance between atoms. We must also conclude that the abnormal surface arrangement is usually limited to the surface layer only.

The surface of a solid (or liquid), therefore, does not contain, as is usually assumed, a transition layer, consisting of several layers of atoms or "molecules," in which the density varies by continuous gradations from that of the solid to that of the surrounding gas or vapor. Instead we find that the change from solid to empty space is most abrupt. In a sense, the rearrangement of the atoms in the surface layer causes this layer to assume the character of a transition layer, but the density of the packing of the atoms in this layer is undoubtedly greater than in the body of the solid, so that there can be no gradual change in density from that of the solid to that of the space. Additional evidence in favor of this view will be given in the remainder of this paper.

The surface of a crystal must then consist of an arrangement of atoms as definite as that existing in the interior of the crystal, although slightly different from the latter. The surface must thus be looked upon as a sort of checker board containing a definite number of atoms, of definite kinds arranged in a *plane* lattice formation. The space between and immediately above (away from the interior) these atoms is surrounded by a field of electromagnetic force more intense than that between the atoms inside the crystal.

There are good reasons for believing that the intensity of this surface field of force is substantially independent of the temperature. The energy in the surface field is measured by  $\gamma_0$ . (Equation 2.) Now the work done, during the formation of a fresh surface by the thermal agitation of the molecules (namely,  $-T d\gamma/dT$ ), should be approximately proportional to the temperature. Therefore,  $d\gamma/dT$ , should be independent of the temperature. Thus we may place

$$\gamma = a - bT \quad (3)$$

where  $a$  and  $b$  are constants. Combining this with (2) we find  $\gamma_0 = a$ . In other words,  $\gamma_0$ , the total energy of the electromagnetic surface field should be independent of the temperature.

In the case of liquids, the free energy necessary for the formation of unit surface is called the surface tension. By analogy we would be justified in calling  $\gamma$  the surface tension of the solid. However, on the whole, it seems preferable with both solids and liquids to refer to the quantity  $\gamma$  as the *free surface energy* and  $\gamma_0$  as the *total surface energy*.

**Sublimation of Solids.**—Sublimation involves two processes; evaporation and condensation. Condensation being in some ways the simpler of the two will be considered first.

*Condensation of Vapors.*—When a crystal is in contact with its own saturated vapor the vapor must be continually condensing on the solid while the solid is evaporating at an equal rate. The rate at which the molecules of the vapor come into contact with the surface of the solid is given by the equation

$$m = \sqrt{\frac{M}{2\pi RT}} p, \quad (4)$$

where  $M$  is the molecular weight of the vapor,  $R$  is the gas constant,  $p$  is the pressure of the vapor and  $m$  is the rate at which the gas molecules strike against the surface, expressed in grams of vapor per sq. cm. per second.<sup>1</sup>

When a molecule of vapor strikes against the solid surface one of two things may happen. The molecule may be *reflected* from the surface, in other words, may rebound elastically, or it may *condense* on the surface, that is, it may be held by attractive forces in such a way that it forms at least temporarily a part of the solid body. It is of importance to know approximately what fraction of the molecules striking the surface are reflected.

In the kinetic theory of gases it has almost universally been assumed that molecules are perfectly elastic. This assumption has become so much a habit of thought that nearly everyone who has applied the kinetic theory to liquids and solids has taken it for granted that the collision between gases and surfaces of solids or liquids are also elastic.<sup>2</sup>

We have seen, however, from a consideration of the heat conductivity of solids that the time of relaxation of the atoms is usually small compared to the time necessary for the atom to complete a single oscillation. This means that before an atom can be displaced a perceptible distance the energy causing the displacement has been dissipated among all the adjacent atoms. From this fact it appears that the collisions of molecules against solid bodies must in general be almost wholly inelastic.

In a recent paper in the *Physical Review*<sup>3</sup> the writer has discussed this question very fully, and gives abundant evidence both experimental and theoretical, for the inelasticity of the collisions between gas molecules and solid surfaces. There are apparently some cases in which a moderate

<sup>1</sup> This equation is a simple modification of the equation giving the rate of effusion of gases through small openings (Meyer's Kinetic Theory of Gases, German edition, 1899, p. 82). Its derivation was given by the writer in an article in the *Phys. Rev.*, **2**, 331 (1913). The importance of this equation in the kinetics of heterogeneous reactions can hardly be over-emphasized. See for example Langmuir, *THIS JOURNAL*, **37**, 1144 (1915).

<sup>2</sup> N. T. Bacon (*J. Phys. Chem.*, **17**, 762 (1913)) suggests that molecules are not elastic, and in this way explains qualitatively the phenomena of adsorption and catalytic action.

<sup>3</sup> *Phys. Rev.*, **8**, 149 (1916).

amount of real reflection does occur, but these cases must be looked upon as the exception rather than the rule.

According to this viewpoint the mechanism of the condensation of a vapor on a solid is as follows:

In the vapor surrounding the solid, the average distance which the molecules travel between collisions (the mean free path) is of the order of magnitude of  $10^{-5}$  cm. if the pressure is atmospheric, while it is correspondingly greater if the pressure is less. When a vapor molecule approaching the surface comes within a distance of about  $2 \times 10^{-8}$  cm. of the surface layer of atoms it begins to be acted upon by the electromagnetic field close to the surface. The vapor molecule thus experiences a force attracting it towards the surface. As it moves closer to the surface the attractive force rapidly increases and soon reaches a maximum intensity. The attractive force then rapidly decreases, and falls to zero when the molecule has traveled a distance only about  $0.6 \times 10^{-8}$  cm. beyond the point at which the force was a maximum. The point at which the force falls to zero may be regarded as an equilibrium position. When the molecule reaches this position its kinetic energy will be very high for a relatively large amount of work has been done upon it by the attractive forces. It will, therefore, not remain in the equilibrium position, but will move still closer to the atoms of the solid, and will thus enter a region in which it is subjected to very strong and rapidly increasing repulsive forces. If the molecule had lost no energy to adjacent atoms it would probably travel a distance  $0.2-0.3 \times 10^{-8}$  cm. against these repulsive forces before being brought to rest. It would then pass again through the equilibrium position and finally out through the region of attractive forces, and might thus again escape from the surface forces, in other words, be reflected.

But the improbability of such a reflection is evident when we consider the ease with which energy is dissipated to adjacent atoms. This energy loss occurs in two ways. In the first place, when the molecule is approaching the surface, the attractive force is exerted by *several atoms* on the surface. These atoms are thus all accelerated towards the incident molecule. A little later when the molecule is in the region of repulsive forces, these forces will be exerted principally by a *single atom* of the solid. The energy used in accelerating the surface atoms can, therefore, only partially be delivered back to the incident molecule. This dissipation in energy, even if only relatively small, will usually make it impossible for the molecule to pass out through the region of attractive forces.

The second kind of loss of energy, which is probably the more important, is that which causes the remarkably small time of relaxation in solid bodies. We have seen that in the interior of crystals the time taken for adjacent atoms to reach thermal equilibrium with each other is of the order of  $10^{-16}$  seconds. The duration of a collision between a molecule and a surface

(that is, the time between successive passages through the region of maximum attractive force) must be of the order of  $10^{-13}$  seconds. Thus in general, the energy delivered to the incident molecule by the attractive forces, is practically wholly dissipated to the adjacent atoms by the time the molecule first reaches the equilibrium position. It, therefore, has not sufficient kinetic energy to enable it to penetrate far into the region of repulsive forces, and certainly not sufficient to allow it to work against the attractive forces and thus escape from the surface.

The condensation of a vapor on a solid surface thus takes place independently of the temperature of the surface.<sup>1</sup>

This is especially evident when we consider that the intensity of the field of force close to the surface, as measured by the total surface energy  $\gamma_0$ , is itself independent of the temperature. The rate of evaporation on the other hand varies extremely rapidly with the temperature.

If practically every molecule of vapor which strikes against the surface of the solid condenses, it is not at first evident how the molecules, especially if they are complex, are able to arrange themselves to form a crystalline mass. In analyzing the mechanism of condensation we must distinguish two extreme sets of conditions that may occur. These may be termed *irreversible* and *reversible* sublimation.

By *irreversible* sublimation I mean the type which occurs for instance when a tungsten filament is heated to a high temperature in a well evacuated bulb. Under these conditions there can be no equilibrium, for the bulb is at a temperature thousands of degrees lower than that at which the vapor can be produced. The vapor is thus enormously superheated with respect to the surface on which it condenses. Such conditions as this can only be realized in practice when the vapor is at very low pressure, for, otherwise, the amount of vapor condensed per unit area per second would be so great that the heat liberated by the condensation could not be removed rapidly enough to maintain a low temperature on the condensing surface.

By the term *reversible* sublimation we may designate that which takes place for example, when iodine or naphthalene is sublimed slowly at ordinary temperatures.

In this case we are dealing with small differences of temperature, and we shall see that under these conditions condensation and evaporation are going on simultaneously at nearly equal rates over every portion of the surface where condensation occurs.

The mechanisms of reversible and of irreversible sublimation are in some ways quite different, and from the experimental side the phenomena show marked distinctions.

<sup>1</sup> It must of course be remembered that what we ordinarily observe during the condensation of a vapor is the difference between the rate of condensation and the rate of evaporation.

In the irreversible sublimation the vapor molecules remain where they first strike the surface, since they can neither be reflected nor re-evaporated. The deposit formed by the condensed vapor is, therefore, homogeneous (when gaseous impurities are absent) and is of uniform thickness. If the temperature of the surface on which condensation occurs is sufficiently low, the deposit will be wholly noncrystalline, since the atoms or molecules become rigidly fixed in position when they strike the surface and thus have no opportunity to arrange themselves as in a crystal. With the condensing surface at higher temperatures, however, a sintering or crystallizing process may go on within the deposit even when the temperature is below that at which perceptible vaporization occurs.

By means of this irreversible sublimation it is possible to obtain any volatile body in a noncrystalline form.

In the case of reversible sublimation the deposit formed from the condensed vapor is ordinarily very crystalline, frequently consisting of groups of separate crystals. In the formation of these crystals every molecule of vapor which strikes the surface condenses just as in the case of irreversible condensation, but most of these molecules re-evaporate again. The tendency of different molecules to re-evaporate will depend entirely on how firmly they are held by the atoms of the crystal. Thus the molecules which strike the surface in such a way as to form a continuation of the space lattice already present, will evaporate much less frequently than molecules which are not in positions where they can fit in with the crystal structure. The continual evaporation and condensation going on over the whole surface of the crystal allows the atoms to arrange themselves in the most stable positions. The smaller the differences in temperature and the more nearly equal the rates of condensation and evaporation, the more perfect will be the development of the crystals.

*Evaporation of Solids.*—We have seen that the condensation of vapors on a solid body takes place at a rate which is practically independent of the temperature. The rate of evaporation, however, increases rapidly with temperature.

Since evaporation and condensation are in general thermodynamically reversible phenomena, *the mechanism of evaporation must be the exact reverse of that of condensation*, even down to the smallest detail.

In the condensation of a monatomic vapor such as that of a metal, each atom as it approaches the surface comes into a region in which it is attracted. It is thus accelerated, but it gives up its newly acquired energy to adjacent atoms nearly as fast as it receives it. It soon reaches a region of repulsive forces, and is then brought to a stop. It then continues to move about an equilibrium position with an irregular motion due to thermal agitation.

Conversely in the evaporation of an atom of a metal the atom must

acquire energy from adjacent ones and thus be accelerated outward. As it moves it must receive successive increments of energy from its neighbors until finally it passes out of the region of attractive forces. From the smallness of the time of relaxation we are thus compelled to believe that an atom only escapes when it thus receives a very large number of successive impulses from the adjacent atoms.

The very small probability of such a sequence of favorable impulses is the reason that so few atoms evaporate at lower temperatures.

We may picture to ourselves the mechanism of evaporation by imagining a large number of heavy balls suspended (according to a two-dimensional lattice) from a ceiling by steel springs. Each ball is to be coupled to each of its neighbors by springs under tension. If some of the balls are set in motion the energy will be rapidly propagated to the others so they will all be in a state of agitation. To properly imitate the structure of a solid the coupling between the balls should be so stiff that the total energy of one ball can be transmitted to its neighbors in a very small fraction of the time required for a single oscillation.

When all the balls have been in motion long enough for a steady state to have been reached the velocities will be distributed among them according to the probability laws, in other words, according to Maxwell's distribution law.

If the springs are of brittle wire so that they snap when elongated more than a certain amount, then from time to time balls which have acquired an unusually large downward displacement will break their springs and escape. This will be quite analogous to evaporation.

The rate of evaporation of a solid is thus determined by the number of surface atoms per second which reach a certain critical condition. By means of Maxwell's distribution law it can thus be readily shown<sup>1</sup> that the rate of evaporation should increase with the temperature according to an equation of the form

$$m = A\sqrt{T} e^{-\lambda/RT} \quad (5)$$

where  $\lambda$  is the internal latent heat of evaporation per gram atom, and  $A$  is a constant whose value will depend primarily on the degree of coupling between adjacent atoms.

In the study of the disintegration of radioactive substances it has been

<sup>1</sup> Richardson (*Phil. Trans.*, 201, 516 (1903)) calculated in this way the rate of evaporation of electrons from heated metals (thermionic emission). The derivation of Equation 5 is also given by the writer (*THIS JOURNAL*, 35, 122 (1913)) in connection with a study of the reaction between oxygen and tungsten at high temperatures. It was also pointed out that this equation is substantially equivalent to Arrhenius' equation for the temperature coefficient of reaction velocity.

The significance of Maxwell's distribution law in relation to the kinetics of chemical reactions has been very fully treated in a recent paper by R. Marcellin (*Annales de Physique*, 3, 185 (1915)).

customary to speak of the life or period of the atom. In a similar way we may calculate the "life" of an atom on the surface of an evaporating solid.

The number of atoms evaporating per second per sq. cm. of surface will be  $Nm/M$  where  $N$  is the Avogadro constant and  $M$  is the atomic weight of the substance. If  $N_o$  is the total number of atoms per sq. cm. of surface then  $t$ , the average live of an atom on the surface will be

$$t = \frac{N_o M}{Nm}. \quad (6)$$

The "half period," that is, the time which must elapse before half of any selected lot of atoms will have evaporated, is equal to

$$t_{1/2} = 0.693 \frac{N_o M}{Nm}. \quad (7)$$

We have just seen that the constant  $A$  in Equation 5 is dependent on the coupling between the atoms. The time of relaxation of the atoms is also a measure of this coupling. It should thus be possible to estimate the time of relaxation from the rate of evaporation, and it will be of interest to see how the result calculated in this way compares with that found from the heat conductivity.

We see from Equation 5 that the rate of evaporation,  $m$ , depends on the latent heat of evaporation. If we substitute  $\lambda = 0$  in Equation 5 we obtain a hypothetical value of  $m_o$  (let this be  $m$ ), that represents the rate of evaporation which would occur if attractive forces did not prevent the escape of atoms from the surface. Thus we obtain from (5)

$$\frac{m}{m_o} = e^{-\lambda/RT}. \quad (8)$$

By Equation 6 the average life of an atom on the surface of a solid evaporating at the rate  $m_o$ , is

$$t_o = \frac{N_o M}{Nm_o}. \quad (9)$$

Eliminate  $m_o$  between (8) and (9).

$$t_o = \frac{N_o M}{Nm} e^{-\lambda/RT}. \quad (10)$$

Or from (5)

$$t_o = \frac{N_o M}{NA\sqrt{T}}. \quad (11)$$

The quantity  $t_o$  thus represents the average length of time an atom would remain on the surface if there were no attractive forces to hold it. Now the "time of relaxation" has been defined as the time required for an atom to give up all but  $1/e^{th}$  of its excess energy to adjacent atoms. It is evident that the time required for an atom at rest to be set in motion

will also be measured by the time of relaxation. Thus  $t_0$  should be of the same order of magnitude as the time of relaxation, and probably only differs from it by some constant factor not very far from unity.

The rates of evaporation of tungsten<sup>1</sup> platinum and molybdenum<sup>2</sup> in a very high vacuum, have been measured by Mr. G. M. J. Mackay and the writer. The values of  $t_0$ , calculated from these data by Equation 10 are given in Table II.

TABLE II.

	W.	Mo.	Pt.
$N_0$ .....	$1.46 \times 10^{16}$	$1.32 \times 10^{16}$	$1.51 \times 10^{16}$
$t_0$ at $300^\circ \text{K.}$ .....	$3.4 \times 10^{-19}$	$3.5 \times 10^{-20}$	$1.1 \times 10^{-16}$
$t_0$ at $2000^\circ \text{K.}$ .....	$5.2 \times 10^{-18}$	$1.0 \times 10^{-18}$	$3.0 \times 10^{-16}$
$t_r$ by Equation 1.....	$1.3 \times 10^{-16}$	.....	$2.3 \times 10^{-18}$

For comparison, the "times of relaxation"  $t_r$  calculated by Equation 1, are given in the last line. It will be remembered that Equation 1 gives too high a value for  $t_r$  because it was assumed in its derivation that an atom could take up energy only from atoms in one given direction. It is seen that the order of magnitude of  $t_0$  is not very different from that of  $t_r$ . We must not expect any very good agreement between  $t_0$  and  $t_r$  because of the very great effect of slight errors in  $\lambda$  on the value of  $t_0$  calculated by Equation 10. Thus if  $\lambda$  is taken one per cent. too large the value of  $t_0$  will be 20 times too small. On the whole, therefore, we may conclude that the values of  $t_0$  calculated as above, furnish confirmatory evidence that the time of relaxation of the atoms in solids is hundreds if not thousands of times smaller than the "natural period" of atomic vibrations.

So far we have considered the evaporation of solids which give monatomic vapors. When a crystal such as sodium chloride evaporates the atoms must group themselves together in pairs *before* they escape from the surface forces.

The latent heat of evaporation does not correspond to the energy required to separate the atoms from each other, but only to the energy needed to separate one group of atoms from other similar groups. This makes it appear that evaporation in these cases is the result of a tautomeric change taking place among the surface atoms. Thus in the case of solid sodium chloride the sodium atoms are ordinarily held to the adjacent chlorine atoms by secondary valence. If, however, a tautomeric change occurs by which a pair of adjacent chlorine and sodium atoms becomes attached to each other by *primary* valences, then this pair will be held to the surface by much weaker forces than those holding other atoms not so combined. The pairs held by primary valences may thus be enabled to evaporate from the surface. We should not assume, however, that

<sup>1</sup> *Phys. Rev.*, **2**, 329 (1913).

<sup>2</sup> *Ibid.*, **4**, 377 (1914).

every pair of atoms so combined, or even the majority of them, will evaporate, for if we do, it would follow that only a very small fraction of molecules of salt vapor striking a surface would condense. It is more likely that the tautomeric changes take place with high frequency, but that the time during which a pair of atoms exists consecutively in the tautomeric form is comparable with the time of relaxation, that is, of the order of  $10^{-17}$  seconds. Now the time required for an atom or a group of atoms to move out of the region of attractive forces (a distance of about  $10^{-8}$  cm.) must be at least  $10^{-14}$  seconds, since molecular velocities are always less than  $10^6$  cm. per second. We are thus led to believe that a sodium chloride molecule only evaporates when the tautomeric change occurs at a moment when the atoms are already displaced from their equilibrium positions to an unusual degree.

The evaporation of compound substances of the polar type thus involves rather complicated chemical changes in which the atoms rearrange themselves according to their primary valences. This conception of the mechanism of evaporation receives support from the fact that so few complex polar compounds or molecular compounds can be volatilized without dissociation. Thus nearly all inorganic salts except those which are compounds of the first order (halide salts for instance) are decomposed or dissociate on heating. Crystals containing water of crystallization can never be distilled with their water of crystallization. Even compounds like sulfuric acid give vapors which are dissociated.

Nonpolar compounds, such as most organic substances, usually contain fixed molecules which, even in the solid condition, are held together by primary valences, the secondary valences merely serving to hold the fixed molecules together. In this case evaporation involves only a breaking of the secondary valence forces so that it becomes quite similar to the evaporation of metals or other substances giving monatomic vapors.

*Relation between Condensation and Evaporation.*—When a solid is in equilibrium with its own vapor, condensation and evaporation are occurring simultaneously at equal rates. We have seen that we are justified, in the majority of cases, in considering that all the molecules of vapor which strike against the surface condense (are not reflected). Now the rate at which the molecules strike the surface is given by Equation 4

$$m = \sqrt{\frac{M}{2\pi RT}} p. \quad (4)$$

Since all of the molecules condense, and since the rate of evaporation must be equal to the rate of condensation, we may use this same equation to calculate the rate of evaporation,  $m$ , in terms of the pressure  $p$ , of the saturated vapor. If the condensation and evaporation go on independently of one another, then Equation 4 should give a means of calculating the rate at which a solid evaporates into a perfect vacuum. Or

conversely if we determine the rate of evaporation of a solid in a high vacuum we can calculate the vapor pressure by the above equation.<sup>1</sup>

This theoretical relation between the rate of evaporation and vapor pressure was first obtained by Hertz.<sup>2</sup> Hertz himself and others who have used the equation have not considered that the reflectivity is negligible and hence looked upon the calculated value of  $m$  as being greater than the true rate of evaporation.

R. Marcellin<sup>3</sup> has recently attempted to measure the maximum rate of evaporation of naphthalene, nitrobenzene and iodine, in a vacuum, and compares his results with those calculated by Equation 4. He concludes that at 40° only about one molecule out of 20 striking the surface condenses, while at 70° about one out of five condenses. That is, the reflectivity decreases rapidly at higher temperatures. It should be noted on the other hand that R. W. Wood<sup>4</sup> finds no reflection of mercury atoms from a surface at very low temperatures but concludes that the atoms are all reflected at higher temperatures.

Marcellin measured the rates of evaporation of substances in capillary tubes. By plotting the rate of evaporation against the length of the tube through which the vapor had to pass, he *extrapolated* back to zero length of tube, and expected in this way to find the rate of evaporation in a perfect vacuum. When we consider that this extrapolation was carried out over a length of tube at least eight times the diameter of the tube, we realize how very few of the molecules evaporating from the surface could have escaped, from the end of the tube. The great majority of them must have struck the walls of the tube and thus have been afforded an opportunity of returning back onto the surface. Measurements of this sort, to have any value, must be made so that molecules evaporating from the surface may move off in straight lines without meeting any obstruction until they strike the cooled surface on which they permanently condense.

If Marcellin had plotted the reciprocal of the speed of evaporation (which should be a linear function of the length of the tube) instead of the speed itself, it would have been apparent, first that the observed rates were much lower than the true maximum rates, and second, that even with the small capillaries he used he did not succeed in keeping the temperature of the evaporating surface up to that of the bath surrounding the tube. Therefore, it appears that Marcellin's experiments are entirely

<sup>1</sup> The writer, together with Mr. G. M. J. Mackay, has used this method for measuring the vapor pressures of the metals tungsten, platinum, molybdenum, iron, nickel, copper and silver, and the results have been, or will be, published in the *Physical Review*. The reasons which justify the assumption that the reflectivity is negligible, are given in detail in a recent article (*Phys. Rev.*, 8, 149 (1916)).

<sup>2</sup> *Ann. Physik*, 17, 177 (1882).

<sup>3</sup> *Annales de Physique*, 3, 185 (1915).

<sup>4</sup> *Phil. Mag.*, 30, 300 (1915).

consistent with the view that the true rate of evaporation is accurately given by Equation 4.

The writer has also shown<sup>1</sup> that Wood's experiments may equally well be explained by assuming, instead of a reflection of mercury atoms, at the higher temperatures, a condensation followed by evaporation.

For the case of a clean surface of liquid mercury evaporating into a good vacuum Knudsen has recently<sup>2</sup> proved that Equation 4 gives the actual rate of evaporation.

Wood makes the statement that atoms of mercury which are "diffusely reflected" (or according to our theory, condensed and re-evaporated) from a surface, do not seem to be distributed quite according to Lambert's cosine law, but there seem to be too few atoms leaving the surface in directions nearly parallel to the surface. Now if evaporation and condensation can go on simultaneously, although independently, it must follow, according to Maxwell, that the number of atoms leaving the surface in different directions must be proportional to the projected area in that direction (Lambert's cosine law).

Observations on the evaporation of metals in high vacuum have convinced the writer that Lambert's cosine law does hold accurately for evaporation, and the Wood's conclusion is incorrect.

Wood drew his conclusions from the *apparent* sudden decrease in the thickness of a film of metal deposited on glass, in the region close to the plane of the surface from which "reflection" took place. In the writer's experience, this sudden decrease which he has often observed, and which certainly seems very real, is only apparent. It is due to the fact that, although the *thickness* of the film varies *linearly* with the distance from the plane of the surface, the *light absorption* varies *exponentially*.

Kaye and Ewen<sup>3</sup> have reported that at pressures of a few mm. of gas, the sublimation from heated metals (Fe, W, Cu, Ag or Ir) appear to consist of two parts, one of which, diffuses like a gas, but the other, often the larger part, is projected in straight lines in a direction perpendicular to the surface at which it originates. In the experience of the writer such effects are due to convection currents (which often produce very freakish effects at pressures of a few mm.) or to electric discharges through the gas. They are usually enormously stimulated by the presence of traces of moisture. In a thoroughly dry gas or in a good vacuum, and in the absence of electric discharges, the evaporation of heated metals takes place without any evidences of such "projection" of particles in definite directions. Of course in a really good vacuum the atoms leaving the heated surface, travel in perfectly straight lines until

<sup>1</sup> *Phys. Rev.*, *loc. cit.*

<sup>2</sup> *Ann. Phys.*, **47**, 697 (1915).

<sup>3</sup> *Proc. Roy. Soc.*, (A) **80**, 58 (1914).

they strike an obstacle, and in this way "shadows" of interposed objects may be obtained. But this projection of particles takes place according to Lambert's cosine law and is in full accord with the ordinary conceptions of the kinetic theory.

We have assumed so far that evaporation and condensation can go on simultaneously without influencing each other. For example, in calculating by Equation 4 the rate of evaporation in a vacuum from the pressure of the saturated vapor, we had to assume that the true rate of evaporation in presence of saturated vapor is the same as that in vacuum, in other words, that the condensation of the vapor has no effect on the rate of evaporation.

There are, however, reasons which might lead us to expect a difference in the rate of evaporation in presence of and in the absence of vapor.

In the first place, when a vapor atom or molecule condenses on a surface an amount of energy corresponding to the latent heat of evaporation must be liberated, and must result in a local rise of temperature. It would seem that this might cause the evaporation of an adjacent atom which would otherwise not evaporate. Thus the condensation of vapor might stimulate the evaporation. This would be equivalent in many ways to a reflection of vapor molecules from the surface.

The following considerations make it very improbable that condensation has any such effect on evaporation. The "average life" of an atom on a surface may be readily calculated from Equations 4 and 6. The life will be inversely proportional to the vapor pressure, and will be proportional to  $\sqrt{MT}$ . If we choose  $M = 25$ ,  $T = 400$  and  $p =$  one megabar (atmospheric pressure) and assume that  $N_0 = 10^{16}$  atoms per sq. cm. we thus calculate that the life of an atom on the surface would be  $3.8 \times 10^{-9}$  seconds. In the evaporation of substances in vacuum the equilibrium pressure would always be extremely small compared to one megabar, so that the life of the atoms on the surface would be much more than  $10^{-8}$  seconds. Now the time taken by an atom to receive or give up its energy to adjacent atoms is of the order of  $10^{-17}$  seconds, or about  $10^{+9}$  times less than the life of the atom on the surface. These figures show that the critical conditions necessary to cause the evaporation of an atom are of relatively rare occurrence. The chance is negligibly small, therefore, that an atom condensing on the surface will be able to give up its energy to an adjacent atom at a moment when the latter is nearly in its critical condition.

These considerations make it appear probable that the energy liberated by the condensation of vapor is totally without influence on the mechanism of evaporation.

There is, however, another kind of effect by which condensation may, and probably does, influence the rate of evaporation. Let us consider

for example solid naphthalene in contact with its saturated vapor. When a molecule of naphthalene vapor strikes against the surface of the crystalline substance it undoubtedly condenses in the position in which it strikes. The chances are small that this position will be one in which the molecule forms a continuation of the space lattice of the crystal. If the temperature is sufficiently high the molecule may, by a sort of sintering process, readjust its position in conformity with the underlying group of molecules. But at lower temperatures this readjustment will often be impossible.

Such irregularly placed molecules will tend to evaporate from the surface more rapidly than those in the regular lattice positions.

We have already seen that this greater rate of evaporation manifests itself in the tendency for larger and more perfect crystals to be formed, as the sublimation of a substance is made more nearly reversible.

Since the rate of evaporation of the irregularly placed molecules must be finite, it follows that the surface must be more or less completely covered by such molecules. In other words, the surface of a crystalline solid in equilibrium with its saturated vapor may be covered by a layer of irregularly placed molecules, in other words, there may be an amorphous surface film.

The extent to which the surface is covered by such a film will depend upon the ease with which the molecules rearrange themselves, and also upon the relative rates of evaporation of the regularly and irregularly placed molecules.

It is of interest to consider the evaporation and condensation of a crystal of naphthalene under various conditions:

1. *Irreversible Condensation.*—If a stream of naphthalene vapor is admitted at low pressure into a well exhausted bulb immersed in liquid air, we should expect that all the molecules would condense in the positions in which they first strike the cooled bulb. The condensed material should then be wholly amorphous, both on its surface and in its interior.

2. *Irreversible Evaporation.*—If a naphthalene crystal is suspended in an exhausted bulb and the latter is immersed into liquid air, the naphthalene crystal will evaporate irreversibly, since no molecules of naphthalene will return from the surface of the bulb. In this case there will be no amorphous surface layer on the crystal.

3. *Reversible Evaporation or Condensation.*—If a naphthalene crystal is placed in one arm of an inverted and exhausted U-tube and the other arm is maintained at a very slightly lower temperature, the naphthalene will slowly sublime from one arm to the other, and form crystals in the cooler arm. These crystals as well as the one in the warmer arm will have amorphous surface layers.

If we calculate the rate of evaporation from the pressure of the saturated vapor by Equation 4 we obtain a value which corresponds to the rate

of evaporation from the amorphous surface layer, and not from the true crystalline surface. Therefore, the rate of evaporation of a crystal in a good vacuum (Case 2, Irreversible Evaporation) should be lower than that calculated from the vapor pressure, notwithstanding the fact that no reflection of molecules from the surface takes place.

It is probable that in the great majority of cases, especially with substances such as metals which give monatomic vapors, that this effect is entirely negligible, because of the great ease with which the atoms can arrange themselves on the surface.<sup>1</sup>

Even with substances having molecules as complicated as that of naphthalene it seems improbable that the difference between the rates of evaporation of crystalline and amorphous surfaces would be great enough to very seriously affect the validity of Equation 4, when applied to the calculation of the rate of evaporation in a vacuum. Accurate experimental determinations of the rates of evaporation of complex organic compounds in high vacuum should prove of great interest.

There are cases, however, where we may expect very radical differences between the true rates of evaporation *in vacuo* and the rate calculated from the vapor pressure by Equation 4.

Red phosphorus should furnish an example of this sort. The transformation of yellow into red phosphorus takes place very much more slowly than the rate at which molecules of phosphorus vapor strike against a surface of red phosphorus. Therefore, the molecules of phosphorus vapor which impinge against the surface and condense, must evaporate again without having been in the condition of red phosphorus.

The surface of the red phosphorus is, therefore, covered, at least in part, by a layer of fixed molecules which constitute an adsorbed film of yellow phosphorus. The rate of evaporation calculated by Equation 4 corresponds to the evaporation from this adsorbed film of yellow phosphorus plus that from the uncovered portion of the surface of red phosphorus. On the other hand if the red phosphorus is placed in a good vacuum the adsorbed film of yellow phosphorus will distill off and the observed rate of evaporation will correspond to the rate of conversion of

<sup>1</sup> According to the principle already enunciated, by which every element in the mechanism of a reversible process must itself be reversible, it follows that any rearrangement of molecules on the surface, which takes place during the condensation of a vapor, must take place to the same extent, but in the reverse direction, in the evaporation of the substance. Thus if molecules rearrange themselves into regular positions, an equal number of molecules must be continually leaving regular positions to assume irregular positions. This leads to the conclusion that even with substances which give monatomic vapors, the surface must in part be amorphous. However, an amorphous structure due to this cause will be present to the same extent when the evaporation is irreversible as it is in the case of reversible evaporation. Therefore no error is made in calculating the rate of evaporation in a vacuum from the vapor pressure, according to Equation 4.

red into yellow phosphorus. This rate will be very much less than that calculated from the equilibrium pressure.

It is thus probable in the case of red phosphorus that the equilibrium pressure is not a true vapor pressure in the ordinary sense, but is rather to be regarded as a dissociation pressure.

The rate of evaporation of ammonium chloride in a vacuum, both in the presence of and in the absence of traces of moisture, should throw a very interesting light upon the mechanism of the evaporation or dissociation<sup>1</sup> of this substance.

### The Dissociation of Solids and the Kinetic Interpretation of the Phase Rule.

Sometime ago it was pointed out to the writer by Mr. R. E. Wilson that a difficulty arises in the application of the kinetic theory to the dissociation of a substance such as calcium carbonate.

We may assume that in the equilibrium between calcium carbonate, calcium oxide and carbon dioxide two opposing reactions are taking place at equal rates. Off-hand, the most natural assumption in regard to these reactions would seem to be that the rate at which carbon dioxide is converted into carbonate is proportional to the pressure  $p$  of carbon dioxide and to the fraction  $\theta_1$  of the surface which is covered by CaO. On the other hand the rate of dissociation of the carbonate would be proportional to the fraction  $\theta_2$  of the surface covered by  $\text{CaCO}_3$ .

If we equate these two rates we obtain for equilibrium

$$p\theta_1 = K\theta_2 \quad (12)$$

where  $K$  is the equilibrium constant. This equation indicates that the pressure of the  $\text{CO}_2$  should depend on the ratio between  $\theta_2$  and  $\theta_1$ ; in other words it should depend on the relative proportions of the CaO and  $\text{CaCO}_3$ . This is contrary to fact. Evidently, therefore, we have made wrong assumptions regarding the mechanism of the reaction.

If we examine Equation 12 in the light of the Phase Rule we see that it would fit the facts well if there were a single solid phase of variable composition instead of two phases of constant composition. It would apply for instance to the dissociation of ferric oxide recently studied by Sosman and Hostetter<sup>2</sup> who found a "continuous series of solid solutions from  $\text{Fe}_2\text{O}_3$  over to a point very near  $\text{Fe}_3\text{O}_4$  if not over the entire range to  $\text{Fe}_3\text{O}_4$ ."

Furthermore, when we analyze the assumptions made in the derivation of Equation 12 we readily see that they imply a solid solution phase. Thus if the rate of dissociation of  $\text{CaCO}_3$  were proportional to the fraction of the surface covered by  $\text{CaCO}_3$  it is evident that the surface would soon

<sup>1</sup> See papers by Abegg and Johnson, *Z. physik. Chem.*, 61, 455 and 457 (1908); Scheffer, *Proc. Akad. Wetenschappen Amsterdam*, 18, 446 (1915).

<sup>2</sup> *THIS JOURNAL*, 38, 807 (1916).

consist of  $\text{CaO}$  and  $\text{CaCO}_3$  molecules distributed haphazard over the surface. This is exactly the kind of surface we should expect a solid solution to have.

The assumptions made above evidently are not consistent with the existence of separate phases of constant composition.

The Phase Rule, however, indicates that in the dissociation of calcium carbonate two solid phases,  $\text{CaO}$  and  $\text{CaCO}_3$ , are present together. In order that  $\text{CaCO}_3$  may dissociate and form a phase of  $\text{CaO}$  (instead of a solid solution) it is *necessary that the reaction shall occur only at the boundary between two phases.*

Now the  $\text{CaO}$  phase is generally so porous that  $\text{CO}_2$  readily diffuses through it. We are then forced to conclude that the  $\text{CO}_2$  in passing through the  $\text{CaO}$  does not react until it reaches the boundary of the  $\text{CaCO}_3$  phase. In a sense, therefore, calcium carbonate must be looked upon as a catalyst for the reaction between calcium oxide and carbon dioxide.

From the kinetic point of view this must mean that carbon dioxide molecules are only absorbed to form calcium carbonate when by so doing they form a continuation of a calcium carbonate crystal already present.

It will be remembered that in the calcite crystal each carbon atom is surrounded by three systematically placed oxygen atoms. By examining a model of such a crystal it is readily seen that in the cleavage surfaces two of the oxygen atoms are probably close to the surface, while the third lies well under the surface. In the readjustment of the positions of the surface atoms which must occur when a cleavage surface is found, the atoms must tend to assume positions in which the forces between the atoms are balanced against one another. Such an arrangement may have a considerable degree of stability.

If we imagine one of the carbon atoms, with the pair of oxygen atoms adjacent to it, to be removed from the surface, the symmetry of the arrangement of the surface atoms will be destroyed. This disturbance of the surface will certainly have an effect on the balance of forces holding the adjacent atoms. These atoms, therefore, will shift their positions. The neighboring carbon atoms (with their oxygen atoms) will then be held to the surface by a force which is *different* from that obtaining before the first  $\text{CO}_2$  was removed.

Now if this force has been *strengthened*, then the adjacent molecules of  $\text{CO}_2$  will be less likely to leave than others further from the disturbed region. Therefore, if the crystal is sufficiently heated,  $\text{CO}_2$  would leave from all portions of the surface and a *solid solution* of  $\text{CaO}$  in  $\text{CaCO}_3$  would be found. On the other hand if the removal of one  $\text{CO}_2$  molecule sufficiently *weakens* the force by which the adjacent ones are held, then the  $\text{CO}_2$  molecules will leave the surface only from positions adjacent to those from which they have already left. Under these conditions a

separate phase of CaO would grow, starting from the point (nucleus) where the first CO<sub>2</sub> molecule left the surface.

We may therefore conclude, in the case of the dissociation of calcium carbonate that the removal of a CO<sub>2</sub> molecule causes a weakening of the forces by which adjacent molecules are held, whereas in the case of the dissociation of ferric oxide the removal of an oxygen atom does not weaken the forces holding the adjacent oxygen atoms.

When a molecule of CO<sub>2</sub> strikes a surface of the CaO phase it presumably condenses and may be held to the surface by forces no different in kind from those holding the calcite crystal together. However, if the removal of one CO<sub>2</sub> molecule from a surface weakens the forces by which adjacent ones are held, it is probable that the forces acting on a single CO<sub>2</sub> molecule in the midst of a surface of CaO would be extremely weak. Therefore, the CO<sub>2</sub> molecule would remain on such a surface such a short time, that the total number present in the CaO phase would not be of importance.

If, on the other hand, the forces holding the CO<sub>2</sub> molecule in the CaO phase were at all comparable with those acting at the boundary of the CaCO<sub>3</sub> phase, then we should have a variable phase, consisting of a solid solution of CO<sub>2</sub> in CaO, together with a constant phase of CaCO<sub>3</sub>.

It is readily seen that the mechanism we have assumed, is capable of accounting for the different kinds of heterogeneous equilibria covered by the Phase Rule.

When there are two solid phases of constant composition and a gas, as in the dissociation of calcium carbonate, it follows directly from this mechanism that the pressure of the gas is dependent only on the temperature and not on the relative proportions of the phases.

Thus the rate at which CaCO<sub>3</sub> dissociates is proportional to the number of *CaCO<sub>3</sub> groups adjacent to empty spaces*, while the rate at which CaCO<sub>3</sub> is formed is proportional to the pressure of CO<sub>2</sub> and to the number of *empty spaces adjacent to CaCO<sub>3</sub> groups*. Therefore, the pressure must be constant at a given temperature.<sup>1</sup>

This theory of the mechanism of heterogeneous equilibria appears to be particularly useful in accounting for various conditions not usually predicted by the Phase Rule.

Faraday<sup>2</sup> noted a case that fully justifies the assumption that in some

<sup>1</sup> Since developing the above theory of the mechanism of such heterogeneous equilibria I have found that this subject has been treated by A. Thiel (*Sitzber. d. Ges. zur Beforderung d. gesamt. Naturwiss. in Marburg* (1913); *C. A.*, 8, 2284 (1914)). Thiel accepts as an axiom the relation given by Equation 12 and hence concludes that  $\theta_1/\theta_2$  is necessarily constant at a given temperature. This result is at complete variance with the theory given above, and, in the writer's opinion, is wholly unsupported by experimental evidence. In a subsequent paper the writer expects to discuss Thiel's theory in more detail.

<sup>2</sup> "Experimental Researches," page 109, Everyman's Library Edition.

equilibria the reaction can occur only when the surface has been disturbed. To quote from Faraday: "As a curious illustration of the influences of mechanical forces over chemical affinity, I will quote the refusal of certain substances to effloresce when their surfaces are perfect, which yield immediately upon the surface being broken. If crystals of carbonate of soda, or phosphate of soda, or sulfate of soda having no part of their surfaces broken, be preserved from external violence, they will not effloresce. I have thus retained crystals of carbonate of soda perfectly transparent and unchanged from September, 1827 to January, 1833; and crystals of sulfate of soda from May, 1832 to the present time, November, 1833. If any part of the surface were scratched or broken, then efflorescence began at that part, and covered the whole. The crystals were merely placed in evaporating basins and covered with paper."

It is well known that there is often great difficulty in removing the last traces of water of crystallization from a substance even when the hydrate gives a definite vapor pressure. According to the theory given above, the velocity of the dissociation is proportional to the area of the boundary between the phases. This boundary will usually have its maximum extent when both phases are present in more or less equivalent amounts. But the great difficulty in removing the last traces is undoubtedly due to the formation of solid solutions (adsorption!). Let us consider a crystalline substance AB which dissociates into a solid phase A and a gas B. The dissociation of AB and the recombination of A with B takes place most easily at the boundary between the phases AB and A. However, in general, we should expect that A and B also combine throughout the phase A, but that this compound is more unstable, and therefore dissociates at a higher rate. The rate at which A and B combine in this way in a unit volume of the phase A, will be proportional to the pressure  $p$ , while the rate at which it dissociates will be proportional to the concentration of B in A. By equating the two rates we see that the concentration of B in A should be proportional to the pressure of B.

There will, therefore, be the same kind of difficulty in removing the last trace of B from A as there is in producing a perfect vacuum.

The tendency of different substances to form these solid solutions will depend upon the extent to which the removal of one molecule of B from the phase AB affects the forces holding the adjacent molecules of B in AB.

It is a common experience that substances that are too thoroughly dehydrated are poor absorbers of moisture. A familiar example is overburnt lime or plaster of Paris. In some cases this phenomena may be due to a decrease in the porosity of the substance by sintering, but there is much evidence that this is not always the explanation.

According to the theory given above, the rate at which a partially dehydrated substance (which has a definite vapor pressure of moisture)

will absorb moisture, should be proportional to the extent of the boundary between the hydrated and dehydrated phases. According to this simple theory a thoroughly dehydrated substance should be incapable of absorbing any moisture. However, in general, there is no reason why vapor should not be slowly absorbed to from a solid solution even with a dehydrated substance. Gradually nuclei would develop in this solid solution and the hydrated phase would appear. The rate of absorption of moisture would then rapidly increase as the surface area of the hydrated phase grows.

### Adsorption of Gases by Solids.

Unless the molecules of a gas which may strike a solid surface *all* rebound elastically there will necessarily be a higher concentration of molecules of the gas in the surface layer of the solid than in the body of the gas. If any molecules impinging on the surface are condensed, a certain time interval must elapse before they can evaporate. This time lag will bring about the accumulation of molecules in the surface layer, and may thus be looked upon as the cause of adsorption.

In the condensation of a vapor we have seen that the collisions are wholly inelastic, so that every molecule striking the surface condenses.

The reasons that have led us to this conclusion apply with nearly equal weight to gas molecules of almost any kind striking any surface.<sup>1</sup>

Let  $\mu$  represent the number of gram molecules of gas striking each sq. cm. of surface per second. The quantity  $\mu$  can be readily calculated from the pressure by means of the following equation, derived from Equation 4:<sup>2</sup>

$$\mu = 43.75 \times 10^{-8} \frac{p}{\sqrt{MT}} \quad (13)$$

The rate at which gas condenses on the surface will then be  $\alpha\mu$ , where  $\alpha$  is a quantity usually very close to unity (never exceeding unity).

If the surface is that of a crystal, there will be a definite number of spaces,  $N_0$ , on each sq. cm. of surface capable of holding adsorbed gas molecules. A greater number of gas molecules can only be adsorbed by the formation of additional layers of molecules. The forces acting between two layers of gas molecules will usually be very much less than those

<sup>1</sup> There is good experimental evidence that this rule is not of universal application. When hydrogen molecules strike surfaces at room temperature apparently something like 80% are diffusely reflected. This probably represents nearly the extreme case. However, even if 80% of the molecules are reflected, the adsorption of the gas on a surface is only 5 times less than it would be if none were reflected. Therefore every gas must be adsorbed to some extent on every surface. The evidence in regard to the reflection and condensation of gas molecules on surfaces is given in detail in a recent article (*Phys. Rev.*, 8, 149 (1916)).

<sup>2</sup> The nomenclature used here is the same as that employed in a recent paper on the dissociation of hydrogen (*THIS JOURNAL*, 38, 1148 (1916)).

between the crystal surface and the first layer of molecules. The rate of evaporation in the second layer will, therefore, generally be so much more rapid than in the first, that the number of molecules in the second layer will be negligible.<sup>1</sup> When a gas molecule strikes a portion of the surface already covered, it thus evaporates so quickly that in effect it is equivalent to a reflection. Therefore, the rate of condensation of the gas on the crystal surface is  $\alpha\theta\mu$  where  $\theta$  represents the fraction of the surface which is bare. Similarly the rate of evaporation of the molecules from the surface is equal to  $\nu_1\theta_1$  where  $\nu_1$  is the rate at which the gas would evaporate if the surface were completely covered and  $\theta_1$  is the fraction actually covered by the adsorbed molecules. When a gas is in equilibrium with a solid surface these two rates must be equal so we have

$$\alpha\theta\mu = \nu_1\theta_1. \quad (14)$$

Furthermore

$$\theta + \theta_1 = 1. \quad (15)$$

Whence

$$\theta_1 = \frac{\alpha\mu}{\nu_1 + \alpha\mu}. \quad (16)$$

The quantity  $\theta_1$  is a measure of the amount of gas adsorbed. It should be noted that for low gas pressures the amount of adsorbed gas is proportional to the pressure, but as the pressure increases  $\theta_1$  increases more slowly and finally the surface becomes saturated ( $\theta_1 = 1$ ). These relations are in good qualitative agreement with known facts.<sup>2</sup>

Equation 16 indicates that at low temperatures (small value of  $\nu_1$ ) the amount of adsorption should be large and nearly independent of the pressure, while at higher temperatures (large value of  $\nu_1$ ) the amount of adsorption should be small, and should be proportional to the pressure even at high pressures. These deductions also are in qualitative accord with experimental facts.

From Equation 16 we see that the tendency of a gas to be adsorbed on a surface is determined by  $\nu_1$ , the rate of evaporation from the surface. This quantity in turn depends on the magnitude of the forces acting between the atoms of the crystal and those of the adsorbed substance.

<sup>1</sup> The detailed development of this theory of adsorption, taking into account the evaporation from each of the layers and other complicating factors, will be published as Part II of the paper in the *Phys. Rev.* References to previous literature on the subject will be given at that time. The present paper deals principally with the chemical aspects of the theory.

<sup>2</sup> Equation 16 gives the amount of adsorption on a plane crystal surface. No reliable quantitative experimental data seem to be available for the adsorption of gases on such surfaces. The writer is, therefore, undertaking measurements of this kind at present and will report the results at a later date. The theoretical reasons for believing that Equation 16 is not quantitatively applicable to adsorption by porous bodies such as charcoal will be discussed further on in this paper.

These forces will be of the same nature as those which hold solid bodies together. We may, therefore, profitably look upon them as chemical forces and apply our knowledge of the chemical properties in studying the phenomena of adsorption.

With a gas such as nitrogen, in which the atoms are mutually very thoroughly saturated, we know that there is only a weak field of force around the molecules. When a nitrogen molecule strikes a surface the forces holding it are only those due to weak secondary valence. It is to be expected, however, in general, that the forces by which molecules or atoms may be held on a surface, should show, for different substances, as great a range of intensity as is observed in the case of the forces acting inside of solid bodies.

Solid nitrogen is held together by comparatively weak forces, while the forces in solid carbon or tungsten are among the most powerful known. In the case of adsorbed films the magnitude of the forces should vary all the way from the weak forces observed with adsorbed nitrogen (or better helium) up to forces which are as intense as those holding together the atoms of the most stable chemical compounds. Just as we find either secondary or primary valences active between atoms in solids, so should we expect both kinds of valence to take part in the formation of adsorbed films. When we thus speak of adsorption as a chemical phenomena it should be remembered that we must also regard evaporation and condensation in general as chemical phenomena. The point to be emphasized is, that there is no real distinction between these so-called physical phenomena, and true chemical phenomena except that in general the "physical" phenomena depend on secondary valence rather than primary. Since, however, chemical phenomena involve secondary valence as well as primary, it seems best to classify all such phenomena as chemical. By so doing we do not in any way fail to recognize the close relationship between evaporation, condensation and the adsorption of the relatively inert gases.

This chemical theory of adsorption has received striking confirmation by many experiments in this laboratory.

**Experimental Evidence that Adsorption is a Chemical Phenomena.**—It has been found<sup>1</sup> that atomic hydrogen, produced by heating a metallic wire in dry hydrogen at very low pressures, has a remarkable tendency to be adsorbed on surfaces. According to the usual "physical" theory of adsorption by which the adsorbed film is assumed to be a layer of highly compressed gas we should expect that a gas of such low density as atomic hydrogen would be only slightly adsorbed. Furthermore, we should expect that an adsorption film in high vacuum would very rapidly reach equilibrium with its surroundings.

<sup>1</sup> Langmuir, *THIS JOURNAL*, 34, 1310 (1912).

The experiments showed, however, that even in the highest vacuum quantities of hydrogen as large as 0.01 to 0.03 cubic mm. (at atmospheric pressure) per sq. cm. could be adsorbed on cold glass, and that this adsorbed film was remarkably stable, being able to remain unchanged on the surface for several days. To account for these adsorption phenomena it was suggested in 1912<sup>1</sup> that "perhaps the unsaturated chemical affinity of the atomic hydrogen gives it unusual tendencies to be adsorbed on surfaces." It was observed that the amount of atomic hydrogen which could accumulate on a given surface was strictly limited and it was shown that this was not due to a balance between the rate at which atomic hydrogen spontaneously escaped from the surface, and the rate at which it was deposited. On the contrary, it was shown that the amount was limited because, after a certain amount of atomic hydrogen was present on the surface, fresh atoms of hydrogen striking the surface combined with those already present, and thus removed them.

It is interesting to compare the amount of atomic hydrogen adsorbed on the glass with the amount necessary to form a layer one atom deep. If we take the diameter of the hydrogen atom to be the same as that of the molecule, namely about  $2.5 \times 10^{-8}$  cm., we may conclude that the number of hydrogen atoms per sq. cm. needed to form a layer one atom deep is about  $1.6 \times 10^{15}$ . This corresponds to 0.032 cubic mm. of molecular hydrogen at 20° and one megabar pressure. The maximum amounts of atomic hydrogen which were found adsorbed on glass surfaces were of this same order of magnitude (0.01 to 0.03 cubic mm. per sq. cm.).

In a subsequent paper<sup>2</sup> it was shown that atomic hydrogen could diffuse several feet through glass tubes at room temperature, but could not pass even through a short tube cooled in liquid air. This may be taken as evidence that practically all hydrogen atoms striking a cold glass surface condense. With the glass cooled by liquid air these atoms do not evaporate at a perceptible rate, but from glass at room temperature they evaporate sufficiently rapidly to permit the passage of the atomic hydrogen through a long tube.

The experiments with atomic hydrogen thus furnish evidence that

1. The adsorption is determined by chemical affinity.
2. The adsorbed layer does not exceed one atom in thickness.
3. Hydrogen atoms striking glass surfaces are not reflected.

Similar evidence has been obtained from experiments with tungsten filaments in oxygen at low pressures. It was shown<sup>3</sup> that 15% of all oxygen molecules striking a tungsten filament at 2770° K. react with it to form  $\text{WO}_3$ . More recent experiments (as yet unpublished) have shown that this

<sup>1</sup> *Loc. cit.*, p. 1313.

<sup>2</sup> Freeman, *THIS JOURNAL*, 35, 927 (1913).

<sup>3</sup> Langmuir, *Ibid.*, 35, 105 (1913).

coefficient continues to increase at higher temperatures, so that at  $3300^{\circ}$  K. about 50% of all the oxygen molecules which strike the filament react with it to form  $\text{WO}_3$ . Since there are three atoms of oxygen in  $\text{WO}_3$ , and only two in the oxygen molecule, it is evident that *at least* one-half of the tungsten surface even at  $3300^{\circ}$  K. must be covered with oxygen in some form. When we consider that the pressure of oxygen in these experiments was usually not over 5 bars we realize the extraordinary stability of the film, and are thus led to believe that the oxygen atoms are held by chemical forces to the tungsten atoms which form the lattice structure of the tungsten crystals.

It is very evident that the adsorbed film does not consist of tungsten oxide  $\text{WO}_3$ , since this substance distills very rapidly from the filament even at temperatures as low as  $1200^{\circ}$  K. The film has no perceptible effect on the optical properties of the tungsten surface, since low pressures of oxygen do not cause any perceptible change in the characteristics (volts, amperes, candle-power) of the tungsten filament.

The existence of this oxygen layer on a tungsten filament in oxygen at low pressure, shows itself in many other ways. Thus a pressure of 0.001 bar of oxygen lowers the electron emission from a tungsten filament at  $1800^{\circ}$  to a very small fraction of its normal value. Even more striking evidence has been recently found in connection with experiments (as yet unpublished) with tungsten filaments in mixtures of various gases at low pressures. It is found that a tungsten filament at  $1500^{\circ}$  K. in a mixture of oxygen and hydrogen reacts with the oxygen exactly as if no hydrogen were present. While this oxidation of the tungsten is going on, none of the hydrogen reacts with the oxygen, and the hydrogen does not reduce any of the tungsten oxide<sup>1</sup> formed, nor is any atomic hydrogen produced. However, after all of the oxygen has been used up (partial pressure reduced to less than 0.01 bar) the hydrogen *suddenly* begins to disappear by being dissociated into atoms which then react with the  $\text{WO}_3$  previously deposited on the bulb.

Simultaneous measurements of the electron emission show that this emission increases suddenly at the same moment at which the hydrogen begins to disappear.

This experiment proves:

1. That in presence of even 0.01 bar of oxygen the surface of the tungsten at  $1500^{\circ}$  K. is practically completely covered with oxygen.
2. That this layer of oxygen will not react with hydrogen even at  $1500^{\circ}$  K.
3. That such a layer of oxygen prevents the formation of atomic hydrogen.

<sup>1</sup> This is especially remarkable since  $\text{WO}_3$  is readily reduced by hydrogen at atmospheric pressure at temperatures as low as  $500^{\circ}$ .

4. That the decrease in electron emission produced by oxygen is due to the same cause as that which prevents the dissociation of hydrogen.

It is very evident from this work that the oxygen layer has totally different properties from those we should expect, either with a layer of oxide, or a film of highly compressed gas. The facts are in good accord, however, with the theory that the oxygen atoms are chemically combined with the tungsten atoms. From this viewpoint the two primary valences of the oxygen are turned downwards, and are saturated by the tungsten, so that a hydrogen molecule striking the surface cannot react with the oxygen, and cannot come in contact with the tungsten. The hexavalent tungsten atoms, on the other hand, are not saturated by the oxygen, so that they are held firmly to the underlying layer of tungsten atoms. Only when the tungsten atoms on the surface become saturated by taking up two other oxygen atoms do they cease to be held to the other tungsten atoms, and thus evaporate off as  $\text{WO}_3$ .<sup>1</sup>

The stability of the oxygen layer is due to the strength of the chemical union between oxygen and tungsten atoms, which results in a very slow rate of evaporation of the oxygen atoms from the surface.

The action of oxygen in preventing the dissociation of hydrogen by a heated tungsten filament is clearly that of a *catalytic poison*. It has been shown previously<sup>2</sup> that the dissociation of hydrogen takes place only among hydrogen molecules adsorbed on the surface of the tungsten. The only way in which oxygen can prevent such action in a high vacuum is by the actual presence of oxygen atoms on the surface. Since the dissociation at  $1500^\circ \text{K}$ . is entirely prevented by the oxygen, and since the range of atomic and molecular forces does not exceed the dimensions of the atoms, it must follow that much more than half the surface must be covered by oxygen atoms or molecules. For if the surface were only half covered, then, according to probability laws, uncovered areas several times as large as the diameters of atoms would not be of rare occurrence, and on these areas dissociation could occur.

Now if this adsorbed oxygen were present on the surface as a layer of compressed gas<sup>3</sup> it would be inconceivable that it should not react at all

<sup>1</sup> The fact that the tungsten atoms leave the surface only after they have been completely saturated chemically seems to be an example of a general tendency. Thus when tungsten is heated in chlorine at very low pressures the hexachloride  $\text{WCl}_6$  only is formed, although several stable lower chlorides of tungsten exist. When Pt is heated at high temperatures in oxygen at moderate pressures the oxide  $\text{PtO}_2$  distills from the surface, while an osmium filament in oxygen at low pressures gives  $\text{OsO}_4$ . Molybdenum in oxygen gives only  $\text{MoO}_3$ .

<sup>2</sup> THIS JOURNAL, 38, 1145 (1916).

<sup>3</sup> The commonly accepted theories of adsorption are based upon the assumption that there is a transition layer (van der Waals) in which the density varies gradually from that of the solid or liquid phase to that of the surrounding gas. Eucken (*Verh. deut. physik. Ges.*, 16, 345 (1914)), for example, considers that this transition layer is a

with hydrogen at a temperature of  $1500^{\circ}$  K. Even if we should regard the adsorbed layer as consisting of adsorbed tungsten oxide we would be no nearer an explanation, for tungsten oxide is readily reduced to metallic tungsten by hydrogen at temperatures of  $500^{\circ}$ . We should have to say, with Bancroft, that the oxide is stabilized by adsorption. But, of course, this is a mere description and not an explanation of the phenomena.

It is very clear that the oxygen by being adsorbed has undergone a complete change in chemical properties and it is certainly not logical to consider that this has been brought about by a mere compression of the gas into a surface layer.

If, however, we assume that the oxygen atoms are chemically combined to the mass of the tungsten filament and form a *continuous* surface layer, all of the observed facts are readily accounted for. The oxygen atoms are saturated chemically by the tungsten (primary valence) and the field of force holding the oxygen atoms lies wholly below the surface where hydrogen molecules cannot reach it. When the pressure of oxygen falls so low that the supply of this gas at the surface is not sufficient to make up for the loss by evaporation, then gaps are formed in the continuous covering and the hydrogen is then able to make a *flank attack* on the oxygen. In this way the oxygen covering is *suddenly* removed when the pressure of oxygen falls below a certain critical value, and the dissociation of hydrogen, therefore, begins at once.<sup>1</sup>

The resemblance between the action of oxygen on a tungsten filament and the phenomena of electrochemical passivity is very striking, so much so, in fact, that the mechanism of passivity is probably similar to that of the effects described above.<sup>2</sup>

According to this theory the effect of oxygen in poisoning the catalytic activity of tungsten is due to the formation of an exceptionally stable film of oxygen which is combined with and completely covers the surface of the tungsten.

The effects of the poisoning of tungsten by oxygen are also to be seen in many other reactions in gases at low pressures (10–100 bars), of which the following may be briefly mentioned.

sort of miniature atmosphere. Bakker (*Z. physik. Chem.*, 89, 1 (1915)) has a similar theory to account for surface-tension phenomena.

<sup>1</sup> The strongest evidence of the correctness of this theory is obtained from experiments at higher filament temperatures than  $1700^{\circ}$  K. The hydrogen and oxygen then begin to react with each other on the surface of the filament. The further development of this theory is reserved for a future paper, in which the detailed experimental results will be published.

<sup>2</sup> An outline of this theory of passivity together with a brief description of the experiments with mixtures of oxygen and hydrogen in contact with a hot tungsten filament was given by the writer in a discussion of Bennett and Burnham's paper on Passivity, at the Washington meeting of the American Electrochemical Society, April 28, 1916. This discussion has been published in Vol. 29 of the Transactions.

When a tungsten filament is heated in a mixture of carbon monoxide and oxygen, tungsten is oxidized just as if no carbon monoxide were present. None of the CO reacts with the oxygen even when the filament is heated as high as  $2800^{\circ}\text{K}$ ., whereas hydrogen begins to react with oxygen in contact with a tungsten filament when the temperature exceeds about  $1700^{\circ}\text{K}$ . Evidently CO will not combine with oxygen adsorbed on a heated tungsten filament even if it has a chance to make a "flank attack."

Mixtures of methane and oxygen at low pressures do not react with one another in contact with tungsten at  $1500^{\circ}$  or even  $1800^{\circ}\text{K}$ . but the tungsten is oxidized to form  $\text{WO}_3$  as in the previous cases. In absence of oxygen, methane is gradually decomposed, setting free hydrogen, while the carbon is taken up by the tungsten filament, forming a solid solution. Even this action is prevented by the presence of traces of oxygen. On the other hand, if the filament is first heated in methane, so that it has taken up carbon, and then oxygen is admitted, the oxygen reacts with the carbon in the filament forming CO, and until all the carbon from the surface layers has been removed, the oxygen does not react with the tungsten. This proves that when carbon is taken up by tungsten some of the carbon remains as an adsorbed layer of carbon atoms.

Dry ammonia at low pressures is decomposed fairly rapidly by a tungsten filament at  $1000^{\circ}\text{K}$ . but with a platinum filament the same rate of decomposition only occurs at a temperature of nearly  $1400^{\circ}\text{K}$ . In the presence of small amounts of oxygen, however, the tungsten filament fails to decompose ammonia even at  $1200^{\circ}\text{K}$ . At  $1300^{\circ}\text{K}$ . the tungsten oxidizes just as if the ammonia were absent, the oxide  $\text{WO}_3$  distilling to the bulb. Some of the ammonia seems to react with the oxygen, but with an excess of ammonia this reaction goes on slowly until the oxygen is consumed, and the remainder of the ammonia is then rapidly dissociated. The oxygen thus poisons the tungsten even in the case of the simple dissociation of ammonia by heat. In contact with platinum, however, ammonia and oxygen react together at a temperature well below  $1000^{\circ}\text{K}$ . Particularly interesting effects are observed when a tungsten or platinum filament is heated in mixtures of cyanogen and oxygen. In this case, with a filament at  $1500^{\circ}\text{K}$ . the oxidation of the tungsten is largely prevented until the cyanogen has been slowly oxidized to carbon monoxide and nitrogen. If there is an excess of oxygen this then reacts with the tungsten when the supply of cyanogen is used up. Any excess of cyanogen is decomposed by the filament giving nitrogen, the carbon being taken up by the filament. Thus cyanogen may be looked upon as having a stronger poisoning effect on tungsten than oxygen has.

It is well known that cyanogen poisons the catalytic activity of platinum. Experiments at low pressures furnish a remarkable demonstration of this fact.

A platinum filament at a temperature of  $600^{\circ}$  K. causes carbon monoxide and oxygen to combine rapidly, the carbon monoxide, however, itself, acting as a catalytic poison.<sup>1</sup> At higher temperatures ( $900^{\circ}$  K.) the poisoning effect of the carbon monoxide disappears and the velocity of the reaction becomes enormously high, being then limited only by the rate at which the two gases can come into contact with the platinum surface, according to Equation 4.

But if a trace of cyanogen is added to the mixture of oxygen and carbon monoxide (at a pressure of 10 bars) the catalytic action of the platinum disappears completely even at  $900^{\circ}$  K. By raising the temperature to about  $1000^{\circ}$  the cyanogen reacts with the oxygen to form nitrogen and carbon monoxide. As soon as the cyanogen is all oxidized the catalytic activity of the platinum is restored and the oxygen and carbon monoxide then react rapidly to form carbon dioxide.

The catalytic effect of platinum on the reaction between oxygen and hydrogen is also poisoned by traces of cyanogen. If the temperature of the platinum is then raised, the cyanogen and hydrogen react together to form hydrocyanic acid.

The fact that these low pressures of cyanogen (or oxygen) can exert such a powerful poisoning effect is proof that adsorbed films of great stability are formed, in other words, films in which the rate of evaporation of the adsorbed molecules is remarkably low. The effect of these poisons is thus merely to cover up the active surface.

The property of cyanogen in poisoning metallic catalyzers is thus closely related to the chemical facts that cyanogen forms very stable compounds with metals, and shows an unusual tendency to form complex salts. The cyanogen radical is one in which both the primary and the secondary valences are strongly developed.

Water vapor has the same effect in poisoning the catalytic activity of tungsten that oxygen has. A partial pressure of 0.4 bar of water vapor (vapor pressure of water at  $-78^{\circ}$ ) is sufficient to prevent the dissociation of hydrogen by a tungsten filament at  $1500^{\circ}$  K.

It is a remarkable fact that carbon dioxide, although it oxidizes a tungsten filament to form  $WO_3$ , does not have any effect upon the rate of dissociation of hydrogen. We must, therefore, conclude in this case that only a very small fraction of the tungsten surface is covered by adsorbed oxygen. This conclusion is also supported by the fact that the rate of oxidation of tungsten by carbon dioxide is extremely slow compared to the rate of oxidation by oxygen. We shall see that further evidence of the same kind is furnished by measurements of the electron emission. However, since the oxygen from at least two molecules of carbon dioxide

<sup>1</sup> Langmuir, *THIS JOURNAL*, 37, 1163 (1915).

is needed to produce a molecule of  $\text{WO}_3$ , it is certain that the reaction depends upon the presence of adsorbed oxygen partially covering the surface. The velocity of the reaction between carbon dioxide and tungsten seems to be approximately proportional to the square root of the pressure of  $\text{CO}_2$  and inversely proportional to the pressure of carbon monoxide.

When molybdenum filaments are heated in oxygen at low pressures the filaments become tarnished unless the temperature is maintained above  $1500^\circ \text{K}$ . Above this temperature the surface of the filament remains apparently clean, and the oxide formed,  $\text{MoO}_3$ , distills to the bulb. With tungsten, notwithstanding the fact that  $\text{WO}_3$  is much less volatile than  $\text{MoO}_3$ , it is only necessary to keep the temperature above about  $1250^\circ$  in order to have a clean surface.

Although oxygen is clearly adsorbed on molybdenum, it appears that the stability of the film is much less than that of the corresponding film on tungsten. This is shown not only by the electron emission (see below), but by the comparatively small effect of oxygen in poisoning the catalytic activity of molybdenum. Thus when molybdenum is heated to a temperature between  $1500$  and  $1800^\circ \text{K}$ . in a mixture of oxygen and hydrogen, it is found that the hydrogen disappears slowly until the oxygen is all used up, by reacting with the molybdenum. After that the rate of disappearance of the hydrogen is much greater. The fact that a part of the hydrogen disappears before the oxygen is consumed indicates that the poisoning effect of the oxygen is not complete.

Experiments with carbon filaments in oxygen, and in carbon monoxide or dioxide<sup>1</sup> have shown that oxygen acts as a catalytic poison, on the reaction between oxygen and carbon, and on that between carbon dioxide and carbon. It was also proved that this poisoning effect is due to a remarkably stable film of adsorbed oxygen, so stable in fact that the filament must be heated in a good vacuum for nearly half an hour at  $2300^\circ \text{K}$ . in order to distill it off. In this case there is very clear evidence that this film consists of oxygen atoms chemically combined by primary valences to the carbon atoms forming the body of the filament, according to the formula

A very peculiar case of adsorption occurs when a tungsten filament

<sup>1</sup> THIS JOURNAL, 37, 1154 (1915).

is heated to about  $2700^{\circ}$  K. in a low pressure of carbon monoxide contained in a bulb cooled by liquid air.<sup>1</sup>

With the bulb at this temperature the tungsten filament is attacked by the CO and a very stable adsorbed film is formed on the filament. This distills off at a constant rate (independent of the pressure of CO) taking the tungsten with it as a compound of the composition WCO. The most remarkable fact is that when the temperature of the bulb is raised to  $20^{\circ}$  or above, the CO no longer attacks the tungsten of the filament, but combines only with the tungsten which evaporates from the filament, still forming the compound WCO.

Before attempting to look for the probable mechanism of this action let us consider one more case of adsorption: that of nitrogen by *molybdenum vapor*. When a molybdenum filament is heated to  $2200^{\circ}$  K. in nitrogen contained in a bulb cooled in liquid air, nearly every molybdenum atom evaporating from the filament combines with the *first* nitrogen molecule which it strikes to form a compound  $\text{MoN}_2$  (stable at  $360^{\circ}$  in a vacuum). When the bulb is at room temperature the molybdenum atoms still combine with the first nitrogen molecule they strike, but most of the molecules thus formed are so unstable that they decompose when they strike the bulb, giving nitrogen and a spongy molybdenum deposit.

Thus when the nitrogen is at low temperature the compound appears to be  $\text{MoN}_2$  in which the atoms are held by primary valence, while the compound formed with the nitrogen at higher temperatures is  $\text{Mo} : \text{N}_2$ , in which the nitrogen and molybdenum are held by secondary valence. This seems then to be a kind of adsorption of one gas by another.

A somewhat similar explanation seems necessary for the reaction between tungsten and carbon monoxide. Thus when carbon monoxide molecules of low velocity and low internal energy (low temperature) strike the surface of the filament they combine with it by primary valences to form a stable structure, probably as follows:

The strength of the union between the oxygen and carbon, and between the tungsten and carbon, is so great, that the whole group WCO distills off as a single molecule. The fact that the tungsten is partially saturated

<sup>1</sup> A brief preliminary account of these experiments was published in *THIS JOURNAL*, 37, 1160 (1915). A more detailed paper will be presented later.

by the carbon should make this group somewhat more volatile than the tungsten itself. As a matter of fact the rate of evaporation of the WCO from the surface is only about five times greater than that of tungsten.

When the temperature of the bulb is higher, so that the CO molecules possess more internal energy (and a higher velocity) the CO is incapable of combining with the solid tungsten in the above manner. We must still assume that nearly every CO molecule which strikes the filament condenses on it, but that the union in this case is by secondary valence, so that the molecule almost immediately distills off again.

A more thorough study of this reaction may throw some light on the paradox that the residual valence of CO is small, although this substance contains a divalent carbon atom.

### **The Effect of Gases on the Electron Emission from Heated Metals as Evidence of the Presence of Stable Adsorbed Films.**

The effect of adsorbed films of the thickness of a single molecule on the electron emission from heated tungsten filaments was described by the writer in 1913.<sup>1</sup> A little later<sup>2</sup> the following theory of the effect was proposed. "The decrease in the electron emission from a hot cathode caused by certain gases is due to the formation of a film on the surface of the cathode. Whether this film consists of adsorbed gas, or of a chemical compound of the gas with the cathode material, is not definitely established, but most of the evidence is in favor of the latter view. The amount by which the electron emission is affected depends on the *extent* to which the surface is covered. The film should be looked upon as consisting of a single layer of molecules, or at most, of a very few layers. The extent to which the surface of the cathode is covered by the film depends upon: (1) The rate of formation of the film. (2). The rate of destruction of the film," etc.

The more recent work on chemical reactions at low pressures, and further experiments on electron emission, have furnished abundant evidence of the correctness of the above viewpoint, and have fully verified the conclusion that the film is held to the surface by chemical forces.

In every case with tungsten, chemically inert gases have been found to be without effect on the electron emission, whereas nearly all gases that react with the tungsten lower the emission.

The decrease of the electron current produced by a gas is thus caused by the formation of an adsorbed film of great stability, which covers the surface. The evidence is very strong that the electron emission at a given temperature depends only on the nature of the layer of atoms forming the actual surface of the filament. Here again we have proof of the ab-

<sup>1</sup> Langmuir, *Phys. Rev.*, **2**, 450 (1913).

<sup>2</sup> *Physik. Z.*, **15**, 520 (1914).

sence of a transition layer in which the density varies gradually from that of the filament to that of the surrounding space.

The lowering of the electron emission of heated filaments by adsorbed films thus bears a close relationship to the effect of these films in poisoning the catalytic activity of the filament. Both effects are caused by a film of great stability which covers the surface. The following experimental evidence shows, in fact, that there is a remarkable parallelism between the electron emission and the catalytic activity of a filament.

As has already been pointed out, oxygen enormously lowers the electron emission from tungsten. This effect of oxygen is in accord with its action as a catalytic poison for tungsten. Thus in mixtures of oxygen and hydrogen the electron emission undergoes a sudden increase at the moment at which the hydrogen begins to dissociate (after the consumption of all the oxygen).

It might be thought that the electron emission itself would have an effect on the chemical reactions occurring on the surface of a heated filament. But experiment has never shown any such direct effect. Thus the rate at which oxygen, hydrogen, carbon dioxide, and other gases disappear in contact with heated tungsten are found to be entirely independent of the thermionic currents. The presence of a negatively charged electrode close to the heated filament causes all electrons emitted to be driven back into the filament, but this does not affect the rate of disappearance of the gases. In some cases, however, electric discharges do cause the clean-up of gases, but this effect is due to the bombardment of the filament by positive ions, and not to the electron emission.

Nitrogen does not normally attack a tungsten filament at any temperature, although it combines (to form  $WN_2$ ) with tungsten vapor as fast as this evaporates from the filament.<sup>1</sup> Similarly nitrogen has no effect on the electron emission from tungsten if low voltages are used in making the measurements of the thermionic current. But if voltages high enough to cause ionization of the nitrogen are employed, then the tungsten is attacked by the rapidly moving positive nitrogen ions, and simultaneously the electron emission is greatly decreased, indicating that a film of adsorbed nitrogen is formed. If the filament is now allowed to cool to room temperature and the remaining nitrogen is pumped out, and the filament is then heated again to the same temperature as before, it is found that the electron emission is at first the same as it was in the presence of the nitrogen, showing that the electron emission is determined not by the gas around the filament, but by the film adsorbed on it. Gradually the adsorbed film distills off, and the electron emission returns to its normal value.

By the study of such lag effects, the rate of evaporation and the rate of

<sup>1</sup> THIS JOURNAL, 35, 931 (1913).

formation of the adsorbed films can be measured with accuracy, and it has thus been proved that the fraction of the surface covered often depends upon a dynamic equilibrium.

The fact that the rate of evaporation of these films even at temperatures of  $1800^{\circ}$  K. is slow enough to measure proves that they are remarkably stable.

Extremely interesting phenomena are observed after a tungsten filament has been heated in  $\text{CH}_4$  or  $\text{C}_2\text{N}_2$ , or other gas which gives up carbon to the filament. The most minute trace of carbon,<sup>1</sup> in the surface of the filament cuts down the electron emission to about one-third of that of an uncontaminated filament. But a filament which has taken up carbon is no longer sensitive to the effect of bombardment by positive nitrogen ions. In other words nitrogen has no effect on the electron emission from such a filament even if high anode voltages are used. Still more remarkable is the fact that oxygen instead of lowering the electron emission of a carbon-containing filament gradually raises it. The carbon is then gradually oxidized and the electron emission returns to the value corresponding to pure tungsten. Then when the carbon has all been removed, the oxygen begins to attack the tungsten and the electron emission suddenly decreases to one per cent. or less of its former value. After the excess oxygen has been consumed it is found that the electron emission is again sensitive to the effect of bombardment by positive nitrogen ions, the thermionic current decreasing as the voltage is raised.

This experiment is an excellent demonstration of the closeness of the relationship between the electron emission and the chemical activity of the filament.

Another illustration is afforded by the fact that water-vapor, which reacts rapidly with tungsten, and poisons the tungsten surface, has as great an effect on the electron emission as oxygen, while carbon dioxide, which reacts slowly with tungsten, and is not a catalytic poison, has practically no effect on the electron emission.

So far we have considered the effects of gases on the electron emission from tungsten. Striking effects of another kind are obtained when the filament contains minute amounts of thorium.<sup>2</sup> If such a filament is heated in a very high vacuum to  $2900^{\circ}$  K. for a short time and the electron emission at  $1800^{\circ}$  K. is then measured, it is found that the emission is the same as that of pure tungsten. By now heating the filament a few minutes at a temperature between  $2000^{\circ}$  and  $2500^{\circ}$  K. (preferably  $2300^{\circ}$  K.),

<sup>1</sup> Probably just enough to form a layer one atom deep over the surface of the filament is sufficient.

<sup>2</sup> An account of these phenomena was given before the American Phys. Soc., Oct. 31, 1914 (*Phys. Rev.*, 4, 544 (1914)). A paragraph describing the effect was given in a paper before the American Electrochemical Soc. (see *Trans. Am. Electrochem. Soc.*, 29, 353 (1916)).

the electron emission at  $1800^{\circ}$  K. is found to have increased enormously (more than 10000 fold). By heating again to  $2900^{\circ}$  the emission returns to its normal value.

This effect is due to the formation of an adsorbed layer of thorium atoms on the surface of the filament. At  $2900^{\circ}$  K. the thorium, being more volatile than tungsten, distills off the surface and leaves pure tungsten. At  $2300^{\circ}$  K. however, the rate of distillation is not very marked, but the rate of diffusion of the thorium through the tungsten is sufficient to allow the accumulation of thorium atoms on the surface. At  $1800^{\circ}$  the rate of diffusion is negligible, so that if the thorium is distilled off a fresh supply does not diffuse to the surface.

The tendency of thorium to form an adsorbed film on tungsten is in accord with other properties of thorium. Gibb's has shown that any substance which lowers the surface energy tends to be adsorbed on the surface. The Eötvös-Ramsay-Shields relation indicates that the surface energy of a substance at temperatures low compared to its critical temperature, should be approximately proportional to  $T_c A^{-2/3}$  where  $T_c$  is the critical temperature and  $A$  is the atomic volume. Now the critical temperature of thorium must be lower than that of tungsten, since the vapor-pressure of thorium is considerably greater than that of tungsten. The atomic volume of thorium is about 21, while that of tungsten is 9.6. Thus both  $T_c$  and  $A$  differ, for these metals, in such a way as to make the surface energy of thorium less than that of tungsten. Therefore, according to Gibb's rule thorium should tend to be adsorbed on the surface of tungsten.

By a study of the rate of growth of the adsorbed film at  $2100^{\circ}$  K. and the rate of evaporation at  $2700^{\circ}$  K. it has been possible to prove that the film grows until it is one atom deep but does not grow beyond this.<sup>1</sup> The real evidence in favor of these conclusions, however, can only be given in connection with a full discussion of the detailed experimental results. It is intended to publish these before long.

When oxygen is brought into contact with a tungsten filament (at  $1900^{\circ}$  K.) coated with a layer of thorium atoms, the electron emission is suddenly decreased to a value far below that corresponding to pure tungsten. With tungsten the effect of oxygen in decreasing the emission disappears as soon as all the oxygen has been consumed. But with a thorium-coated filament the effect of oxygen is more permanent, so that the emission remains low even after all oxygen has been removed. Only by heating the filament to  $2900^{\circ}$  and following this by a treatment at  $2300^{\circ}$  can the

<sup>1</sup> That the layer is never more than one atom deep is readily proved by the fact that the activity of the film always begins to decrease *at once* at  $2700^{\circ}$  no matter how long it may have been previously heated at  $2300^{\circ}$  K.

activity be restored. This behavior is in accord with the known facts that thorium has an unusually strong affinity for oxygen.

In the case of this oxidized thorium-coated filament the adsorbed film evidently consists of a layer of thorium atoms covered by a layer of oxygen atoms. It should not be looked upon as a layer of adsorbed thorium oxide.

Interesting effects are observed if a small amount of methane is brought into contact with an oxidized thorium-coated tungsten filament at about  $1900^{\circ}$  K. The electron emission suddenly increases to that of pure thorium, and then as suddenly decreases to a value below that of pure tungsten. The methane reacts with the oxygen on the surface of the filament, forming carbon monoxide, which evaporates off, leaving the layer of thorium atoms. The excess of methane is then decomposed, and a layer of carbon atoms is formed on the surface of the filament, and covers the thorium atoms. The electron emission then becomes that of a carbon surface which is a little less than that of tungsten, notwithstanding the presence of thorium atoms just under the surface layer.

Kruger and Taegge<sup>1</sup> have recently studied the effect of catalytic poisons on the photoelectric activity of platinum, using ultraviolet light. They find that minute traces of  $H_2S$ ,  $HCN$  or  $CO$  very greatly decrease the photoelectric electron emission. The mechanism of this action is undoubtedly identical with that of the effect on the thermionic electron emission. Debye<sup>2</sup> and Richardson<sup>3</sup> have shown that there is a very close relationship between the photoelectric and thermionic electron emission.<sup>4</sup>

**Adsorption Phenomena at Higher Gas Pressures.**—The effect of poisons on the activity of catalyzers is essentially the same with gases at atmospheric pressure as at lower pressures. There is every reason for believing that the theory of adsorption outlined in the preceding pages is applicable to the adsorption of gas at atmospheric pressures. In the second part of this paper we shall see that a similar theory also applies to adsorption in surface layers of liquids.

As the pressure of a gas increases the amount adsorbed on a plane surface should gradually increase until the surface becomes completely covered by a layer one molecule (or atom) deep. The surface thus becomes *saturated*. This is in full accord with experimental facts.

In the case of the adsorption of vapors at such high pressures that they approach the state of saturated vapors, there will be a tendency for the adsorbed film to become several molecules deep.

<sup>1</sup> *Z. Electrochem.*, **21**, 562 (1915).

<sup>2</sup> *Ann. Phys.*, **33**, 441 (1910).

<sup>3</sup> *Phil. Mag.*, **23**, 266, 615 (1912); **24**, 570 (1912).

<sup>4</sup> For a review of the recent work on this subject and its relation to contact potentials see a paper by Langmuir, *Trans. Am. Electrochem. Soc.*, **29**, 341 (1916).

According to this theory it is very improbable that films more than one or two molecules deep would ever be held on a surface by adsorption, except with nearly saturated vapors. We must assume that after a layer two or three molecules deep is formed, the rate of evaporation of additional molecules would be nearly identical with that from the liquefied or solidified gas. If the vapor pressure were well below saturation, the rate at which such additional molecules would condense in the surface would be much less than the rate at which they would evaporate. The adsorbed film would thus grow thinner.

There is considerable experimental evidence that the amount of moisture taken up by glass surfaces is greatly in excess of the amount needed to form a layer one molecule deep.

When a 40-watt incandescent lamp bulb is heated to  $500^{\circ}$  for several hours (after having been exhausted and dried out at room temperature) it gives off about 0.45 cc. of water vapor, 0.030 cc. of carbon dioxide, and 0.005 cc. of nitrogen.<sup>1</sup> The internal surface of this bulb was about 200 sq. cm. The number of molecules of gas given off per sq. cm. was thus  $56 \times 10^{15}$  molecules of  $H_2O$ ;  $37 \times 10^{15}$  molecules of  $CO_2$  and  $0.6 \times 10^{15}$  molecules of  $N_2$ . If we calculate the number of molecules of each of the gases necessary to cover a sq. cm. one molecule deep (taking the molecules to be cubical in shape) we find  $1.0 \times 10^{15}$  for  $H_2O$ ;  $0.77 \times 10^{15}$  for  $CO_2$  and  $0.67 \times 10^{15}$  for  $N_2$ . Thus the quantities of gas obtained from this bulb correspond to: a layer of water 55 molecules deep, a layer of carbon dioxide 4.8 molecules deep and a layer of nitrogen 0.9 molecule deep.

The adsorption(?) of water vapor by pulverized synthetic quartz and anorthite has been studied by J. R. Katz.<sup>2</sup> The amount of water taken up reaches a fairly definite limit when the vapor pressure of the water is about 0.7 of the saturated vapor. The quantities of water adsorbed per sq. cm. of surface under these conditions were  $1.3 \times 10^{-6}$  grams for quartz and  $6.2 \times 10^{-6}$  grams for anorthite. These correspond to layers of water 43 and 205 molecules deep, respectively. Freundlich<sup>3</sup> reviews the literature on the thickness of adsorbed films, and comes to the conclusion that these films in general range from  $10^{-7}$  to  $10^{-6}$  cm. in thickness. Since the diameters of atoms and molecules usually lie between  $2 \times 10^{-8}$  and  $5 \times 10^{-8}$  cm., the adsorbed films, according to Freundlich, should be many molecules thick. The evidence on which this conclusion is based is very meagre, and for the most part is quite indirect. The best data referred to are probably those of Ihmori.<sup>4</sup> According to Freund-

<sup>1</sup> Langmuir, *Trans. Am. Inst. Elec. Eng.*, 32, 1921 (1913).

<sup>2</sup> *Proc. Amsterdam Acad.*, 15, 445 (1912).

<sup>3</sup> "Kapillarchemie," Leipzig (1909), p. 265.

<sup>4</sup> *Wied. Ann.*, 31, 1006 (1887).

lich, Ihmori "found with polished metals (brass, steel, etc.) thicknesses for the surface layer of water ranging between 3 and  $10 \times 10^{-7}$  cm.; and with quartz, an average thickness of  $22 \times 10^{-7}$  cm."

However, by referring to Ihmori's original article, it appears that this investigator found that the amount of "adsorbed" moisture increased greatly (about 10 fold) if the metal had previously been allowed to stand in the air for a few weeks. With carefully cleaned (polished or ignited) platinum he could not detect any adsorption whatever, that is, the adsorbed film in this case must have been less than  $2 \times 10^{-8}$  cm. thick. Ihmori says "the small amount of water adsorbed by the metals designated as 'polished' is, perhaps, due to the presence of a thin film of oxide."

In Ihmori's experiments the pressure of the water vapor was about 92% of that at saturation.

From the cases considered above it appears that certain surfaces adsorb moisture in quantities very large compared to that necessary to form a layer one molecule thick. There is no evidence, however, that in any of the cases studied the phenomena is a true adsorption.

The term adsorption should be restricted to gas taken up *on a surface* without any penetration of the gas molecules between the atoms or molecules of the solid surface. The theory of adsorption developed in this paper indicates that the amount thus truly adsorbed should never exceed a layer one or two molecules in thickness.

But there is no reason whatever why molecules of gas or vapor should not penetrate in between atoms of the surface and thus be absorbed. Dried jellies can absorb large quantities of moisture, and dehydrated salts usually absorb moisture even when no definite hydrates are formed (solid solutions).

The absorption of moisture by a surface of glass is to be looked upon as a process of solution of the water into the glass. Dried sodium silicate absorbs moisture in this way in very large quantities, and it is not at all surprising that this property should not be wholly lost, when lime and other oxides are fused with the alkali silicate. The whole behavior of glass surfaces in giving up their moisture confirms this theory that the moisture penetrates to a very considerable depth into the surface. The remarkable slowness with which the moisture is given up on heating, and the length of time needed for the reabsorption of the moisture indicate that we are not dealing with a true adsorption phenomena.

In the case of Katz's experiments with anorthite and quartz, there is probably also a penetration of the moisture into the crystal substance. It is, however, quite possible that what he measured was the moisture actually condensed as liquid in the fine capillary spaces between the grains of the extremely fine powder experimented with.

We may safely assume that water vapor would not penetrate at all into

a metal, so that a *clean* metal surface should never take up more moisture than enough to form a layer one molecule deep. This is in accord with Ihmori's results, since he could not detect absorption of moisture by platinum. The other metals used by Ihmori all oxidize in contact with air. The oxide layer formed is usually thick enough to see. When we consider that a film of metallic *tungsten* ten atoms thick only absorbs about 20% of the light striking it, it is evident that a film of *oxide* thick enough to see must be of very great thickness compared to that of a molecule. Furthermore, such a film must be quite porous, since the oxygen required for its growth must have diffused through it. It is, therefore, not remarkable that relatively large quantities of moisture are absorbed by such films.

**Adsorption by Porous Bodies.**—Nearly all quantitative measurements of the adsorption of gases by solids have been made with porous bodies such as charcoal. In these cases it is impossible to know definitely the area on which adsorption takes place.

It is often assumed that the surface of even a polished metal is porous to such an extent that its "true surface" is much greater than its apparent surface. As far as the writer knows, there is no experimental evidence to support any such assumption and theoretical considerations would make it seem extremely improbable. The strong surface forces (quite analogous to that in liquids) would tend to make the atoms in the surfaces of solids arrange themselves in such a way as to make the total surface a minimum. Therefore, in the absence of definite causes which produce a porous structure (such as those considered below), we should assume that the atoms of the surfaces are packed closely together and are arranged with considerable regularity. Thus a surface of glass should not be considered as porous, although it is capable of absorbing considerable quantities of moisture. The absorption is here a solution process, in other words, a chemical change by which the water molecules become combined (secondary valence) with the atoms of groups of atoms forming the glass. There is no more reason for assuming a porous structure than there is in the case of a liquid.

Truly porous bodies, such as charcoal, probably consist of atoms combined together in branching chains of great complexity. The fibers of cellulose from which charcoal is usually formed probably consist of practically endless groups of atoms

valences in the direction of their length and by secondary valence in the transverse directions. When the hydrogen and oxygen atoms are driven out by heat, the carbon atoms for the most part remain in their chains, but a certain number of cross linkages occur between these chains. The

porosity of the charcoal thus undoubtedly extends down to atomic dimensions. The unsaturated state of the remaining carbon atoms explains the practical impossibility of removing the last traces of oxygen and hydrogen from any form of amorphous carbon.

It is evident that with a structure of this kind, it is meaningless to talk about the surface on which adsorption can take place. With plane surfaces, we have seen that adsorption is usually limited to the formation of a layer one molecule deep, so that we can estimate the maximum adsorption from the extent of the surface. With charcoal, on the other hand, there is no definite surface which can be covered by a layer one molecule deep. Between the atoms of carbon, there must be spaces of all possible sizes and shapes, some just too small to hold a gas molecule, others big enough to hold one but not hold two, etc. There are some spaces in which a molecule would be closely surrounded by carbon atoms on nearly all sides, whereas in other places a molecule would be able to hold on to only a single carbon atom. Under these conditions there will be some spaces from which evaporation of adsorbed molecules would occur very slowly and others from which it would take place much more rapidly. There would be, however, a fairly sharp limit to the number of molecules which could come into intimate contact with carbon atoms. This limit would correspond to the saturated state observable in adsorption even by porous bodies. But it is evident that Equations 14, 15 and 16 which apply to adsorption by plane surfaces, could not apply to adsorption by charcoal. The real reason for this failure is that we can no longer assume (as in the derivation of Equation 14) that the rate at which the adsorbed gas evaporates from the surface is proportional to the amount present on the surface.

Strong support for the above views on the structure of porous bodies and the nature of adsorption by them is furnished by experiments in which molybdenum filaments were vaporized in nitrogen at low pressures. These experiments will be described in a future publication.<sup>1</sup>

### General Conclusions Regarding Kinetics of Heterogeneous Reactions.

The theory developed in this paper and the experimental work on electron emission and chemical reactions at low pressures leads to the following conclusion: *In a heterogeneous chemical reaction, the activity of a surface depends in general upon the nature of, the arrangement of, and spacing of the atoms forming the surface layer.* The atoms forming the second layer below the surface are of importance only insofar as they determine the arrangement of the surface atoms.

In the second part of this paper, it will be shown that the surface tension in liquids depends upon these same factors, in other words, it de-

<sup>1</sup> A brief preliminary description of these results was given in *THIS JOURNAL*, 37, 1159 (1915).

pend<sup>o</sup>s primarily upon the *surface layer of atoms* and only secondarily upon the group molecules of which these atoms form parts.

According to this view, the velocity of reactions in general is not limited by the rate of diffusion through an adsorbed film, but by the rate at which the molecules strike (according to Equation 4) against that portion of the surface which is active. Of course, there are many chemical processes which are actually limited by physical factors, such as the rate of diffusion through layers of gas or moderately thick films covering the solids substances. The rusting of iron, the oxidation of aluminum, the solubility of very soluble salts, etc., are examples of this type. But there is no present justification for believing that such physical factors determine the velocity of the typical catalytic reactions.

This theory of heterogeneous reactions can be readily developed along quantitative lines. Some of the principles upon which this development is based have been outlined in a recent paper on the dissociation of hydrogen.<sup>1</sup> A brief, but more general treatment will, however, not be out of place here.

The velocity of a reaction usually depends on the fraction of the surface which is covered by adsorbed atoms or molecules. This in turn depends on the rate of condensation and on the rate of evaporation of the adsorbed substance. In the sections of this paper dealing with condensation and evaporation, we considered only the case where the vapor condensing and the surface on which condensation occurred, consisted of the same substance. In the case where different substances are involved, some additional factors must be taken into account.

*Condensation.*—The surface on which condensation occurs contains a definite number  $N_0$  of elementary spaces, per unit area. Let  $\theta$  be the fraction of these spaces which are unoccupied and  $\theta_1$  be the fraction occupied by adsorbed atoms or molecules.

If each molecule condensing requires only one elementary space, the rate of condensation will be equal to  $\alpha\theta\mu$ .<sup>2</sup> But it may happen that each molecule requires two such spaces before condensation can occur. The chance that one space will be vacant is  $\theta$ , but the chance that two given spaces will be simultaneously vacant is  $\theta^2$ . Therefore, the rate of condensation is equal to  $\alpha\theta^2\mu$ . In general, the rate of condensation will be  $\alpha\theta^n\mu$  where  $n$  is an integer.

*Evaporation.*—In evaporation it may occur that two atoms must lie in adjacent positions in order that they may leave the surface together as a molecule. In such cases the rate of evaporation will be  $\nu_1\theta_1^2$  instead of  $\nu_1\theta_1$ .

Chemical reactions may take place either between adjacent atoms

<sup>1</sup> THIS JOURNAL, 38, 1145 (1916).

<sup>2</sup> Compare with the derivation of Equation 14.

on the surface or may occur when gas molecules strike molecules or atoms on the surface. In the former case the velocity of the reaction, in general, will be proportional to  $\theta^n \theta_1^m \theta_2^p$  where  $\theta_1$  and  $\theta_2$  are the fractions of the surface covered by the reacting substances and  $n$ ,  $m$  and  $p$  are integers. The reason for the occurrence of the factor  $\theta^n$  in this expression is that the number of elementary spaces occupied by the products of the reaction may be greater than that occupied by the reacting substances. The reaction will thus only occur when vacant spaces are available.

We see that the reaction on surfaces will be governed by a "law of surface action" analogous to the "law of mass action." The velocity in both cases is proportional to a continued product of factors having integral exponents. A radical difference between the two laws exists in the presence of the factor  $\theta^n$  in the case of reactions on surfaces.<sup>1</sup>

Let us consider a few simple special cases of heterogeneous reactions.

To simplify the problem, we will assume that the velocity of the reaction is slow compared to the rate at which the gas condenses and evaporates from the surface. In other words, we will limit ourselves to a consideration of those cases where the velocity of the reaction is not fast enough to materially affect the equilibrium between the adsorbed film and the surrounding gas.

There are two types of cases to consider. First, those in which the adsorbed film covers only a very small fraction of the surface ( $\theta = 1$ ). Secondly, those in which the surface is nearly completely covered by the adsorbed film.

*First Case. Surface only covered to a small extent.*

Let us consider a single gas which undergoes a chemical change (for example a dissociation) in contact with a solid body. The rate of condensation on the surface will be  $\alpha_1 \mu_1$  and the rate of evaporation of the unchanged gas will be  $\nu_1 \theta_1^n$  where  $n$  represents the number of elementary spaces occupied by each molecule of the substance while on the surface. Then, since the adsorbed film is in equilibrium with the surrounding gas, we have<sup>2</sup>

$$\alpha_1 \mu_1 = \nu_1 \theta_1^n. \quad (17)$$

<sup>1</sup> Since  $\theta + \theta_1 + \theta_2 + \dots = 1$  this law bears a close relationship to Reichstein's "Constant Sum Hypothesis," which has been used to explain various kinds of passivity phenomena.

<sup>2</sup> This equation becomes identical with Equation 14 only when  $n = 1$  and  $\theta = 1$ . It is thus seen that the theory of adsorption which led to Equation 16 does not apply to the case where a molecule occupies more than one elementary space. Equation 17 shows that when  $n = 2$ , the amount of gas adsorbed is proportional to the square root of the pressure, even at very low pressures.

The equations that follow (19), (21), etc., may be derived in several different ways (see THIS JOURNAL, 38, 1149 (1916)) by making different kinds of assumptions. By experiment it will be possible to determine which set of assumptions correspond with the facts.

Now the product of the chemical reaction is formed from the adsorbed film by the combination of the substance from  $m$  adjacent spaces. In case of a dissociation  $m$  will be equal to unity. If  $\omega$  represents the velocity of the chemical change, we have

$$\omega = \nu_2 \theta_1^m. \quad (18)$$

Combining these two equations gives

$$\omega = \nu_2 \left( \frac{\alpha_1 \mu_1}{\nu_1} \right)^{m/n} \quad (19)$$

The velocity of the reaction thus varies with the  $m/n^{\text{th}}$  power of the pressure ( $\mu$ ) of the gas. In the case of the dissociation of hydrogen molecules by a heated wire, we have  $m = 1$  and  $n = 2$ , so that the velocity at which the gas is dissociated is proportional to the *square root* of the pressure of molecular hydrogen. The recombination of hydrogen atoms in contact with a heated wire, however, takes place in proportion to the *square* of the pressure of the atomic hydrogen. It has been shown previously that these conclusions are in accord with experiments.

Bodenstein and Ohlmer<sup>1</sup> mention that the velocity of the reaction between carbon monoxide and oxygen in presence of heated crystalline quartz is proportional to the pressure of the carbon monoxide and to the *square root* of the pressure of oxygen.

Now if we assume that each carbon monoxide molecule occupies one elementary space while each oxygen molecule occupies two (*i. e.*, is present on the surface in the form of atoms), we obtain

$$\begin{aligned} \alpha_1 \mu_1 &= \nu_1 \theta_1 \\ \alpha_2 \mu_2 &= \nu_2 \theta_2^2 \\ \omega &= \nu_3 \theta_1 \theta_2 \end{aligned} \quad (20)$$

where the subscript 1 refers to CO, 2 refers to O<sub>2</sub> and 3 refers to CO<sub>2</sub>.

These equations give

$$\omega = k \mu_1 \sqrt{\mu_2} \quad (21)$$

where  $k$  is a constant involving  $\alpha_1$ ,  $\alpha_2$ ,  $\nu_1$ , etc. Thus the relation found by Bodenstein and Ohlmer follows directly from the assumption that the oxygen adsorbed on the surface is present as separate atoms.

It has been found by Bodenstein and Kranendieck (p. 99 Nernst Festschrift) that the rate of decomposition of ammonia by heated quartz glass is proportional to the square root of the pressure. It will be shown in a subsequent paper that this fact is readily explainable by assumptions analogous to the above.

Freundlich and Bjercke<sup>2</sup> have recently found that the rate of oxidation of phenyl-thiourea by oxygen in contact with blood charcoal is proportional to the square root of the concentration of oxygen.

<sup>1</sup> *Z. physik. Chem.*, 53, 175 (1905).

<sup>2</sup> *Ibid.*, 91, 1 (1916).

It should be noted that the velocity of gas reactions is frequently proportional to the square root of the pressure, whereas according to the law of mass action, we should expect velocities proportional to some integral power of the pressure. The above theory of heterogeneous reactions offers a simple explanation of these fractional exponents. According to the Bodenstein-Fink theory of heterogeneous reactions, such square-root relations are to be explained by diffusion through films whose thickness varies in proportion to the square-root of the pressure. There is definite experimental evidence in the case of the dissociation of hydrogen (which gives a square root relation) that the adsorbed film covers only a very small fraction of the surface with a layer one atom deep. Hence the Bodenstein-Fink theory cannot possibly explain this case. It is very probable that such square root relations are never caused by diffusion through adsorbed films.

*Second Case. Surface nearly completely covered.*

Let us consider a reaction in which two gases are in contact with a solid body. One of the gases, which we shall designate by the subscript 1, is present in such quantity and evaporates so slowly from the surface that the surface remains nearly completely covered by an adsorbed film of this substance. A second gas, 2, undergoes a chemical change when its molecules come in contact with the uncovered surface. This reaction may be of several kinds. For instance, the gas molecules condensing in vacant spaces may dissociate, may react with the underlying solid, or may react with the adsorbed gas in adjacent spaces. The rate at which the first gas will condense is  $\alpha_1 \theta^n \mu_1$ , where  $n$  is the number of elementary spaces occupied by each molecule which condenses. The rate of evaporation will be constant  $\nu_1$ , since the surface is nearly covered. Therefore, for equilibrium

$$\alpha_1 \theta^n \mu_1 = \nu_1. \quad (22)$$

The rate at which the second gas will enter into reaction will usually be proportional to  $\theta \mu$ . It is quite possible, however, in some cases that  $\theta$  may have any integral or even fractional exponent. We thus obtain for the rate of reaction

$$\omega = \nu_2 \theta \mu_2. \quad (23)$$

Combining these equations we find

$$\omega = \nu_2 \mu_2 \left( \frac{\nu_1}{\alpha_1 \mu_1} \right)^{1/n}. \quad (24)$$

The velocity of the reaction is thus proportional to the pressure of gas 2, and *inversely proportional to the  $n^{\text{th}}$  root of the pressure of gas 1.*

Now this is a relation which has been found to hold for a very great number of heterogeneous reactions in which the velocity is influenced by catalytic poisons. A few of these will be briefly mentioned.

Fink<sup>1</sup> found in the case of the reaction (in contact with platinum)

that the velocity is proportional to the pressure of  $\text{SO}_2$  and inversely proportional to the square root of the pressure of  $\text{SO}_3$ . This relation follows directly from Equation 24 if we place  $n = 2$ . We may thus conclude that the platinum surface was practically completely covered by a layer of adsorbed  $\text{SO}_3$  in which each molecule of  $\text{SO}_3$  required two elementary spaces for its condensation. Fink actually measured the amount of adsorbed  $\text{SO}_3$  and found it to be of the order of magnitude of a single layer of molecules. According to the Fink-Bodenstein theory, the amount of adsorbed  $\text{SO}_3$  in these experiments should have been proportional to the square root of the  $\text{SO}_3$  pressure, whereas according to the above theory the amount adsorbed should have been practically independent of the pressure (saturation). It is, however, obvious that a film one molecule thick (as found by Fink) cannot have a *thickness* which varies in proportion to the square root of the pressures over a wide range.

Bodenstein and Ohlmer found that the reaction between oxygen and carbon monoxide in contact with quartz glass takes place at a rate proportional to the pressure of oxygen and inversely proportional to the pressure of carbon monoxide. Evidently here  $n = 1$  so that each molecule of carbon monoxide occupies only one elementary space.

The writer has found<sup>2</sup> that the same relation holds when these gases react with each other at very low pressures in contact with platinum. It was also found<sup>3</sup> that in the catalysis of oxygen-hydrogen mixtures by a platinum wire, the velocity is proportional to the pressure of oxygen and inversely proportional to that of the hydrogen.

An interesting application of this theory arises in connection with enzyme action. The velocity of many of these reactions varies in accordance with Schutz's rule.<sup>4</sup> Consider a reaction in which a substance A is converted into B by the action of an enzyme. Let  $x$  be the amount of B formed in the time  $t$ , assuming that the substance B is absent when  $t = 0$ . Let  $E$  be the amount of enzyme present. Then according to Schutz's rule

$$x = k\sqrt{Et}. \quad (25)$$

Thus the amount of B formed is independent of the concentration of A, but is proportional to  $\sqrt{Et}$ .

By squaring and differentiating (25) we obtain, if  $E$  remains constant

<sup>1</sup> Dissertation, Leipzig, 1907; see also Bodenstein and Fink, *Z. physik. Chem.*, **60**, 1 (1907).

<sup>2</sup> THIS JOURNAL, **37**, 1162 (1915).

<sup>3</sup> More recent experiments show that this is not the usual manner in which hydrogen and oxygen react in contact with platinum even at low pressures. The factors which cause the above type of reaction have not yet been determined with certainty.

<sup>4</sup> See Euler, *Allgemeine Chemie der Enzyme*, pp. 125, 106 and 113.

$$\frac{dx}{dt} = \frac{1}{2} k^2 \frac{E}{x}. \quad (26)$$

Thus another way of stating Schutz's rule is to say that the velocity of the reaction is proportional to the amount of enzyme, is inversely proportional to the amount of B formed, and is independent of the amount of A.

It is generally recognized that enzymes are colloids on the surfaces of which reactions occur. We may thus interpret Schutz's rule as an indication that the product B of the reaction is adsorbed on the surface of the colloidal particles forming a layer one molecule deep nearly completely covering the surface. By comparing Equations 26 and 24 we see that  $n = 1$  from which we conclude that each adsorbed molecule occupies only one elementary space. The reaction thus takes place only on that fraction of the surface which is not covered by molecules of B.

By Equation 24 we should expect the velocity of the reaction to be proportional to the concentration of A, but according to Schutz's rule the velocity is independent of this concentration. This seems somewhat difficult to explain. It is, perhaps, possible that molecules of A are adsorbed over practically all the surface not occupied by B, and that molecules of B are able to *displace* molecules of A thus adsorbed. Let  $\theta_a$  and  $\theta_b$  be the fractions of the surface covered by A and B, respectively. Then according to the above hypothesis, we would have

$$\alpha_b \theta_a \mu_b = \nu_b \theta_b. \quad (27)$$

$$\omega = \nu_a \theta_a. \quad (28)$$

Since  $\theta_b$  is nearly equal to unity, we thus have

$$\omega = \left( \frac{\nu_a \nu_b}{\alpha_b} \right) \frac{1}{\mu_b}, \quad (29)$$

which is of exactly the same form as (26) and is thus equivalent to Schutz's rule.

#### SUMMARY.

1. The work of the Braggs on crystal structure is reviewed from the viewpoint of the chemist and the relation of this work to theories of chemical constitution such as those of Werner, Stark, J. J. Thomson, and Lewis, is discussed in detail.

2. It is concluded that the substances whose structures have thus far been studied by the X-ray spectrograph are not representative of compounds in general. Only polar compounds have been studied.

3. Solid polar compounds are, in general, built up of atoms bound together by secondary or residual valence. The whole crystal must be regarded as a single molecule.

4. Solid nonpolar compounds consist in general of "Group Molecules" in which the atoms are usually held together by primary valence. These

group molecules in turn are bound together by secondary valence to form a large "Crystal Molecule," which includes the whole solid mass.

5. There is no present justification for dividing interatomic (or intermolecular) forces into *physical* and *chemical* forces. It is much more profitable to consider all such forces as strictly chemical in nature. Evaporation, condensation, solution, crystallization, adsorption, surface tension, etc., should all be regarded as typical chemical phenomena. The object of this paper is largely to show that *chemical knowledge already available* is directly applicable to the study of these phenomena.

6. From a consideration of such properties as specific heat, compressibility, coefficient of expansion, etc., it is concluded that collisions do not take place between the atoms of solids, but that these move about equilibrium positions under the influence of both attractive and repulsive forces.

7. The "time of relaxation" of the atoms of solids is calculated approximately from the heat conductivity and is found to be of the order of  $10^{-14}$  to  $10^{-7}$  seconds. An independent method by which the "time of relaxation" can be calculated from the rate of evaporation of a substance in vacuum, gives substantially similar results. Thus the time necessary for an atom of a solid to reach thermal equilibrium with its neighbors is very small compared to the time necessary to make a single oscillation about an equilibrium position. The "oscillations" are thus extremely strongly damped.

8. Since solid substances in general are held together by secondary rather than primary valence, there are few limitations to the number of compounds that can exist in the solid state. Most of these compounds do not show a composition which could be predicted from the ordinary rules of valence. Metallic compounds, minerals, solid solutions and glasses are discussed from this point of view.

9. By considerations based largely on the compressibility, it is concluded that the attractive forces between atoms usually reach a maximum intensity when the distance between adjacent atoms in solids is increased by about  $0.6 \times 10^{-8}$  cm. (10-30% of the normal distance between atoms).

10. Since energy must be expended in breaking apart a solid, the surfaces of solids must contain more potential energy than do the corresponding number of atoms in the interior. Since this potential energy is probably electromagnetic energy in the field between atoms, the interatomic forces are more intense on the surface than in the interior. This intense surface field of force (unsaturated chemical affinity) is one of the causes of the phenomena of condensation and adsorption.

11. Because of the small time of relaxation and because an atom approaching the surface is attracted by many, but later is repelled by few

atoms, it follows that the surfaces of solids are almost wholly inelastic in regard to collisions of molecules impinging on the surface. There is also a great deal of experimental evidence of this inelasticity. As a result, nearly every molecule or atom striking a solid surface condenses no matter what the temperature may be. While condensed it is held to the surface by forces quite similar to those holding solids together (either primary or secondary valence). At high temperatures evaporation may take place almost immediately after condensation, but at lower temperatures, the condensed atom or molecule may remain indefinitely.

12. The phenomena of condensation and evaporation (sublimation) of solids is discussed at some length. In general, the rate of evaporation ( $m$ ) of a substance in a high vacuum is related to the pressure ( $p$ ) of the saturated vapor by the equation

$$m = \sqrt{\frac{M}{2\pi RT}} p.$$

Red phosphorus and some other substances probably form exceptions to this rule.

13. The mechanism of the dissociation of a solid, such as  $\text{CaCO}_3$  is discussed. It is shown that when, according to the phase rule, separate phases of constant composition are present, the reaction must take place exclusively at the boundaries of these phases. This kinetic interpretation of the phase rule indicates clearly the distinction between reactions in which solid solutions are formed and those in which separate phases appear. This theory offers a ready explanation for the fact that hydrated crystals frequently fail to effloresce unless scratched and for the fact that thoroughly dehydrated substances often absorb moisture with great difficulty.

14. Adsorption is a direct consequence of the time lag between the condensation and the subsequent evaporation of molecules. The adsorbed substance may be held to the surface either by secondary or primary valence. In either case it is profitable to regard the phenomena as chemical in nature. A large number of experimental results are given which prove conclusively that adsorption is very frequently the result of the strongest kind of chemical union (primary valence) between the atoms of the adsorbed substance and the atoms of the solid.

15. It is shown that the action of a typical catalytic poison depends on the formation of a very stable film one atom deep over the surface of the catalyzer. The chemical activity of any solid surface depends upon the nature of, the arrangement of, and the spacing of the atoms forming the surface layer. There is a very close relation between the chemical activity of a surface and the electron emission from it (either thermionic or photoelectric emission).

16. A brief quantitative development of this theory of heterogeneous reactions is given. A "law of surface action" analogous to but different

from, the "law of mass action" is proposed. This theory is in accord with and affords an explanation of Reichinstein's "Constant Sum Hypothesis." An outline is given of the application of this theory to heterogeneous gas reactions and to enzyme action.

The second part of this paper will deal with the Structure of Liquids with particular reference to surface tension phenomena. It will be shown that the surface tension of organic liquids is a characteristic *chemical* phenomena. It depends particularly upon the *shapes* of the group molecules and upon the relative intensities of the chemical activity of *different portions* of the molecules. A method will be described (together with experimental data) by which the *cross sections*, *lengths* and other dimensions of group molecules of liquids may be determined.

## THE THERMODYNAMIC PROPERTIES OF SILVER AND LEAD IODIDES.

By HUGH STOTT TAYLOR.

Received July 10, 1916.

The thermodynamic properties of silver and lead iodides have been the subject of considerable recent experimental investigation. The object of the work has been to obtain accurate data on the free energies and heats of formation with a view to testing the newer thermodynamic conceptions relative to these two magnitudes.

The relation between free energy and heat of formation is representable, according to the two laws of thermodynamics, by the fundamental equation,

$$A - U = T dA/dT.$$

With the aid of this equation, given the maximum work or free energy,  $A$ , at any temperature,  $T$ , together with its temperature coefficient  $dA/dT$ , it is possible to evaluate the heat effect of the reaction  $U$ . The values obtained by such a procedure should show concordance with the direct calorimetric observations. Alternatively, if it be desired to proceed from the thermal data to an evaluation of the free energy, classical thermodynamics, without the aid of new assumptions, is inadequate. This will readily be grasped if the form of the above equation be somewhat modified. Since

$$A - U = T dA/dT,$$

it follows that

$$A dT - T dA = U dT,$$

Dividing each side by  $T^2$  there results,

$$\frac{A \, dT - T \, dA}{T^2} = \frac{U \, dT}{T^2},$$

whence

$$A = -T \int \frac{U \, dT}{T^2} + IT$$

where  $I$  is the constant of integration.

Obviously, in order to evaluate  $A$  from the thermal data it is necessary to know  $U$  as a temperature function and also the value of the integration constant  $I$ . As regards the variation of  $U$  with temperature it is well known that this magnitude varies with the specific heats of the reacting substances (Kirchhoff's Law) according to the equation

$$dU/dT = \Sigma nC$$

the summation sign indicating an algebraic summation (reactants positive, resultants negative) of the molecular heats of the substances participating, multiplied by their respective molecular coefficients,  $n$ . The necessity of evaluating this equation has led to the determination of specific heats of many substances down to very low temperatures with a resultant considerable development in the theory of specific heats, some of the newer features of which will later be developed. Concerning the constant of integration,  $I$ , classical thermodynamics teaches nothing. New assumptions are necessary, the consequences of which must be submitted to experimental verification before they are finally accepted.

The fundamental assumption made by Nernst in the Nernst heat theorem is

$$\lim (dU/dT) = \lim (dA/dT) \text{ for } T = 0$$

for all reactions which take place in condensed systems, *i. e.*, in systems which persist continuously, without change of state of aggregation, down to the absolute zero of temperature. Obviously, therefore, this assumption applies to reactions between pure solids and liquids which supercool but not to those between gases and solutions. The deductions which may be made from this assumption are independent of the manner in which  $A$  and  $U$  are expressed as functions of temperature provided the functions be continuous. Thus, the fundamental thermodynamic equation may be generalized to give

$$\varphi(T) = f(T) + T\varphi'(T),$$

in which  $A = \varphi(T)$ ,  $U = f(T)$ , and  $dA/dT = \varphi'(T)$ .

This yields on differentiation,

$$\varphi'(T) = f'(T) + T\varphi''(T) + \varphi'(T)$$

whence

$$\varphi''(T) = -1/T \cdot f''(T).$$

If this equation be integrated, there follows

$$\varphi'(T) = - \int 1/T \, f''(T) dT + I.$$

For the small temperature  $dT$  above the absolute zero, this equation yields

$$\varphi'(dT) = -f'(dT) + I,$$

which is only reconcilable with the assumption of Nernst, *i. e.*,

$$\lim f'(T) = \lim \varphi'(T) \text{ for } T = 0$$

if,

$$(a) \lim \varphi'(T) = \lim f'(T) = 0$$

and

$$(b) I = 0.$$

Accordingly, if the Nernst hypothesis be accepted, it follows that the integration constant is zero and the evaluation of free energy from thermal data becomes at once possible when  $U$  is known as a temperature function since the  $IT$  term of the original equation becomes zero and consequently,

$$A = -T \int_0^U \frac{dT}{T^2}$$

Nernst was led to his assumption reasoning from the approximate equality of  $A$  and  $U$  at moderate temperatures with reactions between solids and pure liquids in agreement with the Berthelot principle. Its final acceptance or rejection will depend however on experimental verification, to which end accurate determinations of heats of reaction, free energies and specific heats will all be requisite.

For such purposes of experimental measurement the halides of several of the metals have been eminently suitable owing to the relative simplicity of structure and of the reactions which result in their formation and interaction. Also, they have proved suitable for direct determination of the free energy magnitudes and of the calorimetric data. In the case of one of these salts, silver iodide, an examination of the literature reveals that the conclusions reached by different workers as a result of careful experimental investigation are not only not concordant but are actually diametrically opposed as to the value which must be assigned to the integration constant.

Ulrich Fischer in a research on the affinity between iodine and silver<sup>1</sup>—elsewhere characterized by Nernst as “*der sehr eingehend und genau untersuchte Fall der Bildung des Jodsilbers*”—determined electrometrically and with the aid of the fundamental thermodynamic equation by measurements of the electromotive force and temperature coefficient of cells of the type

the heat of the reaction

This was supplemented by a calorimetric determination of the same

<sup>1</sup> *Z. anorg. Chem.*, 78, 41 (1912).

quantity. Concordant values by both methods yielded as a mean for  $T = 288^\circ \text{K.}$  a value for  $U$  of 15,000 calories with a maximum deviation from the mean of 180 calories. Calculating from the electromotive forces of the cells with the aid of the Nernst heat theorem (assuming  $I = 0$ ) a value of 15,079 calories was obtained, forming strong evidence in support of the truth of the theorem.

More recently, a publication by Jones and Hartman<sup>1</sup> described similar measurements with cells of the same type, though different in construction, for which a considerably higher degree of constancy and reproducibility is claimed than was obtained by Fischer. From measurements of the electromotive force at two temperatures with the aid of the most reliable specific heat data it was concluded that the integration constant was not zero but had a value equal to 2.33 calories per degree, so that in the free energy equation not only was  $IT$  not equal to zero but on the contrary at  $273^\circ \text{K.}$  possessed a value  $273 \times 2.33 = 636$  calories, greater in magnitude than the sum of all the terms involving the specific heats of the substances concerned.

It is evident therefore that between these two investigations there exists a considerable discrepancy which is more manifest in view of the following considerations. Calculation with the aid of the Gibbs-Helmholtz equation using the values for  $A$  and  $dA/dT$  obtained by Jones and Hartmann yields as a mean value for  $U$  the heat of reaction, 14,565 calories, a deviation from the mean obtained by Fischer of 435 calories. Independently, and apparently overlooked by Jones and Hartmann, the calorimetric determination of the heat of formation of silver iodide was carried out by Braune and Koref<sup>2</sup> and found to be 15,100 calories, somewhat higher than that determined by Fischer using the same method, and deviating still further from the value of Jones and Hartmann. With the aid of new determinations of the specific heat of silver iodide, Braune and Koref recalculated the value of  $U$  according to the Nernst heat theorem and obtained a value, 15,188 calories.

The divergencies between the three sets of data are readily grasped from the following table:

$U$ from $dA/dT$ and $A$ .	$U$ thermo- chemically.	$U$ from Nernst heat theorem.	Author.
15169	14820	15079	Fischer
...	15100	15135	Braune & Koref
14565	...	14500	Jones & Hartmann

The values of Jones and Hartmann have been calculated by the author from their electromotive force data and according to the theorem from their value for  $U_0$ , since they did not attempt determination of  $U$  but

<sup>1</sup> *THIS JOURNAL*, 37, 752 (1915).

<sup>2</sup> *Z. anorg. Chem.*, 87, 175 (1914).

concentrated attention on the method for determining  $I$  from measurements of the temperature coefficients of the cells.

It will be obvious that any experimental evidence which can help to a decision on the merits of the several sets of determinations will be of extreme importance, since the conclusions from these investigations involve important evidence on the general theorem that  $I = 0$ .

From the researches of Jones and Hartmann it would seem that the integration constant is not equal to zero, while the work of Fischer and of Braune and Koref suggests the opposite conclusion. This latter verdict is supported by work of Braune and Koref on the corresponding reaction with lead and iodine. In a manner similar to that employed by Fischer they investigated calorimetrically the heat of formation of lead iodide and also the electrometric relationships of cells of the type

using, to attain reproducible electrodes, 0.72 per cent. lead amalgam instead of lead. The results obtained were reduced to those of metallic lead electrodes by use of the accurate data of Brönsted<sup>1</sup> on the e. m. f. of lead—lead amalgam cells. Concordant results were obtained by the several methods and they agreed with the value calculated from the Nernst theorem as the following summary shows:

REACTION:  $\text{Pb} + \text{I}_2 = \text{PbI}_2$  ( $T = 293^\circ \text{K.}$ ).

From  $TdA/dT = A - U$ .....  $U = 41960$  calories.

Thermochemically.....  $U = 41850$  calories.

According to the theorem.....  $U = 42034$  calories.

In the present research an attempt has been made to throw light on the point at issue by investigation of a cell which consists essentially of a combination of the two cells previously discussed. It was apparent that if such a cell could be constructed and yielded constant and reproducible results information would be obtained allowing of a test of the two earlier combinations.

It is evident that a cell of the type

possesses certain advantages over cells of the type

since by elimination of the iodine electrode there is eliminated from the system a liquid potential effect at the junction of the two halves of the cell and also an osmotic work effect caused by the different concentrations of iodide ions on the two sides. The corrections for these two effects are considerable and, at the same time, are uncertain as compared with the accuracy with which the cells may be reproduced. Thus, in the cell of Jones and Hartmann with 0.05  $N$  KI at  $25^\circ \text{C.}$  the liquid poten-

<sup>1</sup> *Z. physik. Chem.*, 56, 668 (1906).

tial correction amounted to +0.0032 volt while the osmotic work correction amounted to -0.0177 volt, a considerable percentage of the total e. m. f. measured, *viz.*, 0.6992 volt. On the contrary, with insoluble salts like silver and lead iodides a homogeneous electrolyte was readily obtainable and the various corrections disappear.

From a determination of the electromotive force of the combination and its temperature coefficient, a value for the heat of the reaction

may be deduced. The results obtained may then be compared with the electrometric and calorimetric data previously detailed and may also be employed in calculations according to the Nernst theorem. In the following the results of such an investigation are presented.

### Experimental.

**Preparation of the Silver-Silver Iodide Electrodes.**—Constant and reproducible silver electrodes were readily obtained, after a little experience, by following closely the detailed directions supplied by Jones and Hartmann, so that the method of preparation does not call for further detailment here. The reproducibility obtained was excellent as the table below shows. The several electrodes (5-9) were separately and successively made from June 2nd to 4th. After preparation, they were kept in a solution of potassium iodide saturated with silver iodide and of the same normality as that in which it was designed to use them.

Electrode 5 against.....	6	7	8	9
June 7th. Difference.....	-0.00002	+0.00006	+0.00002	+0.00003
The maximum difference of any pair is 0.00008 volt.				
The average difference from the mean is 0.00002 volt.				

**The Lead Amalgam Electrodes.**—Lead amalgam was prepared, of strength exactly 0.72% lead by weight, from three times distilled mercury and the very purest lead procurable. The lead employed was bright and lustrous, the coating of oxide being removed from the sample from which the lead employed was cut. The amalgam showed a marked tendency to oxidize. If made in contact with the air it was soon covered with oxidation products. Accordingly, the weighed quantity of mercury was covered with a solution of potassium iodide of the same strength as was later to be used with the amalgam in the cells. From this solution the oxygen was removed by bubbling through pure hydrogen, after which the lead was added in small pieces and in the calculated amount. Hydrogen was bubbled through until the amalgam was homogeneous. By this method of preparation clean bright amalgam was obtained. Its constancy and reproducibility is manifest from the constancy of the complete element described below.

**The Cell.**—Since the solution could be homogeneous and it was necessary only to limit the diffusion between the two electrodes, the H type

of cell was chosen. Into one limb the amalgam was introduced, contact with the outside being established by means of a platinum wire sealed through the base of the limb. Over the amalgam was placed, about 1 cm. deep, a layer of a paste composed of lead iodide and the solution of potassium iodide of the normality chosen. Each limb was then filled to the cross-piece with a solution of potassium iodide saturated, the one with silver iodide, the other with lead iodide, the latter naturally over the lead amalgam. Contact between the two limbs was then made by filling the H-piece carefully with the pure potassium iodide solution. Into the limb containing the silver iodide in potassium iodide the silver-silver iodide electrode was introduced. The electrode was held in position by means of a cork which served also to close the limb. The other limb was closed by means of an ordinary cork stopper. After setting up, the cells were immediately placed in an oil-bath thermostat regulated carefully to  $25^{\circ} \pm 0.01^{\circ}$ .

The potentials of the cells immediately after setting up were low and varied among themselves, but rose steadily to constant and concordant values. The cells apparently maintain their constancy for a considerable period of time and with varying treatment. The tables communicated below show that after a series of constant measurements extending over several days had been obtained at  $25^{\circ}$  C. the cells gave concordant values for a further period of time at  $0^{\circ}$ , returning to their original values when replaced in the  $25^{\circ}$  thermostat.

Two strengths of potassium iodide solution were used, 0.1 and 0.05 *N*. As regards constancy, there is little to choose between the two dilutions. Tables I and II record typical measurements at  $0^{\circ}$  and  $25^{\circ}$  with the two sets of cells.

A certain percentage of the cells set up showed initially a normal potential, but, in the course of a few days fell away in electromotive force and gave irregular and fluctuating values. In several cases this was identified with the passage of suspended silver iodide through the H-piece and deposition on the lead iodide. Presumably when this penetrated thus far the irregularities observed were obtained. A typical example of this behavior is recorded in Table II, Cell 10.

The potential measurements were made with the aid of a Wolff direct-reading potentiometer and a Leeds and Northrup high sensitivity galvanometer. For the potentiometer settings, use was made of the exceptional facilities of this laboratory in the matter of standard cells, so that the electromotive forces determined could readily be checked to the hundredth of a millivolt.

In Table III are recorded the accepted means for the different cells at the two temperatures and the accepted means for the two combinations.

Cells were set up in which water was used as the liquid medium but neither constancy nor reproducibility was attainable. This is doubtless due to secondary reactions—probably at the amalgam electrode—as it was found that in preparing the amalgam in the manner previously described, if distilled water were used as the protecting liquid, lead hydroxide readily formed and was noted by the resulting cloudiness of the aqueous layer. The small solubility of the two iodides may also have contributed to the observed irregularities.

### Evaluation of the Results.

To convert the values obtained with the amalgam cells to those obtaining in the case of metallic lead as electrode, use was made of the formula of Brönsted for lead—lead amalgam cells. Brönsted showed that such cells gave constant and reproducible values over a wide temperature range, representable by a linear interpolation formula

$$E = 0.0051 + 0.000233t,$$

where  $t$  is the temperature in degrees centigrade. Hence it follows, that to the observed means in the present series must be added (a) at  $0^\circ$  0.0051 volt, and (b) at  $25^\circ$  0.01092 volt. This yields for the electromotive forces of the combinations  $\text{Pb} \mid \text{PbI}_2 \mid N/x \text{ KI} \mid \text{AgI} \mid \text{Ag}$ .

$$(a) \quad x = 0.05. \quad \begin{array}{l} \text{At } 25^\circ \text{ 0.21157 volt.} \\ \text{At } 0^\circ \text{ 0.21475 volt.} \end{array}$$

$$(b) \quad x = 0.10. \quad \begin{array}{l} \text{At } 25^\circ \text{ 0.21069 volt.} \\ \text{At } 0^\circ \text{ 0.21415 volt.} \end{array}$$

The temperature coefficients of the two combinations are, respectively,

$$(a) \quad \frac{0.21157 - 0.21475}{25} = -0.000127 \text{ volt per degree.}$$

$$(b) \quad \frac{0.21069 - 0.21415}{25} = -0.000138 \text{ volt per degree.}$$

These two sets of data, when employed in the Gibbs-Helmholz equation, give values for  $U$

$$(a) \quad 11500 \text{ calories.} \quad (b) \quad 11610 \text{ calories.}$$

The mean value for  $U$  from the two sets of determinations is, therefore,

$$U = 11550 \pm 50 \text{ calories,}$$

which represents the heat of the reaction

as determined by means of the cell combination employed.

A comparison of this value with the data obtained from the previously tabulated results of Fischer, Braune and Koref, and Jones and Hartmann is most interesting.

Calorimetrically, from the data of Braune and Koref one obtains

$$U = 41850 - 2(15100) = 11650 \text{ calories}$$

in good agreement with the value found above.

Combining the electrometric data of Fischer and Braune and Koref, there results

$$U = 41960 - 2(15170) = 11620 \text{ calories,}$$

also in good agreement with the observed value.

Combining the electrometric data of Braune and Koref with those of Jones and Hartmann for silver iodide there results

$$U = 41960 - 2(14565) = 12830 \text{ calories,}$$

or a discrepancy of more than 1000 calories.

This conclusion is somewhat anomalous, judged from the standpoint of the experimental work, since the determinations of Jones and Hartmann are, apparently, considerably more concordant and reproducible than are those of Fischer, while those of the present work are comparable in every way with those of Jones and Hartmann in this regard.

It should be observed that both Fischer, and Braune and Koref omitted to allow for the liquid potential effect and that therefore their results are in error to the extent of about 3 millivolts or about 0.4 % in the case of the silver cell and 0.3 % in the case of the lead cell. Further, according to Jones and Hartmann, the correction employed by the earlier workers for the osmotic work due to the presence of triiodide causes an error in the value for the electromotive force of the cell and also in the value for the temperature coefficient. These facts vitiate any combination of the measurements of Jones and Hartmann with those of Braune and Koref.

Recalculating the results of Fischer in accordance with the method of Jones, it can readily be shown that  $U$  in the Gibbs-Helmholz equation would be 15010 calories or 200 calories less than the value deduced by Fischer. Since Braune and Koref adopted the same procedure as Fischer with regard to the two effects it is evident that the error thus caused in their value for  $U$  will be of the same magnitude. This brings down the discrepancy between the experimental values obtained in the present work and those derived from the values of Jones and Hartmann and of Braune and Koref to somewhat more than 600 calories, a still quite definite discrepancy.

An error of this number of calories in the electrometric determination of  $U$  for lead iodide by Braune and Koref would bring agreement between the present work and that of Jones and Hartmann. It would then be necessary to locate the divergencies between the calorimetric data and the electrometric data in the cases of the two iodine cells. The presence of polyiodides in the iodine cells and their absence in the calorimetric method (since the values were obtained from the heats of solution

of iodine plus silver and of silver iodide in a solution of potassium cyanide) might contribute to such a discrepancy. Also, the possibility of the calorimetric data being affected by side reactions between iodine and potassium cyanide is not wholly excluded.

The data which have been obtained have also been utilized in an effort to determine the magnitude of the integration constant of the thermodynamic equation. The calculation has been carried out by each of two methods, that employed by Nernst and that of Jones and Hartmann. The results are not without interest.

In the first place, the data compiled by Braune and Koref have been combined and applied to the present reaction. Thus, for the reaction

it was shown that the following relations hold, assuming  $I = 0$ :

$$(1) \quad A_0 = A_{293} + 654 \text{ calories.}$$

$$(2) \quad U_{293} = U_0 + 160 \text{ calories.}$$

Correspondingly for the formation of silver iodide it was calculated

$$(1) \quad A_0 = A_{293} - 487 \text{ calories.}$$

$$(2) \quad U_{293} = U_0 - 40 \text{ calories.}$$

Combining these two sets of data it is apparent that for the new reaction

$$(1) \quad A_0 = A_{293} + 654 - 2(-487) \text{ calories} \\ A_{293} + 1628 \text{ calories.}$$

and

$$(2) \quad U_{293} = U_0 + 160 - 2(-40) \\ U_0 + 240 \text{ calories.}$$

By interpolation from the experimental results it is found that

$$(a) \quad \text{For } 0.05 \text{ } N \text{ KI} \quad A_{293} = 9870 \text{ calories.}$$

$$(b) \quad \text{For } 0.10 \text{ } N \text{ KI} \quad A_{293} = 9840 \text{ calories.}$$

Or, in the mean

$$A_{293} = 9855 \text{ calories.}$$

Hence,

$$A_0 = 9855 + 1628 = 11483 \text{ calories.}$$

and therefore

$$U_{293} = 11483 + 240 = 11723 \text{ calories.}$$

This value differs from the experimentally determined value by 173 calories, 1.5% of the total value, and from the calorimetrically determined value by 73 calories (0.6%), which must be considered in view of the uncertainty of specific heat data a satisfactory agreement.

In the second place use has been made of the procedure adopted by Jones and Hartmann for evaluation of  $I$  from measurements of the electromotive force at two temperatures, and insertion of the experimentally determined values in the corresponding equations for  $A$ . In this manner two equations are obtained of the form

$$A = U_0 + IT + \text{Terms involving the specific heats,}$$

from which  $U_0$  may be eliminated and the equations solved for  $I$ . The

procedure is in reality the accurate determination of  $dA/dT$ , the equation for which does not involve any term containing  $U_0$ , to which, it is claimed, an error of many hundred calories may be attached.

For the evaluation of the terms in the equation relative to the heat capacities of the reacting substances the formula of Debye for specific heats was used, since as was shown by Nernst and Lindemann<sup>1</sup> this formula gives the best representation of the experimental values at extremely low temperatures. The mode of employment of the Debye equation has been demonstrated by Nernst.<sup>2</sup> The formula for the specific heat as used by him is as follows:

$$C_v = 3R \left( \frac{4\pi^4}{5} \left( \frac{T}{\beta\nu} \right)^3 - \frac{3\beta\nu/T}{e^{\beta\nu/T} - 1} - \frac{1}{12} \frac{\beta\nu}{T} \sum_{n=1}^{\infty} e^{-n\beta\nu/T} \left( \frac{1}{n\beta\nu/T} + \frac{3}{n^2(\beta\nu/T)^2} + \frac{6}{n^3(\beta\nu/T)^3} + \dots \right) \right)$$

which is derived from the Debye equation for  $U$

$$U = \frac{9}{12} R \left( \frac{C_v}{C_\infty} + \frac{3x}{e^x - 1} \right) T$$

where  $x = \beta\nu/T$  and  $C_\infty = 3R$ .

Developed as a series, this gives

$$U = 0.75 \beta\nu R \left( \frac{77.94}{x^4} - \frac{1}{12} \sum_{n=1}^{\infty} e^{-nx} \left( \frac{1}{nx} + \frac{3}{n^2x^2} + \frac{6}{n^3x^3} + \frac{6}{n^4x^4} \right) \right).$$

The integration of this formula according to the thermodynamic equation for  $A$ , viz.,

$$A = -T \int \frac{U}{T^2} dT + IT$$

gives the following expression for  $A$ :

$$A = U_0 + IT - 9R \left( \frac{2.1646}{x^3} - \sum e^{-nx} \left( \frac{1}{n^2x} + \frac{2}{n^3x^2} + \frac{2}{n^4x^3} \right) \right) T$$

In the development, use is made of the relationship

$$\int_x^\infty \frac{e^{-x}}{x^{n+1}} dx = \frac{1}{n} \frac{e^{-x}}{x^n} - \frac{1}{n} \int_x^\infty \frac{e^{-x}}{x^n} dx.$$

By combination of this formula for  $A$  with that for the specific heat, an equation is obtained of the form

$$A = U_0 + IT - 9R \left( \frac{C_v}{36 C_\infty} + \frac{x}{12(e^x - 1)} + \sum \frac{e^{-nx}}{3n} \right) T,$$

which formula is more suitable for calculations. The equation may also be given the compact form

<sup>1</sup> *Sitz. Preuss. Akad., Berlin*, 1160 (1912).

<sup>2</sup> *Ibid.*, 1172 (1912).

$$A = U_0 + IT - 9R \left( \frac{C_v}{36 C_\infty} + \frac{x}{12(e^x - 1)} - \frac{1}{3} C_v (1 - e^{-x}) \right) T,$$

which is identical with the previous one when it is remembered that

$$-\ln(1 - y) = y + \frac{y^2}{2} + \frac{y^3}{3}$$

and

$$y = e^{-x}$$

The formulas employed to represent the specific heats of the several substances are represented in the following table:

Substance.	$C_v$ .
Pb.....	$F(93) + 7.8 \times 10^{-6} T^{3/2}$
Ag.....	$F(216) + 4.8 \times 10^{-6} T^{3/2}$
AgI.....	$F(68.4) + F(215) + 20 \times 10^{-6} T^{3/2}$
PbI <sub>2</sub> .....	$2F(85) + F(129) + 31 \times 10^{-6} T^{3/2}$

$F$  denotes the Debye function,  $F_1$  the older Einstein function, which gives the better run of the curves at the higher temperatures. With the exception of silver iodide the same values were employed by Braune and Koref and interpret fairly accurately the experimental measurement. Their formula for silver iodide was not used since it was found that by its use the experimental data could not be reproduced.<sup>1</sup> The value chosen for silver iodide was that employed by Nernst in his recalculations of Fischer's work.

With these data and with the aid of tables compiled by Nernst and by Pollitzer, the following results were obtained:

$$A_{299} = A_0 + IT_1 - 1789 \text{ calories}$$

$$A_{273} = A_0 + IT_2 - 1624 \text{ calories}$$

The discrepancy between this calculation and that obtained by combining Braune and Koref's values has been traced to the silver iodide values, the values of the latter workers leading to a smaller negative value in calories in the  $A$  and  $U$  curves for the silver iodide-silver-iodine reaction.

Now the difference in magnitude of  $A_{298}$  and  $A_{273}$  can be obtained from the experimental determinations by multiplying the respective temperature coefficients of the two cells by the temperature difference of  $25^\circ$ . Converting to calories this gives in the two cases

$$(a) \quad 0.05 N: \quad 25(-0.000127) \cdot 96500 \cdot 2 \cdot 0.2388 = -146 \text{ cal.}$$

$$(b) \quad 0.10 N: \quad 25(-0.000138) \cdot 96500 \cdot 2 \cdot 0.2388 = -159 \text{ cal.}$$

Consequently the following two relations hold:

<sup>1</sup> It is suggested that the cause of this is probably a typographical error in the  $\beta_v$  values in the original paper. The author has failed to reproduce both specific heat data and the  $A$  and  $U$  calculations of B. and K. with silver iodide although this was readily done in the other case. All the available evidence seems to indicate a typographical error as the cause.

$$(a) \quad -146 = I(298 - 273) - 165$$

$$(b) \quad -159 = I(298 - 273) - 165$$

It is apparent that the two strengths of solution do not give identical figures. To take the mean value is not justifiable until it is shown that there is not a progressive variation in the experimental value with increasing dilution of the solution of potassium iodide. As has been previously stated, reproducible values could not be obtained with an aqueous solution of the two iodides. Even with a 0.02 *N* solution of potassium iodide it has not yet been found possible to obtain results reproducible to less than 5 millivolts, so that for the present the above values must be considered alone. If it were permissible to take the mean, the following equation would be obtained:

$$-153 = I(298 - 273) - 165,$$

so that

$$25 I = 12 \text{ cal.},$$

assuming that the experimental values for the electromotive forces and for the specific heats could be relied upon to one or two calories. On the other hand, if there is a possibility of error in the several determinations amounting to 10 or 20 calories it is obvious that the equation derived above might readily be in agreement with the hypothesis of Nernst and its deduction that  $I = 0$ , the difference being due to experimental error.

Some idea of the experimental error of the specific heat determinations can be obtained. Firstly, as was previously pointed out, there is a divergency between the present calculations and those of Braune and Koref, and this is due to the use by Braune and Koref of a new set of determinations of the specific heats of silver iodide. Their calculations lead to an expression for  $A$  at a temperature of  $20^\circ \text{C}$ .

$$A_{298} = A_0 + IT - 1628 \text{ cal.}$$

With the values employed in the present calculations the corresponding equation is

$$A_{298} = A_0 + IT - 1756 \text{ cal.}$$

It is obvious, therefore, that if one had used the same data as Braune and Koref the difference between the two specific heat terms would have been reduced by nearly 10% or to about 152 calories and that this would have yielded a value intermediate to those obtained experimentally with the two sets of cells for the difference between  $A_{298}$  and  $A_{273}$ .

Secondly, in the present calculations the value of  $\beta\nu$  assumed for lead was 93. The more recent data of Eucken and Schweser<sup>1</sup> at low temperatures point to the value  $\beta\nu = 88$  as more accurate and this is confirmed by the measurements of Kammerlingh Onnes and Keesom<sup>2</sup> at extremely

<sup>1</sup> Eucken and Schweser, *Ber. Akad. Sitzb.*, p. 369 (1914).

<sup>2</sup> *Proc. Amsterdam Acad.*, p. 894 (1914).

low temperatures. If, now, this alteration be made in the calculations as carried out in the present communication, the following equations are obtained:

$$A_{298} = A_0 + IT_1 - 1882$$

$$A_{273} = A_0 + IT_2 - 1701,$$

or a difference in the two specific heats terms of 181 cal., nearly 30 calories greater than the experimental difference between  $A_{298}$  and  $A_{273}$ .

Consequently, for three successive changes in the values for one or other of the specific heat terms the value of  $I$  as calculated by this method has changed successively from 0.5 to 0.0 and then to 1.2. This indicates, with a considerable degree of reliability, the limitations of this particular method of calculating the integration constant. In case the experimental errors of the specific heats are small or in case the cell combination studied possesses a considerable temperature coefficient, the method may be utilized with a fair degree of certainty. When these conditions are not fulfilled great care must be exercised in drawing conclusions from the experimental facts; otherwise, grotesque results may be the outcome. It is evident that, in the present cell combination, even if the integration constant is not equal to zero, its value is considerably smaller than that to which the researches of Jones and Hartmann led in the case of silver iodide alone. This would involve as a consequence that the lead-lead iodide-iodine combination must have a value for the integration constant less than that of the present cell, and, therefore, very probably, a negative value, provided the value for the silver cell be correct.

It is obvious that a considerable increase of experimental evidence relative to the Nernst theorem is eminently desirable. The present investigations have indicated a promising new field of experimental possibilities to which attention is being devoted by the author and for which accurate electrometric and calorimetric determinations as well as the requisite specific heat data are being accumulated.

### Summary.

By an investigation of the cell  $\text{Pb} \mid \text{PbI}_2 \mid N/x \text{ KI} \mid \text{AgI} \mid \text{Ag}$  the thermodynamic relationships of the iodides of silver and lead have been restudied.

It has been shown that the value for the heat of the reaction

as determined by means of the above cell combination agrees satisfactorily with the best calorimetric data for the substances taking part.

The data have been used in an investigation of the assumptions of the Nernst Heat Theorem and of the methods of testing the same. So far as the present experimental evidence relative to specific heats may be employed results favorable to the theorem have been obtained.

In conclusion, I wish to express my indebtedness to Mr. Earle A. Harding for his kind assistance in the preliminary work in connection with this investigation.

## A STUDY OF THE TENTH-NORMAL HYDROCHLORIC ACID CALOMEL ELECTRODE.<sup>1</sup>

BY N. EDWARD LOOMIS AND MERLE R. MEACHAM.

Received August 8, 1916.

### I. Purpose of the Investigation.

The purpose of this investigation was to carefully measure the electromotive force of the system

at 25° with the view of comparing the value so obtained with that of the cell

from which the contact potential has been eliminated. From this comparison the relative potentials of the 0.1 N hydrochloric acid and the 0.1 N potassium chloride calomel electrodes can be determined and thereby the relative degrees of dissociation of the two electrolytes measured.

The degree of dissociation of an electrolyte, as commonly calculated from conductivity data, depends upon the assumption that the mobilities of the ions are independent of the concentration. This assumption was first questioned by Jahn<sup>2</sup> and considerable evidence against it has since been accumulated. The mobility of the hydrogen ion appears to increase with increasing concentration, and consequently the degrees of dissociation of the more concentrated solutions of hydrochloric acid, as determined by conductivity data, are probably too high.

In 1909 Lewis and Sargent<sup>3</sup> assumed that hydrochloric acid and potassium chloride are equally dissociated at equivalent concentrations, even though the apparent dissociation, as indicated by conductivity measurements, is considerably higher for the acid. If the two electrolytes are equally dissociated then the 0.1 N HCl calomel electrode should have the same potential as the 0.1 N KCl calomel electrode. This was assumed to be the case by Lewis and Sargent and their assumption has been adopted by several subsequent workers.

In 1912, however, Lewis<sup>4</sup> showed that the degree of dissociation of 0.1 N

<sup>1</sup> An abstract of this paper was presented at the Urbana meeting of the American Chemical Society.

<sup>2</sup> *Z. physik. Chem.*, 33, 545 (1900); 35, 1 (1900).

<sup>3</sup> *THIS JOURNAL*, 31, 363 (1909).

<sup>4</sup> *Idem.*, 34, 1631 (1912).

HCl was in doubt several per cent., and in a later paper<sup>1</sup> he states that, whereas hydrochloric acid and potassium chloride are equally dissociated at 0.01 *N* concentrations, uncertainty exists in regard to the conditions at 0.1 *N*.

It was to throw light upon the uncertainty which has existed in regard to the relative dissociations of 0.1 *N* HCl and 0.1 *N* KCl that this investigation was undertaken.

## II. Previous Work.

The system

has been carefully studied by several workers. The results which have been obtained at 25°, after correction for the vapor tension of the solution surrounding the hydrogen electrode, and for the new value of the electromotive force of the Weston cell, are summed up in the following table:

Bjerrum <sup>2</sup> .....	0.4273
Loomis and Acree <sup>3</sup> .....	0.4269
Myers and Acree <sup>4</sup> .....	0.4273

Average, 0.4272

This value includes the contact potential existing between 0.1 *N* HCl and 0.1 *N* KCl. Lewis<sup>5</sup> calculates that this potential amounts to —0.0284 volt and as evidence for this value states that Sebastian has obtained for the system

a potential of 0.0284 volt, which represents the contact potential if it is assumed that the two electrolytes are equally dissociated. On the other hand Bjerrum<sup>6</sup> obtains as his best value for the contact potential of the above system —0.0278 and this is just the potential which Myers and Acree obtain by direct comparison of the two electrodes.

It follows then that the difference of potential between the 0.1 *N* HCl hydrogen electrode and the 0.1 *N* KCl calomel electrode lies between 0.3988 and 0.3994 volt, depending upon whether —0.0284 or —0.0278 is adopted for the contact potential. The lower figure 0.3988 is probably nearer the correct value.

At the time this investigation was begun the only figures which were at all reliable for the system

at 25° had been obtained in the laboratories of Acree and Lewis. Loomis and Acree used only two calomel cells and their value for the electromotive force of the system 0.4004<sup>1</sup> can be considered as only a preliminary measurement. Later Myers and Acree studied this combination more thoroughly and found the difference in potential to be 0.4002.<sup>2</sup>

Lewis<sup>3</sup> states that he has obtained as a mean of several direct comparisons of the 0.1 *N* hydrochloric acid hydrogen electrode with the 0.1 *N* hydrochloric acid calomel electrode, 0.3987 volt, which when corrected for vapor tension and for the new value of the Weston cell becomes 0.3990. He states that more recently Sebastian, working in his laboratory, has obtained the same value. No details of these measurements of Lewis and Sebastian have been published so far as the authors are aware.

Since this investigation was begun there has appeared an article by Ellis<sup>4</sup> in which a careful study of the system

has been made at different temperatures and concentrations. In the course of this study four simultaneous measurements with 0.0999 *N* HCl at 25° gave as a mean 0.39884 volt.

It is evident that the electromotive force of the system

has been in doubt by more than 1.5 millivolts.

### III. Experimental Procedure.

All measurements were carried out at 25° ± 0.01, using much the same apparatus and technique as previously described in the articles of Loomis and Acree. The calomel electrode used in the electromotive force measurements was compared before and after each experiment with the mean of several other calomel electrodes, which were assumed to be of standard potential, and any difference in potential was applied to the measured e. m. f. as a "calomel cell correction." This procedure is even more important in the use of hydrochloric acid calomel electrodes than with potassium chloride calomel electrodes.

Several different types of hydrogen electrodes were used, the most satisfactory form for these experiments being a modification of that described by Frary<sup>5</sup> in which a gauze electrode is substituted for his sheet platinum electrode.

<sup>1</sup> The figure given in the original article is 0.4001. The above value is obtained by correcting for the vapor tension at the hydrogen electrode and for the present value of the Weston cell.

<sup>2</sup> To the value given in the original article 0.399803 is to be applied a correction of 0.0004 for the vapor tension at the hydrogen electrode.

<sup>3</sup> THIS JOURNAL, 36, 1973 (1914).

<sup>4</sup> *Idem.*, 38, 737 (1916).

<sup>5</sup> THIS JOURNAL, 37, 2260 (1915).

The system which was being studied involves only very small contact potentials. The only difference in the solutions upon the two sides of the cell is that the acid at the calomel electrode is saturated with calomel. This would produce only a very small contact potential. Consequently no precautions were taken to insure a fresh plane of contact between the two solutions. Care was always taken however to prevent the contamination of the solution about either electrode by that from the other. This was accomplished by keeping at least one stopcock in the system closed except momentarily during measurements.

All measurements were corrected (a) for variations in the potential of the comparison calomel cell, as already noted; (b) for the barometric pressure reduced to  $0^{\circ}$  and corrected for capillarity and latitude; and (c) for the vapor tension of the solution in the hydrogen electrode chamber. The barometric pressure corrections were calculated by the equation

$$e = -\frac{R.T}{2F} \log_e p = -0.02958 \log_{10} p,$$

in which  $e$  represents the desired correction and  $p$  is the corrected barometric pressure in atmospheres. The correction for the vapor tension of the solution is a constant value and equal to  $+0.00040$  volt.

#### IV. Experimental Results.

The following table summarizes the results of the measurements which were carried out. The first column gives the number of the series. Measurements belonging to the same series were carried out with the same set of calomel cells. The second column gives the experiment number. The third column gives the date of the preparation of the calomel, *viz* the day on which it was set to soaking with the solution with which the calomel electrodes were later filled; the date of filling the calomel electrodes; and the date of measurement of the hydrogen electrode against the calomel electrode. The fourth column gives the measured c. m. f.; the fifth the correction to be applied to the calomel cell; the sixth the correction for the barometric pressure; the seventh the correction for the vapor tension; and the eighth column the final value of the corrected e. m. f.

The fourth series of measurements was brought to a close by the breaking of the comparison calomel electrode. An attempt was made to carry out Series V with only four standard calomel electrodes, but after April 15 the agreement of the electrodes among each other became worse and worse, and the measured differences of potential between the calomel electrodes and the hydrogen electrode became unusually low. It was suspected that the electrodes had become contaminated in some way and for that reason the last few measurements of this series are not included.

Of the twenty-nine measurements recorded in the table, No. 8 is considerably the highest and is omitted from the general average. This measurement was made ten days after the one preceding it and the potentials of the different electrodes had become so discordant that there was much doubt in regard to the proper value of the calomel cell correction. Of the remaining twenty-eight measurements the average value is 0.39879. The individual measurements range from 0.39905 to 0.39859, a total variation of 0.46 millivolt and a maximum variation from the mean of 0.26 millivolt. An instrument correction for the potentiometer reduces the average e. m. f. to 0.39876.

In the five sets of calomel electrodes changes were made in the mercury, calomel, and acid in order to eliminate any error due to possible faulty preparation. The variations in the electromotive force are larger than would seem warranted in the measurement of a system involving only very small contact potentials. The only regularity in these variations which could be detected was a general tendency for the potential of the

calomel electrode to increase upon standing. This would be the result if the solution about the mercury electrode were slow in becoming saturated with calomel. It is not believed that such is the case. Ellis showed in the course of his work that hydrochloric acid calomel electrodes rapidly follow temperature changes, and such could not be the case unless saturation is quickly attained. It seems more probable that some chemical change occurs in the system, probably the change of the calomel to the bichloride as suggested by Clarke, Myers, and Acree.<sup>1</sup> These authors agree with us in regard to the 0.1 *N* hydrochloric acid calomel electrode that "its constancy continues over only a short period of time." Ellis finds that calomel electrodes made up with dilute solutions of hydrochloric acid are less satisfactory than those made up with more concentrated solutions, and that with acid of less than 0.03 *N* concentration are for some reason not at all reliable.

It appears then that the 0.1 *N* hydrochloric acid calomel electrode is not nearly as constant and reproducible as the 0.1 *N* potassium chloride calomel electrode. The age of the electrode is an important factor in determining its potential. This is probably the cause of the great variations in previous measurements of the system

and is the cause of the smaller variations in the measurements which are recorded in this paper.

The average value obtained in the measurement of the hydrogen electrode against the 0.1 *N* hydrochloric acid calomel electrode is 0.39876. We have shown in the earlier part of this article that the most probable value of the potential of the hydrogen electrode against the 0.1 *N* potassium chloride calomel electrode, after allowance has been made for the contact potential, is 0.3988. Within the limits of experimental error we have the same electromotive force in each case, indicating that the 0.1 *N* hydrochloric acid calomel electrode has the same potential as the 0.1 *N* potassium chloride calomel electrode. This in turn implies that hydrochloric acid and potassium chloride are equally dissociated at 0.1 *N* concentration. A difference of 1% in the degree of dissociation of the two electrolytes would cause a difference of 0.3 millivolt in the relative potentials of the two electrodes. It follows from these results therefore that the two electrolytes are not more than 1% different in their degrees of ionization at 0.1 *N* concentration.<sup>2</sup>

<sup>1</sup> *J. Phys. Chem.*, 20, 264 (1916).

<sup>2</sup> Since this paper was placed in the hands of the editors there has appeared an article by Harned (*THIS JOURNAL*, 38, 1986 (1916)) in which he arrives by a different method at the conclusion "that the activity of the ions in 0.1 *M* hydrochloric acid is greater than in 0.1 *M* potassium chloride but only slightly greater. If 0.0730 be ac-

## V. Summary.

### 1. The potential of the system

has been found to be  $0.3988 \pm 0.0002$ .

2. The variations in the electromotive force of this system are probably due to a chemical change in the calomel electrode by which the potential increases with time.

3. This series of experiments indicates that within the limits of experimental error, probably within 1%, hydrochloric acid and potassium chloride are equally dissociated at tenth-normal concentrations.

## THE SOLUBILITIES OF LIQUIDS IN LIQUIDS. THE PARTITION OF THE LOWER ALCOHOLS BETWEEN WATER AND COTTONSEED OIL.

BY B. B. WROTH AND E. EMMET REID.

Received September 13, 1916.

### Introduction.

According to the commonly accepted partition law a solute C is partitioned between two immiscible solvents, in contact with each other,

$$\frac{C_a}{C_b} = r = \frac{S_a}{S_b}$$

in which  $C_a$  and  $C_b$  are the concentrations of C in the solvents A and B, respectively,  $r$  is a constant ratio, and  $S_a$  and  $S_b$  are the solubilities of the solute in the two solvents. It has frequently been shown that  $r$  is constant only when the solute C exists in the two solvents in the same molecular aggregation. The equality of  $C_a/C_b = r = S_a/S_b$  has been proved for iodine partitioned between water and carbon disulfide, bromoform, and carbon tetrachloride by Jakowkin.<sup>1</sup> His results are as follows:

From solubilities in				From partition experiments.
A.	B.	$S_a$ .	$S_b$ .	
CS <sub>2</sub>	H <sub>2</sub> O	230	+ 0.3387 = 679	685
CHBr <sub>3</sub>	H <sub>2</sub> O	189.55	+ 0.3387 = 559	558.5
CCl <sub>4</sub>	H <sub>2</sub> O	30.33	+ 0.3387 = 89.6	89.7

cepted to represent the ion-activity of the salt, there is reason to assume that the ion-activity of the acid is 0.0755."

A possible explanation of the slight discrepancy between the conclusion of his article and this one may be found in the value which he adopted for the contact potential of 0.1 N HCl-0.1 N KCl. It will be noted that our conclusion is based upon the assumption that this contact potential is -0.0284 volt. If a lower value of this contact potential, such as found by Bjerrum, is correct, then the potential of the calomel electrode toward a solution of 0.1 N KCl is greater than that of a calomel electrode toward a solution of 0.1 N HCl. In other words, if such is the case, 0.1 N HCl is slightly more dissociated than 0.1 N KCl.

<sup>1</sup> *Z. physik. Chem.*, 18, 590 (1895).

Of course, this law holds strictly only in the ideal case where the solvents A and B are absolutely immiscible and neither modifies the solvent power of the other in the slightest. If any appreciable amount of A dissolves in B, the solvent power of B for C is thereby altered and *vice versa*. Steiner<sup>1</sup> and Gordon<sup>2</sup> have shown that the solubilities of gases in water are much altered by the presence of even small quantities of salts in solutions. However, this is not contradicting the partition law, but simply saying that the value of  $S_a$  and of  $S_b$  should be the solubilities of C in A saturated with B and in B saturated with A, rather than the solubilities in the pure solvents.

Jakowkin<sup>3</sup> has also shown that  $r$  changes progressively with the amount of solute C and that the value of  $r$  approaches  $S_a/S_b$  when larger and larger quantities of C are added. When  $C_a$  and  $C_b$  approach zero,  $r$  approaches another limit which is more properly its ideal value, as only when  $C_a$  and  $C_b$  are very small are the solvents A and B unaltered by the presence of C. When larger amounts of C are present A and B become mutually more soluble and the properties of both solvents are altered. In the present work the smallest practicable amounts of C were used.

Assuming  $C_a/C_b = r = S_a/S_b$ , since there are five quantities in this double equation, we may determine any three and calculate the other two. Thus if we measure  $C_a$  and  $C_b$  and thus find  $r$  we need to measure  $S_a$  in order to calculate  $S_b$ .

Such results must, of course, be considered in the light of the above considerations and be accepted with reserve. The present work was undertaken with the aim of applying this to the calculations of solubilities in the case of certain very soluble liquids. The results are considered as suggestive rather than as conclusive. They mean something, but just what they mean may be left for future consideration.

In a series of experiments in which ethyl alcohol was partitioned between cottonseed oil A, and water B,  $r$  was found to be 28.3. The average of a series of experiments gave the solubility of alcohol in the oil,  $S_a$  as 21.1 g. per 100 cc. Calculation gives  $S_b$  as the solubility of the alcohol in 100 cc. water as 600 g. There are many substances of which water dissolves several times its own weight. For instance, 100 cc. of water dissolve 339 g. of cadmium chlorate at 0° and 549 g. at 65°. In these cases, however, though the solubility is great, it is still limited. One hundred grams of water dissolve 907 g. of calcium iodide at 0° but stops there, and if we shake it with 910 g., 3 g. of the salt are left over, while the 100 g. of water dissolve 600 g. of alcohol, but if more alcohol is added it too disappears in the solution.

<sup>1</sup> *Wied. Ann.*, 52, 275 (1894).

<sup>2</sup> *Z. physik. Chem.*, 18, 520 (1895).

<sup>3</sup> *Ibid.*, 18, 590 (1895).

An examination of the phenomena shows that there is an essential difference between a solid solute and a liquid solute in contact with a solvent. The solid solute, except such substances as gelatine, does not absorb or dissolve the solvent, while the liquid solute plays the role of solvent and the result is two solutions. Thus, if dry ether be added to water, the ether which is not dissolved does not remain anhydrous, but dissolves a considerable amount of the water. The figure 600 obtained for the solubility of alcohol in water, is for anhydrous alcohol in contact with its solution in water. If the alcohol were separated from the water by a semipermeable diaphragm, through which the alcohol alone could pass, this condition might possibly be realized.

Such numbers as these, representing a sort of ideal solubilities, are of interest for the comparison of the properties of the members of a series. They have a practical value in the study of extractions.

The lower alcohols have been studied in the hope of being able to arrange them in a series, so as to show the variation of solubility with molecular weight.

It is difficult to find a suitable liquid for the solvent A, since most liquids that are insoluble in water, dissolve too much of the alcohols, Cottonseed oil was chosen on account of its insolubility in water, its non-volatility, and its accessibility. It served the purpose only fairly well since it is rather difficult to handle and gives up a small amount of volatile matter when steam distilled. It mixes with the higher alcohols, so only partition ratios could be determined with these.

Meyer<sup>1</sup> in a study of the influence of temperature upon the partition coefficient has determined the distribution ratio of ethyl alcohol between olive oil and water. His determinations were made at 3° and 30° with the following results:

	G. substance per 100 cc. of		$C_w/C_o$	Mean.
	Water layer.	Oil layer.		
3°	2.69	0.09	29.8	42.7
3°	3.90	0.07	55.7	
30°	2.64	0.14	18.8	21.3
30°	3.82	0.16	23.8	

The wide variation in his results is due to the fact that he determined the alcohol in the oil layer by difference, throwing all the error on the smaller quantity.

His results at 30° approximate those obtained in the present work for the similar cottonseed oil.

### Materials.

**Cottonseed Oil.**—The ordinary oil was purified by distilling with steam for about two hundred hours. When the density of the distillate ap-

<sup>1</sup> *Arch. exp. Path. Pharm.*, 46, 344 (1901).

proached the density of pure water, the oil was assumed to be ready for use. A small amount of alkali in water was added to neutralize and dissolve any free acid, and the oil filtered through a dry paper in a hot water funnel.

Later in the work it was found that Wessen oil required only one day of distilling with steam before being ready for use, and it was then used in the place of the ordinary commercial oil.

**Ethyl Alcohol.**—The ethyl alcohol was refluxed with lime for a period of several days and distilled. It had a density of  $0.78543^{25}/_4$  corresponding to 99.92% alcohol.

**Methyl Alcohol.**—Difficulty was experienced in dehydrating methyl alcohol. It was first refluxed with lime for several days, then with anhydrous copper sulfate, then finally with metallic calcium. Density  $0.79580^{25}/_4$  corresponding to 99.95% alcohol.

**Propyl, Isobutyl and Isoamyl Alcohols.**—All three alcohols were refluxed with metallic calcium for several days and assumed to be practically anhydrous. Their densities were  $0.80715^{25}/_4$ ,  $0.79949^{25}/_4$  and  $0.81225^{25}/_4$ , respectively, not corrected for air displacement.

#### Procedure.

Weighed amounts of oil and water were placed in a 200 cc. glass stoppered bottle. With the lower alcohols several volumes of oil were used to one of water, so as to increase the alcohol in the oil layer. To this mixture a quantity of alcohol, weighed from a pycnometer, was added. A piece of sheet rubber was stretched over the stopper and securely tied around the neck of the bottle. The bottles were then placed in the shaking machine and shaken for one hour in a constant temperature bath at  $25^{\circ}$ . The bottles were completely submerged in the bath during the shaking. It was found that it required three weeks' standing at  $25^{\circ}$  for the layers to separate clear. To obviate this delay, the bottles containing the mixture were centrifuged at 1350 revolutions per minute until the layers became clear. The temperature of the centrifuge was not regulated but was usually not far from  $25^{\circ}$ .

It was found to require about six hours' centrifuging for the ethyl and methyl alcohol mixtures while the propyl, isobutyl and isoamyl required about three hours.

The bottles were then placed in the  $25^{\circ}$  bath until ready for analysis.

**Estimation of Alcohol in Oil Layer.**—The oil layer containing the alcohol was drawn off by means of a special pipet, shaped something like an Ostwald pycnometer. A suitable amount of the oil was weighed out of the pipet into a Kjeldahl flask, out of which it was distilled with steam. The flask was provided with an efficient trap to prevent splashing over. The receiver was provided with a cork having a small opening, and was placed in an ice bath to diminish evaporation.

The alcohol in the weighed distillate was estimated either by the usual density method or by the interferometer. For the interferometer work a table was prepared for each alcohol. Small weighed bulbs were filled with the anhydrous alcohol, sealed and weighed. These bulbs were broken in glass stoppered bottles containing weighed amounts of water. The interferometer readings of a number of these mixtures were plotted against the percentages of the alcohols. From this a table was calculated, which was used in determining the composition of the distillate.

The interferometer readings with weighed mixtures of alcohols and water are given in the following table:

Methyl Alcohol.				Isobutyl Alcohol.			
CH <sub>3</sub> OH %	0.821%	1.50	3.99	C <sub>4</sub> H <sub>9</sub> OH %	1.89%	2.95	3.18 4.21
Reading	0.62	1.08	2.87	Reading	7.31	11.30	12.17 16.40
Reading for 1%	0.75	0.72	0.72	Reading for 1%	3.86	3.82	3.82 3.89
Propyl Alcohol.				Isoamyl Alcohol.			
C <sub>3</sub> H <sub>7</sub> OH %	1.84%	2.67	3.39 4.24	C <sub>5</sub> H <sub>11</sub> OH %	1.42%	2.31	
Reading	5.75	8.57	11.07 14.48	Reading	5.96	9.72	
Reading for 1%	3.12	3.20	3.26 3.41	Reading for 1%	4.19	4.20	

When cottonseed oil is distilled with steam, no matter how long the process is continued, the distillate always contains a small amount of something which changes its density slightly and also gives a reading in the interferometer. The composition of this distillate remains nearly constant for a long time. The densities of the alcoholic distillates were corrected for this by taking densities of distillates obtained with the same lot of oil containing no alcohol. In the interferometer work the steam distillation of the sample of the oil layer was continued for a considerable time after all of the alcohol had passed over. A specimen of the distillate collected at the end of this distillation was used, instead of pure water, in the other cell of the interferometer. Since the interferometer is a differential instrument, the reading thus obtained represented the amount of alcohol present.

A weighed portion of the filtered water layer was distilled in the Kjeldahl flask and the alcohol determined as above.

For the experiments with ethyl alcohol the pycnometer was used and for the other alcohols the interferometer for estimation of the alcohol.

The absolute solubilities of ethyl and methyl alcohol in the oil were found by adding a weighed amount of alcohol to a weighed amount of oil in a small separating funnel. The mixture was then shaken in a constant temperature bath at 25° for two hours.

The funnels were allowed to remain in the bath until the layers became clear. A sample of the oil layer was then drawn off into a Kjeldahl flask and steam distilled, the amount of alcohol being determined as in the above experiments. The funnel was weighed before and after to

get weight of sample. Since alcohol evaporates from this saturated oil solution very readily, much care was taken to effect this transfer with the least possible exposure to the air, but even then it was difficult to obtain concordant results.

Weighed portions of the alcohol layers were evaporated in wide-mouth weighing bottles on a steam bath. The film of oil gained weight on long heating. This materially interfered with the accuracy of the results.

### Results.

The results are given in the table below.

The experiments are given in the order in which they were made and none are omitted except preliminary experiments at beginning of first two series.

In Column 1 is given volume of oil, which was obtained by dividing the weight of oil put in by 0.922, the density of the oil used. In Column 4 is given weight of alcohol for the total oil layer, calculated from the analysis of a weighed portion of the oil layer, while in Column 5 is the amount of alcohol for the total water layer found in the same way. The sums of these amounts of alcohol are given in Column 6. These sums should equal the amounts put in, which are given in Column 3. The amounts found are usually less, indicating loss of alcohol somewhere in the operations. It is likely that most of this alcohol is lost in handling the water layer as this had to be filtered. Excess of alcohol found over that put in may be explained by error in pycnometer estimation or by presence of volatile matter other than alcohol in the distillate. The distillates from the oil layer were usually about 60 cc. so that the total alcohol present amounted to only about 2% in the distillate.

Columns 7 and 8 contain the amounts of alcohol calculated from 100 cc. of oil and water, and the ratio of these is given in Column 9, as the partition ratio for alcohol between oil and water.

As the greatest error seemed to be in the handling of the water layer, the ratios in Column 10 were also calculated, assuming that the values in Column 4 for alcohol in oil layers are correct and estimating the alcohol in water layer by difference, *i. e.*, the difference between the values in Columns 6 and 4. The values calculated in this way are usually higher and are somewhat more regular.

The values of the partition ratios have not been calculated by difference in the case of isobutyl and isoamyl alcohols since the amounts of these alcohols in the two layers are more nearly equal, and the probable errors of estimating the alcohols in the two layers were nearly the same.

Some results which appear erratic are in parentheses and have not been used in making the averages.

### PARTITION OF METHYL ALCOHOL BETWEEN COTTONSEED OIL AND WATER.

### PARTITION OF ETHYL ALCOHOL BETWEEN COTTONSEED OIL AND WATER.

[illegible]

### Discussion of Results.

The average results are brought together in table.

PARTITION RATIO BETWEEN WATER AND COTTONSEED OIL.					
Alcohol.	Methyl.	Ethyl.	Propyl.	Isobutyl.	Isoamyl.
Ratio.....	103.6	28.3	6.41	1.70	0.47
Square root of ratio.....	10.18	5.32	2.53	1.30	0.68

The ratios decrease rapidly as the number of carbon atoms in the alcohol increase, each ratio being approximately one-fourth of the preceding ratio.

Taking these ratios as fractions, the numerators which represent the solubilities of the alcohols in water, increase as number of carbon atoms decrease, while the denominators, or the solubilities of the alcohols in the oil increase in the opposite directions. For this reason the square roots of these ratios have been plotted against number of carbon atoms in the

curve below.

The solubility of methyl alcohol in cottonseed oil appears to be 4.84 g. per 100 cc. while for ethyl alcohol it is 21.2 or about four times as great. We have  $4.84 \times 103.6 = 505$  and  $21.2 \times 28.3 = 600$ . From this 505 g. methyl alcohol and 600 g. ethyl alcohol should dissolve in 100 cc. water. These represent, in the same approximation, what may be termed ideal solubilities. At any rate the numbers 4.84 and 103.6 represent something real as determined by experiment and their product must have some meaning also. Further work will have to be done before these results can be satisfactorily inter-

preted. It is surprising that methyl alcohol gives the smaller number 505, while ethyl alcohol gives the larger number 600. It was expected that methyl alcohol would give the larger number as the fact that methyl alcohol is more difficult to salt out of a solution than ethyl, seems to indicate a greater affinity for water and, hence a greater solubility in water. The difficulty may be in the numbers 4.84 and 21.2, the directly determined solubilities of the two alcohols in the oil. These do not represent the amounts of alcohol taken up by the oil when in contact with the pure alcohols, but the amounts in the oil when the oil is in contact with solutions of the oil in the two alcohols. If we consider molecular solubilities, the order is what we should expect, since  $505 \div 32 = 15.8$  and  $600 \div 46 = 13.0$ .<sup>1</sup> Taking the higher and more concordant values we find that 100 g. of methyl alcohol dissolve 8.45 g. of cottonseed oil and 100 g. ethyl alcohol, 11.75 g.

Experiments showed that propyl, isobutyl, and isoamyl alcohols mix with cottonseed oil in all proportions. This prevented the determinations of their direct solubilities. The solubilities of isobutyl and isoamyl alcohols in 100 cc. water are given in the tables as 9.55<sup>18°</sup> and 2.67<sup>22°</sup>. According to the above reasoning, the solubilities of these two alcohols in the oil should be  $9.55 \div 1.70 = 5.6$  and  $2.67 \div 0.47 = 5.6$ . This shows that we must be guarded in drawing conclusions and that there are factors which are not taken into consideration in the reasoning as stated above.

These alcohols, when they contain a few per cent. of water, do not mix with the oil. The phenomena of mutual solubility are quite complex and require much further study. This work is being continued in this laboratory.

### Summary.

1. The partition ratios of methyl, ethyl, propyl, isobutyl and isoamyl alcohols between water and cottonseed oil at 25° are found to be 103.6, 28.3, 6.41, 1.70 and 0.47, respectively.
2. These are found to change regularly with increased number of carbon atoms.
3. The solubilities of methyl and ethyl alcohols in cottonseed oil are 4.84 and 21.2 g. per 100 cc. oil.
4. The attempt has been made by using these numbers and the partition law to calculate the ideal solubilities of the lower alcohols in water.

[CONTRIBUTIONS FROM THE BUREAU OF CHEMISTRY, U. S. DEPARTMENT OF AGRICULTURE.]

## THE SEPARATION OF LITHIUM FROM THE OTHER ALKALI METALS.

By SAMUEL PALKIN.

Received August 5, 1916.

Numerous methods for the separation of lithium from the other alkali metals have been proposed, and in a paper by Skinner and Collins<sup>1</sup> these methods are carefully reviewed. Inasmuch as the errors and difficulties involved in each case have been so clearly pointed out by the above mentioned investigators, no attempt will be made in this paper to review fully the literature on the subject, except to mention those instances where the work has a direct bearing on the principles involved in the method herein proposed.

In brief, it may be stated that the methods depending on organic solvents for the extraction of lithium are of two classes: (1) Those in which the dried mixed chlorides are treated with the solvent. The Rammelsberg<sup>2</sup> (ether-alcohol) method, the Kahlenberg-Krauskopf<sup>3</sup> (pyridine) method and the Winkler<sup>4</sup> (isobutyl alcohol) method are of this class. (2) Those in which the sodium and potassium chlorides are precipitated from solution by the organic solvent. This is the case with the Gooch<sup>5</sup> (amyl alcohol) method.

The salient objections to the methods of the first class, as pointed out in the paper of Skinner and Collins, are (1) tendency to occlusion, therefore incomplete extraction of the lithium; (2) possibility of solution of some of the sodium and potassium chlorides in the lithium solvent; (3) formation of lithium hydroxide on drying the chlorides (the hydroxide being insoluble in the organic medium).

The objections to the methods of the second class, which hitherto has been limited to that of Gooch, are as follows: (1) The amyl alcohol dissolves some of the other salts (sodium and potassium chlorides) and a correction must therefore be applied. The separation is consequently not absolute. (2) The unpleasant odor and disagreeable physiological action of its vapors make it quite objectionable to work with.

The method proposed in this paper, like the Rammelsberg<sup>2</sup> method, makes use of alcohol and ether but in a totally different manner. Instead of *dissolving* out the lithium chloride, the sodium and potassium chlorides are progressively *precipitated* from a water solution. The es-

<sup>6</sup> *Loc. cit.*

entials of the method are as follows: The dried mixed chlorides are dissolved in a definite minimum amount of water acidified with HCl, and the major portion of the sodium and potassium chlorides is precipitated by the addition of absolute alcohol followed by ether. The mixture is then filtered, the filtrate evaporated and the residue taken up in absolute alcohol containing a drop of HCl. The residual amount of sodium and potassium chlorides, which under the conditions prescribed rarely exceeds 0.006 g., is then precipitated completely by addition of ether. It will therefore be seen that the objections to the existing methods, as enumerated above, are eliminated in the proposed method.

### Experimental.

In order to determine the relative solubility of sodium and potassium chlorides in mixtures of alcohol and ether containing water and hydrochloric acid, a large number of experiments were performed, with a view of obtaining the optimum proportions for the precipitation of these salts. The few following experiments will serve as illustrations:

TABLE I.  
Relative Solubilities of Sodium and Potassium Chlorides.

	1.	2.	3.	4.	5.	7.	8.
NaCl (g.).....	0.1500	0.1500	0.1500	0.1500	0.0500	....	0.1000
KCl (g.).....	0.1500	0.1500	0.1500	0.1500	0.0500	0.1000	....
H <sub>2</sub> O (cc.).....	6	6	0	0	0	0	0
Conc. HCl (cc.)....	2	2	0.3	0.3	0.3	0.3	0.3
Abs. alcohol (cc.)...	80 <sup>1</sup>	80	60	60	60	60	60
Ether <sup>2</sup> .....	240	240	300	300	300	300	300
Salt recovered (g.)..	0.2702	0.2904	0.2992	0.2993	0.0995	0.0995	0.0996
Salt dissolved (g.)...	0.0298	0.0096	0.0008	0.0007	0.0005	0.0005	0.0004

100 cc. solvent....	0.0091	0.003	0.0002—	0.0002—	0.00011	0.0001+	0.0001+

The experiments on the separate salts, sodium chloride and potassium chloride, respectively, show that only about 0.0005 g. remains in solution in a volume of 360 cc. of liquid. Since only about one-sixth of this volume is used in the final precipitation, the loss is negligible. Experiments on the mixed sodium and potassium chlorides show only a very slightly greater amount dissolved (less than 0.0008 g. per 360 cc.), which is negligible for the volumes used in the actual determinations. Numerous subsequent experiments (Table IV), where separation of lithium from the other alkali metals have been carried out, show quite clearly that the weights of sodium and potassium chlorides recovered are, within experimental errors, practically those used.

<sup>1</sup> In Expt. 1 95% alcohol was used. The remaining ones were carried out with absolute alcohol.

<sup>2</sup> The ether used in these and following experiments was U. S. P., sp. gr. 0.716–0.717 at 25°.

The presence of a large excess of hydrochloric acid was found unnecessary. A slight acidity, however, was found quite essential for the complete aggregation and precipitation of the sodium and potassium chlorides, as illustrated by the following experiments:

TABLE II.  
Effect of HCl on Precipitation of Sodium and Potassium Chlorides.

	1.	2.	3. <sup>1</sup>	4.	5.
Mixed salt NaCl and KCl.....	Excess	Excess	Excess	Excess	Excess
Water.....	0	0	0	0	0

Condition of filtrate.....	Turbid	Clear	Turbid	Clear	Clear

The lithium chloride used was prepared from lithium carbonate by treatment with hydrochloric acid. The lithium carbonate available was found to contain a considerable amount of sodium and potassium salts. The purification of the chloride from the other alkali metals was carried out by the method of separation described in this paper and the resulting residue from the alcohol-ether solution evaporated; gently ignited and powdered. This powder was then tested for purity in the following manner: (a) 1 g. dissolved completely without residue in 20 cc. C. P. pyridine on heating. The pyridine had been previously purified by distillation over KOH, the fraction boiling at  $115+^{\circ}$  being used. (b) 1 g. dissolved completely in 10 cc. absolute alcohol + 1 drop concentrated HCl + 50 cc. ether. No precipitate formed after two hours.

A number of experiments were performed to test the extent of solubility of lithium chloride in varying mixtures of alcohol and ether containing hydrochloric acid. It was found that approximately 10.5 g. were dissolved by 580 cc. of a mixture of one part absolute alcohol and three parts ether at room temperature (about  $24^{\circ}$ ), and that 1 g. of lithium chloride dissolved quite readily in 10 cc. absolute alcohol + 1 drop concentrated HCl, and remained in solution when five times its volume (50 cc.) of ether was added.

Experiments in Table III show the amounts of sodium and potassium chlorides retained in solution after the first precipitation, under the conditions given in the proposed method. The maximum quantity seems to be about 0.006 g. The exact quantity, however, is quite immaterial, as it is all removed in the second or final precipitation. Table IV shows results obtained with mixtures of all three salts, sodium, potassium and

<sup>1</sup> 0.1 cc. HCl was added to No. 3 and allowed to stand  $\frac{1}{2}$  hour and the solution became clear.

lithium chlorides. The sodium and potassium chlorides were prepared by precipitating each from a saturated solution with concentrated hydrochloric acid and heating the precipitate to dull redness. A mixture was prepared consisting of 50% sodium chloride and 50% potassium chloride.

The lithium chloride (purified as described previously) was used in the form of an alcoholic solution in nearly all the experiments, except in those few cases where large quantities of lithium were necessary, when the quantities were weighed. The alcoholic solutions were made up to volume (about 2.5 g. in 500 cc.) at definite temperature (about 24°) and aliquot portions were measured by a pipet at the same temperature, both for the blank determinations and actual experiments, delivered into Erlenmeyer flasks or tall beakers and evaporated to dryness on the steam bath. Weighed quantities of the other salts were then added. The results in Table IV are self-explanatory. The lithium was weighed in most cases as the sulfate, although in a number of instances it was determined by the "optional method for lithium" as described in the proposed method, that is, by precipitating the halogen as a silver salt after titrating the excess of HCl with 0.1 *N* alkali and calculating the lithium chloride therefrom.

Some difficulty was experienced in converting large quantities of lithium chloride into  $\text{Li}_2\text{SO}_4$  and bringing it to a constant weight. A high temperature was necessary. With large quantities of lithium there was some tendency to spatter.

An experiment was made to determine the amount of sodium and potassium chlorides dissolved by the ether-alcohol mixture used in washing. A Gooch crucible containing about 0.5 g. of the mixed salts was ignited, cooled and weighed. This was then washed with 120 cc. of the ether-alcohol mixture (1 part 95% alcohol and 4 parts ether) as directed in the proposed method. The crucible on drying, igniting and weighing showed no change in weight. No residue was found on evaporation of the filtrate.

The method was submitted to three coöperators, Messrs. E. K. Nelson, H. E. Buchbinder and E. C. Merrill, of the Bureau of Chemistry. Definite amounts of lithium were taken in the form of solution, the lithium content of which was previously determined. The mixed sodium and potassium chlorides were, in each case, weighed out by the coöperators. The following results were obtained by them, the lithium being weighed as sulfate.

### The Proposed Method.

The total alkali chlorides are dissolved in a minimum amount of cold water in a tall 200 cc. beaker. About 1.5 cc. will be more than sufficient for 0.5 g. of the salts. One drop of concentrated HCl is added and *gradually* 20 cc. absolute alcohol—the alcohol being dropped into the center of the beaker (not on the sides) while rotating. The sodium and potassium chlorides should be precipitated in a perfectly uniform granular condition. In a similar manner while rotating the beaker, 60 cc. ether are added and the mixture is allowed to stand about 5 minutes, or until the precipitate is well agglomerated and the supernatant liquid almost clear. The beaker is rotated occasionally.

The mixture is then filtered through a weighed Gooch crucible into an Erlenmeyer flask, using a bell-jar arrangement. The beaker is thoroughly washed with a mixture of 1 part alcohol and 4 to 5 parts ether. A rubber tipped rod is necessary for this purpose. The precipitate in the Gooch crucible is also well washed and the crucible set aside. The funnel is well washed in order to remove any lithium therefrom into the flask containing the filtrate.

The filtrate is evaporated to dryness on the steam bath (using a current of air). The residue is taken up with 10 cc. of *absolute alcohol*, warming if necessary, so that practically everything passes into solution. If a slight film remains on the bottom of the flask and sides, it is removed by rubbing with a rubber-tipped glass rod. While rotating the flask, 50 cc. ether are added. *One drop* of concentrated HCl is added, the flask rotated and allowed to stand for one-half hour. It is well to rotate the flask at frequent intervals. When the fine precipitate has agglomerated (only a very small amount is usually precipitated), it is filtered through the same crucible as used in the first precipitation, into a tall beaker. The residue is washed with ether-alcohol mixture, using the same precautions as outlined in the first precipitation. After drying in an oven, the crucible is gently ignited, cooled and weighed.

The ether-alcohol solution of lithium is evaporated on the steam bath. The residue is taken up in a little water and a slight excess of sulfuric acid added. The solution is then carefully transferred to a weighed porcelain or platinum dish. The solution is evaporated as far as possible on the steam bath and the residue is then very gently ignited over a flame. By placing the dish on a triangle over an asbestos gauze and using a low flame, the solution can be evaporated without spattering.

The residue is then carefully ignited over a full flame. When charring has occurred, it is well to repeat the ignition with sulfuric acid. The factor used for conversion of lithium sulfate to lithium chloride was 0.7718.<sup>1</sup>

<sup>1</sup> With the 1916 atomic weights this factor becomes 0.7713, which does not however materially influence the results.

### Optional Method for Lithium.

The solution of the lithium in the ether-alcohol is evaporated to dryness on a steam bath and finally dried in an oven at  $110^{\circ}\text{C}$ . for 15–20 minutes. The residue is taken up in 5–10 cc. alcohol, warming if necessary. This solution is diluted with about 50 cc. of water. If a slight sediment remains, the liquid is filtered through a Gooch crucible and washed with water. A few drops of phenolphthalein are added to the filtrate (the reaction should be acid) and the liquid titrated with tenth-normal alkali. The chlorides are precipitated as the silver salt and from the weight of the latter there is subtracted the amount corresponding to the hydrochloric acid determined in the titration. The factor used for converting  $\text{AgCl}$  into  $\text{LiCl}$  was 0.2958.

Where the total quantity of mixed chlorides is greater than 0.5 g., proportionately larger quantities of solvents are necessary in the first precipitation. The second precipitation is carried out in exactly the same manner as for 0.5 g. of salts indicated in the method. More accurate results have been obtained, however, with quantities of total chlorides not exceeding 0.5 g.

## THE PURIFICATION AND ATOMIC WEIGHT OF YTTRIUM.

[SECOND PAPER.]

BY B. SMITH HOPKINS AND CLARENCE W. BALKE.

Received September 15, 1916.

A preliminary paper on this subject by Egan and Balke appeared in THIS JOURNAL in April, 1913, in which the sources of material, the preliminary processes of purification and the trial determinations of the atomic weight were discussed. Since the publication of this paper, the work has progressed steadily and the purpose of the present communication is to report progress on the problem.

### Historical.

The atomic weight of yttrium has been determined by a large number of investigators. The results obtained previous to 1873 are of little value since the material used certainly contained considerable quantities of rare earths other than yttrium. Some of these early investigators, however, obtained numbers which are surprisingly close to the accepted value.

In 1873 Cleve and Höglund<sup>1</sup> published a memoir in which six determinations of the ratio  $\text{Y}_2\text{O}_3$  to  $\text{Y}_2(\text{SO}_4)_3$  are recorded, the mean value obtained being 89.58. The material used in this series was known to contain a small amount of terbium, which the authors attempted in vain to remove

<sup>1</sup> K. Svenska Vet. Akad. Handlingar, Bb. 1, No. 8 (1873).

by the slight solubility of terbium formate and double potassium sulfate. Nine years later Cleve published another paper<sup>1</sup> in which he described the further purification of his material. The small amount of terbium was removed by fractional precipitation of the nitrate with oxalic acid. By this means four fractions of constant molecular weight were obtained, and with this material twelve determinations of the atomic weight of yttrium were made by observing the gain in weight when the dry oxide, was converted to anhydrous sulfate. The average value obtained in this second series was 89.12.

Jones<sup>2</sup> determined the atomic weight of yttrium in 1894, using material prepared by Professor Rowland, who used the method of fractional precipitation with potassium ferrocyanide. This material was estimated, by examination of its spectrum, to contain less than 0.5% of other elements. Two series of ten determinations each were made; in one the oxide was dissolved in sulfuric acid and the excess acid expelled by heating; in the other the crystallized sulfate was ignited to the oxide with the blast lamp. The results obtained were 88.96 for the first series and 88.98 for the second. These results were criticised by Delafontaine,<sup>3</sup> but Jones' reply<sup>4</sup> was insistent and his results practically determined the international value until recently.

In 1900 Muthmann and Böhm published<sup>5</sup> the result of a single determination, in which the sulfate was ignited to the oxide, obtaining the value 88.97, which agrees exactly with that obtained by Jones.

In 1901 G. and E. Urbain<sup>6</sup> in discussing the purification of yttrium material, stated that a final fraction gave an atomic weight of 88.6, but no information is supplied concerning the method used or the purity of the material.

In the same year Bodman<sup>7</sup> published the results of three determinations, obtaining the value 91.57 from the transformation of the oxide to the sulfate.

K. T. Postius, in his dissertation presented to the Technische Hochschule at Munich in 1902, describes seven determinations of the ratio  $Y_2O_3 : Y_2(SO_4)_3$  with an average value of 88.35. In expelling the excess acid from the sulfate he used temperatures from 350° to 370° only.

Buill<sup>8</sup> in 1905 obtained the value 89.70 from two determinations of

<sup>8</sup> *Z. anorg. Chem.*, 47, 464 (1905).

the same ratio, making use of the microbalance. In this paper there is also an interesting study of the effect of heating yttrium sulfate in an electric furnace for 15-minute periods. He found that the neutral sulfate when heated for this length of time was stable between the temperatures of  $450^{\circ}$  and  $650^{\circ}$ ; that the material was completely transformed into the basic salt corresponding to the formula  $Y_2O_3 \cdot SO_3$  at  $900$ – $950^{\circ}$ ; and that above these temperatures the material began to break down into the oxide, the decomposition becoming complete at  $1100^{\circ}$ .

Feit and Przibylla<sup>1</sup> departed from the usual method of determining the atomic weight of yttrium by using a titration method. The oxide was dissolved in an excess of 0.5 *N* sulfuric acid and the excess acid titrated with 0.1 *N* sodium hydroxide, using methyl orange as an indicator. The proportion of oxygen in the oxide and in turn the atomic weight of yttrium were calculated from the data obtained. The average of their six determinations gave yttrium an atomic weight of 89.35.

A. Bettendorff<sup>2</sup> in 1907 obtained yttria of a high degree of purity by fractional precipitation with potassium ferrocyanide. His purest fraction was shown by spectrographic study to be free from other rare earths. A single determination, the details of which are not given, showed his product to have an atomic weight of 88.76.

In 1913 Meyer and Wuorinen<sup>3</sup> discussed at length the results obtained by various investigators and compared several of the methods used in obtaining pure yttria. By using a combination of methods they prepared a product of a high degree of purity with which the atomic weight was determined by the synthesis of the sulfate. The authors found that the excess of sulfuric acid could not be expelled even at a temperature of  $500^{\circ}$ . Instead of trying to drive off the excess acid they proceeded as follows: The weighed oxide was dissolved in a small excess of sulfuric acid; the solution was evaporated to dryness; the sulfate was then heated to a temperature of  $450^{\circ}$  to  $500^{\circ}$  and weighed; finally the amount of acid retained by the salt was determined by titration with decinormal sodium hydroxide, using methyl orange as an indicator. The acidity determined in this way was calculated as  $SO_3$  and subtracted from the weight of the yttrium sulfate, giving a corrected weight from which the atomic weight was determined. Two determinations were made, giving an average of 88.6.

**The Ratio.**—A review of the methods which have been used in determining the atomic weight of yttrium shows that the sulfate was used in some manner in every case, and that in the majority of investigations the synthesis of the sulfate was relied upon to give the desired ratio. In two

<sup>1</sup> *Z. anorg. Chem.*, **50**, 262 (1906).

<sup>2</sup> *Ann.*, **352**, 88 (1907).

<sup>3</sup> *Z. anorg. Chem.*, **80**, 7 (1913).

cases the values were based upon the decomposition of the sulfate, and in two others they depended upon titration methods. A comparison of the values obtained from the synthesis of the sulfate shows that Bodman's value, 91.57, is the highest, and Postius', 88.35, the lowest. It is perhaps worthy of note also that these two investigations were nearly or quite contemporaneous. It would seem that the difference in the results is much too great to be accounted for wholly by the varying purity of the material used, since if Postius' results are correct then Bodman's product must have contained about 6.5% of erbia or an equivalent amount of other rare earths. This quantity would certainly be detected by the means used in proving the purity of the material and it would seem that this wide variation must be explained in some other way than by differences in the purity of the material employed.

After repeated efforts to obtain concordant results with the sulfate method, we are led to the conclusion that the method is not ideal for three reasons. First, the anhydrous sulfates are extremely hygroscopic and Nilson has shown that they cannot be weighed in a perfectly anhydrous condition if removed from a phosphorus pentoxide desiccator of the ordinary type, and Bunsen declares that a thin glass weighing tube is not sufficient to protect the sulfates from the moisture of the air. It seems that all investigators have not had this point in mind in their manipulation. A second difficulty with the sulfate method as generally carried out, is the impossibility of telling when the excess sulfuric acid has been expelled. It is customary to follow the method suggested by Cleve and heat to constant weight and then if the residue dissolves to a clear solution to consider that only the normal anhydrous sulfate remained. It is obvious that this test is a good one to discover when the heating is carried too far and too much  $\text{SO}_3$  has been expelled, but it is of no value in determining when some acid still remains in the sulfate. If the heat is applied suddenly, as with a flame, we would expect the center of the mass to remain acid for some time after the outer layer had become neutral or basic. Brauner and Pavlicek,<sup>1</sup> in a similar study of the effect of heating lanthanum sulfate, state that in 27 experiments not a single case was discovered in which the mass was homogeneous, the tendency being for the outer layers to become basic, the middle portions neutral, and the central upper layers acid. When such a mass is dissolved in water two facts should be noted: (1) a clear solution may be obtained but its reaction to indicators is a matter of chance; (2) a portion of the mass which is basic should dissolve more slowly than the rest and this experience was noted by Jones<sup>2</sup> who explained the phenomenon by supposing that a hydrate of lower solubility had been formed. We have had a similar ex-

<sup>1</sup> *Trans. Chem. Soc.*, 81, 1243 (1902).

<sup>2</sup> *Am. Chem. J.*, 17, 160 (1895).

perience with nearly every sample of heated sulfate which has been dissolved in water and we are led to believe that the less soluble portion is the basic outer layer which finally dissolves in the acid from the inner portions.

A third reason for questioning the accuracy of the sulfate method comes from the fact that it is impossible to obtain constant weight except at some definite temperature. As long ago as 1887 Bailey showed<sup>1</sup> that on heating "didymium" sulfate containing some free sulfuric acid up to and above 360°, no equilibrium could be obtained, but each increase in temperature is followed by a further loss in weight. Brauner and Pavlicek<sup>2</sup> reported the same experience with lanthanum sulfate, and showed that a temperature of 600° or more is needed to expel all the acid. Brill claims<sup>3</sup> that normal yttrium sulfate is stable between the temperatures of 450° and 650°. It is to be noted, however, that Brill heated his material for 15-minute periods only. In order to discover whether or not the sulfate would continue to remain constant in weight if kept for long periods at a definite temperature we have performed two tests. Two samples of the oxide from different sources were weighed out in platinum crucibles and converted into the sulfate in the usual manner.<sup>4</sup> These sulfates were then heated in an electric muffle, the temperature being determined by a recently calibrated pyrometer. At the end of the heating periods the hot crucibles were placed in weighing bottles whose stoppers were apparently tight, and the bottles put in a roomy sulfuric acid desiccator. When cold the stoppers of the bottles were opened for a moment and the bottles containing the crucibles weighed by substitution, the tare being a similar bottle containing an empty platinum crucible which was treated exactly like the crucibles containing the sulfates. The results are given in the following table, the weights being the values obtained in air:

TABLE I.

No.	Temp.	Hours.	Crucible I.		Crucible II.	
			Sulfate.	Atomic weight.	Sulfate.	Atomic weight.
1	470°	4	0.73574	91.97	0.78520	91.41
2	470°	16	0.73503	92.19	0.78486	91.51
3	485°	14	0.73503	92.19	0.78461	91.58
4	525°	12	0.73358	92.64	0.78477	91.54
5	575°	6	0.73382	92.56	0.78450	91.62
6	580°	7	0.73341	92.69	0.78442	91.64

These results show that there is generally a loss in weight when the sulfates are heated for long periods. The cases in which there is a gain in weight are probably due to the absorption of moisture by the hygroscopic

<sup>1</sup> *Trans. Chem. Soc.*, 51, 683 (1887).

<sup>2</sup> *Ibid.*, 81, 1250 (1902).

<sup>3</sup> *Z. anorg. Chem.*, 47, 464 (1905).

<sup>4</sup> *THIS JOURNAL*, 35, 370 (1913).

sulfate. The sulfates from both crucibles were dissolved in water and showed some basic salts present, hence the gradual loss in weight was not due at all stages to the giving off of occluded sulfuric acid, but to the loss of  $\text{SO}_3$  from the yttrium sulfate. It is difficult to say just where the heating should have been discontinued in order to give the normal salt and the true atomic weight.

On account of the divergent results and the unreliability of the ratio depending on the synthesis of the sulfate, it seems highly desirable that some entirely different ratio should be used. Encouraged by the early results obtained with the ratio  $\text{Y}_2\text{O}_3$  to  $2\text{YCl}_3$ , this method has been carefully studied and we believe it to be the most satisfactory ratio yet proposed for the determination of the atomic weight of yttrium.

#### Experimental.

**Preparation of Material.**—The sources of material, the early treatment and the general methods of procedure have been presented in the preliminary paper<sup>1</sup> and will not be repeated here. An extensive study was made of three methods of purification and the results obtained will be discussed. In this study two methods were used to observe the effect of the treatment. The first was by means of the absorption spectra of the solutions, and the second was by watching the changes in the atomic weight of the material. For the latter work a portion of each fraction was carefully purified by dissolving the oxide in pure hydrochloric acid, reprecipitating twice with redistilled ammonia and twice with a hot solution of pure oxalic acid, each precipitate being thoroughly washed by several liters of boiling water. No effort was made in these trial determinations to remove the alkali metals, which probably accounts in part, at least, for the fact that the trial values run uniformly lower than the actual values.

In making the trial determinations of the atomic weights three methods were used. In the early part of the investigation the synthesis of the sulfate was tried but it was abandoned because of the difficulty of obtaining concordant results. A second method was then tried as follows: A weighed sample of the rare-earth oxide was dissolved in a known amount of 0.1 *N* sulfuric acid; there was added a quantity of a 5 *N* neutral solution of potassium oxalate slightly in excess of the amount needed to precipitate the rare earth present; and finally the excess of sulfuric acid was determined by titration with 0.1 *N* potassium hydroxide, using phenolphthalein as an indicator. This method is rapid and gives quite satisfactory results, although the presence of a rare-earth precipitate in the acid solution makes it difficult to obtain a sharp end point.

The third trial method used in observing the effect of the purification methods upon the yttria is as follows: Two samples of rare-earth oxalate

<sup>1</sup> THIS JOURNAL, 35, 365 (1913).

are weighed out, one in a small Erlenmeyer flask and the other in a platinum crucible. It is absolutely essential that these two samples be uniform in composition. The sample in the crucible is ignited to the oxide and the percentage of oxide in the oxalate determined. The sample in the flask is dissolved in a slight excess of dilute sulfuric acid and the amount of oxalic acid determined by titration with twentieth normal potassium permanganate. Then the percentage of oxalic acid in the oxalate is calculated and the atomic weight determined by the proportion

$$X + 24 : 108 = \text{percentage of oxide} : \text{percentage of oxalic acid}.$$

In order to make sure that the oxalate contained no water-soluble substances which would reduce the permanganate, samples were soaked for 50 hours in conductivity water, at the end of which time the water contained no reducing substance. While this method is somewhat more laborious than the preceding, it has been used more than either of the others for the reason that it gives more concordant results. A comparison of the three methods is shown in Table II, in which are recorded the atomic weights of certain fractions determined by more than one method.

TABLE II.  
Atomic weight determined by

Sample.	KMnO <sub>4</sub> titration.	KOH titration.	Sulfate.
1	89.30	90.12	.....
2	89.70	91.07	.....
3	88.88	89.70	.....
4	89.34	90.26	.....
5	93.76	.....	94.10
6	93.22	94.56	94.70
7	89.34	90.47	90.28

This table shows that the values obtained by the permanganate titration are somewhat lower than those obtained by the other methods and are probably no nearer the true value, but this method is preferred to the others because we have found it more reliable and hence more serviceable in determining the progress of the work. That the results from this method are too low is made evident by comparing the values obtained by its use with the atomic weights obtained by the use of the chloride method.

**The Chromate Method.**—An attempt was made to remove other less basic earths from yttrium by repeated treatment with the chromate method. The process was carried out exactly as described in the preliminary paper.<sup>1</sup> The fractions obtained in the previous chromate treatment were divided into five groups according to their atomic weight and each group was put through the chromate fractionation in a separate flask. The material used for this work contained considerable quantities of erbium and holmium and probably contained small amounts of other

<sup>1</sup> THIS JOURNAL, 35, 366 (1913).

rare earths, especially thulium, dysprosium and possibly terbium. Six fractions were precipitated with potassium chromate and the seventh and largest fraction was thrown down by potassium hydroxide. The results are shown in Table III.

TABLE III.

Flask.	Weight of oxide.	Av. at. wt.	Fractions obtained.	Atomic weight of last fraction.
I.....	160	92.9	7	90.3
II.....	160	92.4	7	89.2
III.....	153	90.8	7	89.1
IV.....	160	.... <sup>1</sup>	7	90.1
V.....	160	94.3	7	91.3

A second run was made in the same manner, using the last fractions from Flasks II and III in Flask I<sub>2</sub> and the last fractions from Flasks I and IV in Flask II<sub>2</sub>; Flask III<sub>2</sub> contained the seventh fraction from Flask V, together with a quantity of yttria of about the same atomic weight. The results are shown below:

TABLE IV.

Flask.	Weight of oxide.	At. wt. of orig. subs.	Fractions obtained.	At. wt. last fraction.
I <sub>2</sub> .....	160	89.15	8	89.35
II <sub>2</sub> .....	160	90.20	8	90.20
III <sub>2</sub> .....	160	91.35	8	90.90

These results show that the limit of efficiency of the chromate method had been reached since both Flasks I<sub>2</sub> and II<sub>2</sub> show the same atomic weight as the original material within the limits of experimental error of the sulfate method which was used to determine these values. Accordingly it was determined to take the material from the last fractions of the second run and try the efficiency of the fractional precipitation with dilute ammonia. The absorption spectra of the last fractions showed a slightly decreased intensity of the holmium lines, considerably less erbium and none of the other rare earths. This method apparently is not able to remove the last traces of either erbium or holmium.

**The Ammonia Method.**—Fractions 7 and 8 from both Flasks I<sub>2</sub> and II<sub>2</sub> and Fraction 8 from Flask III<sub>2</sub> were combined, giving 386 g. of yttrium oxalate, the average atomic weight of the yttrium being 90.31. This was ignited to the oxide, dissolved in HCl, evaporated to dryness and dissolved in about 5 liters of water. To this solution dilute ammonia was added, the mixture allowed to stand for 24 hours, the precipitate filtered out and the solution evaporated to its original volume, when the process was repeated. This material was subjected to 42 fractionations in this manner, the precipitates giving purified oxalates which averaged 3.1 g. in weight. The ammonia added was so dilute that there was no cloudiness when the solutions were first mixed, but on standing a faint precipi-

<sup>1</sup> Flask IV contained no material with higher atomic weight than 92, but the average atomic weight was not determined.

tate appeared. The early fractions were precipitated by two liters of ammonia which was 0.0125 *N*; then the strength was decreased to 0.01 *N* and the volume of precipitant increased to three liters. Fractions from this series are designated as H fractions.

In exactly the same way 37 fractions were obtained from a solution representing 246 g. of the purest oxalate obtained in the work described in the preliminary paper. When a saturated solution of the chloride of this material was examined with the spectroscope, no trace of holmium or dysprosium could be seen, but faint lines of erbium were visible. It was estimated to contain about 0.5 % of erbium salts. The fractions prepared from this material are designated as E fractions and the atomic weights obtained from various fractions of the two series are shown in Table V.

TABLE V.

	Atomic weights.	
	H series.	E series.
Fraction 1.....	94.7	91.2
Fraction 10.....	92.7	89.7
Fraction 15.....	91.8	89.8
Fraction 20.....	90.7	....
Fraction 25.....	90.2	88.7
Fraction 30.....	89.9	88.7
Fraction 35.....	89.9	88.7
Fraction 40.....	89.9	....

Fractional precipitation by dilute ammonia is slow, but is capable of removing the less basic earths from yttrium when they are present in considerable quantities. This method seems to be useless for removing the last traces of both erbium and holmium. That the E series gave material of lower atomic weight than the H series is undoubtedly due to the fact that the latter contained considerable holmium while the former was free from this element.

**Sodium Nitrite Method.**—An extensive study of the effects of fractional precipitation by sodium nitrite was made. This method suggested, by Holden and James,<sup>1</sup> consists in adding a strong solution of sodium nitrite to the nearly neutral solution of the rare-earth nitrates. We have found it expedient to modify in certain features the procedure recommended by Professor James and so our practice is given in full. A quantity of rare-earth oxide weighing from 80 to 110 g. was dissolved in pure nitric acid and the solution evaporated to dryness, care being taken not to overheat any portion. The residue was dissolved in water and made up to about 3 liters, then heated to boiling and a strong solution of sodium nitrite was added drop by drop from a separatory funnel while bumping was prevented by passing in a lively stream of steam. The boiling

<sup>1</sup> THIS JOURNAL, 36, 1419 (1914).

was continued from 30 to 90 minutes after the addition of the nitrite, then the solution allowed to stand, usually overnight, and the precipitate filtered out. The precipitate was dissolved in nitric acid and purified in the usual manner, while the process was repeated with the mother liquor. The nitrite used was of the C. P. grade, whose purity was proven by the U. S. P. test. The usual amount of nitrite added at a time was 35 g. dissolved in 70 cc. of water, but larger or smaller amounts were added, depending upon the number of fractions desired from any run. During the progress of the study it was discovered that if the rare-earth solutions were sufficiently dilute the nitrite could be added in the cold without the immediate formation of a precipitate, but upon boiling the mixture for a few minutes a cloudiness appeared and finally a precipitate settled out. This procedure was followed during the latter part of the study of this method since it seemed to give a slightly more rapid separation. We have also found it advisable to continue the fractional precipitation with sodium nitrite until all of the rare earth is thrown out of solution in place of precipitating the final fraction with oxalic acid.

The material first used in testing this method consisted of 80 g. of yttrium oxide which were obtained by adding oxalic acid to the mother liquor from the H ammonia series. The fractions are marked N fractions and the results are shown in Table VI.

TABLE VI.

Fraction.	Wt. of oxalate.	Color of oxalate.	At. wt.
N <sub>1</sub> .....	7.5	Slight pink	89.34
N <sub>2</sub> .....	16.5	Very slight pink	89.07
N <sub>3</sub> .....	30.4	Less than N <sub>2</sub>	88.78
N <sub>4</sub> .....	19.3	Almost white	88.95
N <sub>5</sub> .....	32.3	White	88.88
N <sub>6</sub> .....	26.4	White	88.85
N <sub>7</sub> .....	24.5	White	87.65
N <sub>8</sub> .....	1.7	White	87.56

The first fractions show an atomic weight lower than the original material, because the permanganate method was used to determine these atomic weights, while the values given in Table V were determined by titration with potassium hydroxide. It is to be noted that Fractions 3 to 6 yield atomic weights which are nearly or quite constant within the limit of error of the method used while Fractions 7 and 8 show a sharp and pronounced decrease. Fraction 8 was too small in quantity to permit an extended study of its composition but an effort was made to discover why Fraction 7 had so low a value. It was at first supposed that the purification of the sample used in determining the atomic weight had not been thoroughly done, so a fresh sample was put through the purification process. This portion gave an atomic weight of 87.77. Then it was thought that possibly these last fractions, being precipitated from

solutions which were becoming heavily loaded with sodium salts, had dragged down enough sodium to account for the low value. So another sample was very thoroughly purified including two precipitations with ammonium sebacate in order to free the yttria from sodium compounds. The material purified in this way gave yttrium an atomic weight of 87.75. Finally the material was tested for scandium by adding a saturated solution of  $K_2SO_4$  to a nearly saturated solution of the rare-earth chloride but no trace of scandium could be detected. Efforts to detect a similar drop in the end fractions of other runs have not been wholly successful, although attention should also be directed to the fact that a similar drop in atomic weight in the last fraction is to be observed in many of the tables given by Holden and James.<sup>1</sup> We are not now prepared to offer an explanation of this peculiar phenomenon.

In order to test further the efficiency of the nitrite method of fractional precipitation, Fractions 3, 4, 5 and 6 of the N series were combined, giving 106.2 g. of material with an average atomic weight of 88.87. This was fractionated again, six fractions being obtained and designated as O fractions, which are described in Table VII.

TABLE VII.

Fraction.	Wt. of oxalate.	Color of oxalate.	Atomic weight.
O <sub>1</sub> .....	10.1	•Very slightly yellow	89.18
O <sub>2</sub> .....	18.2	Faint pink tint	89.42
O <sub>3</sub> .....	14.5	White	88.69
O <sub>4</sub> .....	23.7	White	88.46
O <sub>5</sub> .....	17.8	White	88.42
O <sub>6</sub> .....	4.6	White	88.48

Solutions of Fractions 4, 5 and 6 showed no trace of absorption lines, so it was concluded that both erbium and holmium had been eliminated.

A quantity of yttria equivalent to 37 g. was collected from the last fractions of the E ammonia series (Table V) and subjected to the nitrite fractional precipitation. The original solution showed very slight traces of erbium but there seemed to be no other rare-earth admixture. The results are shown in Table VIII.

TABLE VIII.

Fraction.	Wt. of oxalate.	Color of oxalate.	Atomic weight.
R <sub>1</sub> .....	16.3	White	88.58
R <sub>2</sub> .....	36.3	White	88.50
R <sub>3</sub> .....	9.0	White	88.40
R <sub>4</sub> .....	6.8	White	88.45
R <sub>5</sub> .....	1.4	White	88.42

Solutions from the last three fractions showed no visible absorption lines. The oxide obtained from the later fractions is pure white except for a very faint brownish tint which appears wherever the oxide is heated in contact with platinum.

<sup>1</sup> THIS JOURNAL, 36, 1418-23 (1914).

To test the efficiency of the nitrite fractionation when less pure material is used, 639 g. of yttria from a separate series of bromate fractionations<sup>1</sup> and 583 g. of yttria from the early fractions of the chromate series (Tables III and IV) were converted into the nitrate, which was dissolved in 30 liters of water and neutralized with a dilute solution of sodium hydroxide. This solution contained in a 65 liter evaporating dish was heated over a steam bath and live steam was introduced directly into the solution by means of a perforated block tin coil connected with high pressure steam. A porcelain baffle plate prevented splashing during the heating. Six fractions averaging 364 g. in weight were obtained, the color of the fractions changing gradually from a distinct pink in the first to pure white in the sixth. The original material showed an atomic weight of 91.85 and the lines of both erbium and holmium were distinctly visible. The atomic weight of the yttrium in the sixth fraction was 89.73 and this material, equivalent to 135 g. of the oxide, was again fractionated by the nitrite method, thirteen fractions being obtained. A faint pink color was apparent in the first three fractions, but the others were pure white. The atomic weight of the yttrium in the fourth fraction was 89.75, this value decreasing gradually to 88.73 in the thirteenth fraction. The lines of both holmium and erbium were still faintly visible in these later fractions, but we are convinced not only that the nitrite method of fractionation produces pure yttria, but also that it serves as a rapid and convenient method of removing both erbium and holmium whether they are present in large or small quantities.

#### The Hydrated Yttrium Salts.

With the hope of finding the hydrated salts of yttrium sufficiently stable under some conditions to be used in atomic weight determinations, samples of  $Y_2(SO_4)_3 \cdot 8H_2O$  and  $YCl_3 \cdot 6H_2O$  were prepared. For the preparation of the former, 22.4 g. of oxalate from H ammonia fractions 17, 22, 24, 27 and 28 (Table V) were ignited to the oxide, dissolved in HCl, a small excess of  $H_2SO_4$  added, the solution evaporated to dryness, and the residue heated in an electric furnace at  $525^\circ$  for four hours. The crystals were dissolved in water by the aid of an agitating machine and the solution evaporated to crystallization. The crystals were thoroughly drained from the mother liquor in a powerful centrifuge and the crystallization repeated. Finally the crystals were allowed to dry in air for 24 hours. These crystals were then divided into five parts and each part was placed in a porcelain crucible. One of the parts was heated until it was certain that a portion of the water of hydration had been expelled. Each of the other crucibles was placed in a weighing bottle and the bottle with cap removed was placed in a desiccator. One desiccator had an opening to the air but contained no desiccating agent, the second contained sulfuric

<sup>1</sup> The bromate fractionation was performed by Dr. E. W. Engle.

acid, the third calcium chloride, and the fourth contained the partially dehydrated sulfate. In this manner it was hoped to discover the conditions under which the hydrates would be stable. At intervals the weighing bottles were closed and the weight determined as shown in Table IX.

TABLE IX.

Apr. 5	13.43125	14.87546	13.89608	13.58366

The hydrates did not seem to be stable under any of these conditions, consequently this effort was abandoned.

### The Atomic Weight.

**Preparation of Reagents.**—The reagents used in the final treatment of the yttria preparatory to determining the atomic weight were all carefully purified in this laboratory. Hydrochloric acid was distilled in glass; nitric acid was distilled in quartz and kept in a quartz bottle; ammonia was freshly distilled as needed from a quartz flask into conductivity water contained in quartz. Ammonium sebacate was prepared by suspending the purest sebacic acid in conductivity water into which

ammonia was distilled until the acid had dissolved; then the sebacate was recrystallized twice, the crystals being thoroughly freed from the mother liquor with the centrifuge. Oxalic acid was purified in the following manner: C. P. crystals were dissolved in water containing a small amount of nitric acid; the solution was evaporated to crystallization on the steam bath and then stirred constantly until cold. The fine crystals were freed from the mother liquor in a large centrifuge and recrystallized twice from dilute nitric acid solution, and twice from pure water. The oxalic acid prepared in this manner left no weighable residue on ignition.

**The Yttrium Material.**—The fractions selected for use in the determination of the atomic weight were O fractions 4, 5 and 6 (Table VII) and R fractions 3, 4 and 5 (Table VIII). The three O fractions were mixed, ignited to the oxide, then dissolved in redistilled hydrochloric acid and reprecipitated twice with freshly distilled ammonia. The precipitates were filtered out on a Büchner funnel and washed with several liters of boiling water, care being taken to keep the precipitate hot and flocculent. Then the yttrium material was precipitated twice from an acid solution with pure oxalic acid, twice with ammonium sebacate, and finally with oxalic acid. The yttria was converted into the chloride in a platinum dish, the solution evaporated and left in a vacuum desiccator to crystallize. Only the first crop of crystals were used in the atomic weight work.

The R fractions were purified in a similar manner, except that they were not mixed and the transformation to the chloride was omitted.

The purification of the yttrium material and the preparation of the reagents were made in a room in which no other work was permitted. Great care was exercised to keep the atmosphere of the room free from laboratory gases and the material free from dust.

**The Determinations.**—The apparatus used was similar in principle to that previously described.<sup>1</sup> The drying trains for gases were modified so that all reagents were applied in towers filled with glass beads, making a more compact apparatus. The quartz reaction flasks<sup>2</sup> used were somewhat smaller and lighter than those previously employed. When in use the flask was surrounded by an asbestos oven, which served partly to protect it from the laboratory atmosphere. Within the oven was placed an electric furnace which was provided with a double winding of nichrome wire in such a manner that by the use of external resistance any temperature between that of the room and 1000° or more could be maintained. In order to hasten as much as possible the process of dehydration the gases entering the reaction flask were preheated by passing through a glass coil enclosed within the oven.

<sup>1</sup> THIS JOURNAL, 35, 373 (1913).

<sup>2</sup> *Ibid.*, 35, 373 (1913).

The manipulation was exactly the same as that described in the preliminary paper, except that after the oxide was weighed in the flask, it was dissolved in redistilled hydrochloric acid before the flask was attached to the drying train. This procedure shortened the time during which the flask was exposed to the laboratory atmosphere. Weights were made by substitution, using as tare a quartz flask differing in weight from the reaction flask by only a few milligrams. The weights were recently standardized and in all but the first two determinations the weighings were made in a special insulated balance room. The values obtained are shown in Table XI, correction having been made for air displacement.

TABLE XI.

No.	Material.	Weight of oxide.	Weight of chloride.	Atomic weight.
1.....	O <sub>4</sub> s	0.56492	0.97718	88.89
2.....	O <sub>4</sub> s	0.51059	0.88348	88.80
3.....	R <sub>5</sub>	0.64232	1.11092	88.92
5.....	R <sub>4</sub>	0.82157	1.42087	88.93
6.....	R <sub>3</sub>	0.68246	1.17975	89.06
7.....	O <sub>4</sub> s	0.54164	0.93688	88.89

The fourth determination was lost. No reason is known for the low value in the second except that some difficulty was experienced in getting complete dehydration in this case, due probably to the fact that an attempt was made to shorten the process by dehydrating the crystals formed from the strongly acid solution instead of dissolving them in water and dehydrating the crystals formed from a nearly neutral solution. The high value obtained from R<sub>3</sub> may be due to the fact that this fraction was not quite as pure as the others. The R fractions give slightly higher values than the O fractions, but the rather close check obtained from these different fractions would indicate that the yttria is of a high degree of purity. These results have an average of 88.91, which is somewhat higher than the accepted value (88.7).

The advantages claimed for this method are as follows: (1) the use of a ratio which is independent of the sulfate; (2) simplicity in manipulation; and (3) the fact that there are no transfers during the process.

There are several sources of error which have been carefully guarded against. The length of time which is needed to complete a determination makes it necessary for the reaction flask to be exposed to the laboratory atmosphere for several days, during which condensations might easily take place upon the surface. In order to prevent this the flask was tightly inclosed in the drying oven, the lead tubes were kept covered, and the dehydration was finished within as short a time as possible. After the chloride had been fused the flasks were carefully wiped with a clean linen cloth. Care was then exercised to remove any electrification which might have been caused by the friction.

The volatility of yttrium chloride was a matter of some concern, and for this reason the fusion of the chloride was always made with the direct flame. In this way the temperature was raised quickly to the fusion point and as quickly lowered again. The exit tubes were always examined closely for evidences of a deposit and in no case was there the slightest indication of a deposit on the tube B<sup>1</sup> or the upper part of the side neck near D'. There was a slight deposit on the lower portions of this side neck, but since the tube B was included in the weighed portion of the flask it is improbable that any material was lost through volatilization.

In order to learn if fused yttrium chloride adsorbs HCl as it cools, a simple modification of the usual procedure was undertaken. After the chloride was fused in an atmosphere of hydrogen chloride, it was customary to allow it to cool to about 350° and then replace the HCl with nitrogen as the cooling continued. In the last determination (No. 7) the fused chloride was allowed to cool to room temperature in the atmosphere of HCl. In this way it was expected that the acidity of the chloride would be increased if HCl had been adsorbed. There was no increase in acidity, hence it was concluded that there was little or no adsorption.

#### Summary.

1. Determinations of the atomic weight of yttrium by the synthesis of the sulfate are not reliable since the value may be made to vary widely by changing the length of time and the temperature of ignition.

2. In preparing pure yttria three methods of fractional precipitation were applied to partially purified material.

(a) Fractional precipitation with potassium chromate is effective for removing considerable quantities of other rare earths from yttrium but will not remove all the erbium or holmium.

(b) Fractional precipitation with dilute ammonium hydroxide is tedious and does not produce pure yttria.

(c) Fractionation with sodium nitrite is both a rapid and effective means of freeing yttrium material from admixtures of erbium and holmium.

3. Solutions of materials prepared by the use of all three of these methods gave no visible absorption lines and seemed to be pure yttria.

4. The hydrates  $Y_2(SO_4)_3 \cdot 8H_2O$  and  $YCl_3 \cdot 6H_2O$  are found to be too variable to permit of their use in atomic weight work.

5. The atomic weight of yttrium was determined by the ratio  $Y_2O_3 : 2YCl_3$  using material from six different fractions. The average of the values obtained is 88.9.

The work is to be continued with two points in view: (1) to study further the purity of the yttria, and (2) to attempt to apply other ratios to the determination of the atomic weight of yttrium.

## THE FREE ENERGY OF BROMINE COMPOUNDS.

BY GILBERT N. LEWIS AND MERLE RANDALL.

Received September 8, 1916.

Taking as the standard state of bromine the one which is stable at 25° and a pressure of one atmosphere, namely liquid bromine, we are in a position to calculate the free energy of the various known forms of elementary bromine, of bromide and polybromide ions, and of all the known compounds of bromine with oxygen and hydrogen.

### Elementary Bromine.

$2\text{Br}(l) = \text{Br}_2(g)$ .—The vapor pressure of liquid bromine has been determined by Roozeboom<sup>1</sup> and by Ramsay and Young.<sup>2</sup> Both sets of measurements show excellent self-consistency when tested by plotting  $\log p$  against  $1/T$ . In both cases a few scattering points are obviously in error, but the remaining points give for each set a straight line, and these two straight lines are not only near to one another but are parallel, that is, they have the same slope. From this slope we may determine directly the heat of vaporization at the average temperature (32°) of the points which were plotted. We thus find  $\Delta H_{305} = 7530$ . The heat capacity of liquid bromine has not been accurately determined but we may take as an approximate value for this reaction  $\Delta F = -9.6$ . Since we have adopted permanently for  $\text{Br}_2(g)$  the value<sup>3</sup>  $C_p = 6.5 + 0.004T$ , this means that we are taking for  $\text{Br}(l)$ ,  $C_p = 8.05 + 0.002T$ , an equation which is purely formal, introduced for convenience, and only has experimental significance inasmuch as it gives the approximate value of the specific heat of liquid bromine at room temperature. Having once assumed this equation we must of course apply it consistently in our future equations. We therefore write  $\Delta H = 10450 - 9.6 T$ , which agrees almost precisely with the heat of vaporization determined by Berthelot at 60° and is a trifle higher than the value obtained by Thomsen. The final free energy equation is

$$\Delta F^\circ = 10450 + 9.6T \ln T - 87.21T, \quad (1)$$

where the value of  $I = -87.21$  is obtained from the following determination of  $\Delta F^\circ_{298}$ . The vapor pressure of bromine at 25° is 208 mm. of mercury if we use the data of Roozeboom, and 213 mm. if we use the data of Ramsay and Young. The latter measurements are in somewhat better agreement with the determinations of the boiling point of bromine, and we shall therefore accept Ramsay and Young's value. Hence,

$$\Delta F^\circ_{298} = 755 \text{ cal.} \quad (2)$$

<sup>1</sup> Roozeboom, *Rec trav. chim.*, 3, 73 (1884).

<sup>2</sup> Ramsay and Young, *J. Chem. Soc.*, 49, 453 (1886).

<sup>3</sup> Lewis and Randall, *THIS JOURNAL*, 34, 1128 (1912).

We may use Equation 1 to find the boiling point of bromine by writing  $\Delta F^\circ = 0$  and solving for  $T$ . This gives  $58.7^\circ$ . Such a calculation from an equation like (1) is very instructive, since it shows at once the necessity of the very highest numerical accuracy, notwithstanding the fact that such a coefficient as that of  $T \ln T$  is uncertain, and that the original choice of this constant, rather than some neighboring one, is not very important. It will of course be obvious that such an equation will not be valid over a very wide temperature interval, and if it is so used it will be in a purely formal manner. It must also be noted that we have throughout assumed bromine vapor to be a perfect gas. If reliable data concerning the density and compressibility of the vapor were available we should take as the normal state of  $\text{Br}_2(\text{g})$  not the gas at one atmosphere but in the condition where its activity is  $x$  times as great as at  $1/x$  atmos., where  $x$  is a large number.

$\text{Br}(\text{l}) = \text{Br}(\text{s})$ .—The heat of fusion of bromine was found by Regnault to be 1290 cal. per gram atom. The heat capacity of solid bromine has not been much studied, but judging from the measurements of Koref<sup>1</sup> at low temperatures it is not far from that of liquid bromine at ordinary temperatures. We may write, therefore,  $\Delta F^\circ = 0$  and  $\Delta H_0 = -1290$ . Taking the freezing point as  $-7.3^\circ$  where  $\Delta F^\circ = 0$ , we find

$$\Delta F^\circ = -1290 + 4.86T; \Delta F_{298}^\circ = 157. \quad (3)$$

Without a direct determination of either melting point or heat of fusion we could make this same calculation from the experiments of Ramsay and Young and those of Cuthbertson<sup>2</sup> upon the vapor pressure of solid bromine. We have plotted their data in the usual way, namely,  $\log p$  against  $1/T$ . From the slope of the curve, which gives the heat of sublimation, and from the heat of vaporization of the liquid which we have already discussed, we find a value for the heat of fusion of 1245 cal., which, within the limits of error of the vapor-pressure measurements, coincides with the value of Regnault. Likewise from the vapor-pressure measurements we could calculate directly the value of  $\Delta F_{298}^\circ$ , and here too the calculation, although subject to large errors, agrees with the value which we have given. Similar calculations, based upon more accurate data, we have already made in discussing the various forms of elementary sulfur.<sup>3</sup>

$\text{Br}_2(\text{g}) = \text{Br}_2(\text{in CCl}_4, N = 1)$ .—Before proceeding to determine the free energy of aqueous bromine, partly as a step in this process, but also on account of the frequent use of carbon tetrachloride as a solvent in distribution experiments, and in general where it is necessary to maintain a phase in which the activity of the solute is kept at a known constant value, it will be desirable to calculate the free energy of bromine dissolved

<sup>1</sup> Koref, *Ann. Physik*, [4] 36, 49 (1911).

<sup>2</sup> Cuthbertson, *Proc. Roy. Soc., (A)* 85, 306 (1911).

<sup>3</sup> Lewis and Randall, *THIS JOURNAL*, 36, 2468 (1914).

$\text{CCl}_4$ . Since carbon tetrachloride as a nonpolar substance has essentially the characteristics of a normal liquid, it will be preferable to use a convention for the standard condition in this solvent differing from the one which we have employed in the case of water. We shall therefore use not the concentration of the solute but its mol fraction,  $N$ , and we shall take as a standard or normal condition<sup>1</sup> the one in which the activity (or vapor pressure) is  $1/N$  times as great as that in a dilute solution in which the mol fraction of the solute is  $N$ . Mr. Storch, in this laboratory, has made a number of determinations, which will shortly be published, of the vapor pressure of bromine from dilute solutions in  $\text{CCl}_4$ . He finds at  $25^\circ$ ,  $p = 0.539 N$ , where  $p$  is the partial vapor pressure of  $\text{Br}_2$  in atmospheres and  $N$  is its mol fraction. The measurements extend from  $N = 0$  to  $N = 0.025$ . It is evident that the solution of  $\text{Br}_2$  in  $\text{CCl}_4$  does not obey Raoult's law over the whole range of concentrations, for the equation would lead when  $N = 1$  to a vapor pressure nearly twice that of pure liquid bromine. Our free energy equation in this case is simply

$$\Delta F^\circ_{298} = -RT \ln (N/p) = -366. \quad (4)$$

$2\text{Br}(g) = \text{Br}_2$  (in  $\text{CCl}_4$ ,  $N = 1$ ).—Adding Equations 2 and 4 gives

$$\Delta F^\circ_{298} = 389 \text{ cal.} \quad (5)$$

$\text{Br}_2$  (in  $\text{CCl}_4$ ;  $N = 1$ ) =  $\text{Br}_2(\text{aq})$ .—In discussing the distribution of bromine between water and carbon tetrachloride we shall use the mol fraction of the bromine to express the composition of the  $\text{CCl}_4$  phase and, as usual, mols  $\text{Br}_2$  to 1000 g. of water to express that of the aqueous phase. The well-known experiments of Jakowkin,<sup>2</sup> on the distribution coefficient in this system, we have reviewed in detail and we arrive at conclusions which differ somewhat from those which have usually been drawn from these measurements. His experiments in dilute solutions are vitiated by the fact that the bromine hydrolyzes in the aqueous phase to the extent of 10% or more<sup>3</sup> and his figures are for the total bromine and not for that which occurs simply as  $\text{Br}_2$ . Mr. Storch in hitherto unpublished work, to which we have referred, has determined the partition of bromine between  $\text{CCl}_4$  and water containing  $\text{HCl}$  at  $0.001M$ . It was assumed that water containing this small amount of hydrochloric acid, would prevent the hydrolysis of the bromine, but would not affect materially the activity of the dissolved  $\text{Br}_2$ . In order to test this assumption similar partition experiments were made between  $\text{CCl}_4$  and water containing

<sup>1</sup> The advantage of this choice is obvious in the case of two liquids which like benzene and toluene in all mixtures form perfect solutions (see Lewis, *THIS JOURNAL*, 30, 668 (1908)). Here it is evident that  $F^\circ$  is the same for  $\text{C}_6\text{H}_6$  ( $l$ ) and  $\text{C}_6\text{H}_6$  (in toluene).

<sup>2</sup> Jakowkin, *Z. physik. Chem.*, 18, 583 (1895).

<sup>3</sup> Bray and Connolly, *THIS JOURNAL*, 33, 1485 (1911).

an equivalent amount of sulfuric acid. He found for  $m/N$ , 0.3705 with HCl and 0.3710 with  $H_2SO_4$ , where  $N$  is the mol fraction of  $Br_2$  in the  $CCl_4$  and  $m$  the number of mols per 1000 g.  $H_2O$ . We shall write  $m/N = 0.371$ . In these measurements  $N$  was equal to 0.01373. When we consider Jakowkin's experiments at the higher concentrations, where hydrolysis plays no important role, we find that this partition coefficient, owing to the high concentrations, varies more than the ratio which we use involving the mol fraction instead of the concentration. Without repeating the rather laborious calculations which we have made in reducing his measurements to our units (assuming that  $Br(l)$  and  $CCl_4$  mix without change of volume) we may state merely that the value of  $m/N$  varies regularly from 0.35 at  $N = 0.14$  to values in dilute solutions which agree closely with the one obtained by Storch, 0.371. Taking this value as the partition ratio in dilute solution we find for this reaction

$$\Delta F^\circ_{298} = -R'T \ln(m/N) = 588. \quad (6)$$

$2Br(l) = Br_2(aq)$ .—Adding Equations 5 and 6 we find

$$\Delta F^\circ_{298} = 977. \quad (7)$$

Such an equation as (7) is of course applicable only to solutions which are so dilute that the activity of the solute is proportional to the concentration. It is interesting to see the magnitude of the deviation from such proportionality in the case of a saturated aqueous solution of bromine by comparing the measured solubility of bromine with that obtained from Equation 7. Bray and Connolly<sup>1</sup> found for the saturated solution of bromine at 25°,  $m = 0.2068$ , whereas from Equation 7, writing 977 =  $-R'T \ln m$ ;  $m = 0.1923$ , a difference of 7.5%.

$Br_2(g) = 2Br(g)$ .—The dissociation of bromine vapor into the monatomic gas has been studied by Perman and Atkinson<sup>2</sup> who measured the density of bromine vapor between 650° and 1050°. Their method of calculation is not easy to follow, but if we divide what they call vapor density by 80.3, which seems to be the best value of this quantity at the lowest temperature (where we may assume that no dissociation occurs) we should get the ratio between the actual density and the density calculated on the assumption of no dissociation. The equilibrium constants,  $K_p$ , calculated from these ratios, are given in the second row of Table I, the absolute temperature being given in the first row.

TABLE I.

T.....	1073	1123	1173	1223	1273	1323
$K_p$ .....	0.000179	0.000403	0.00140	0.00328	0.0077	0.0182

Now if we plot  $\log K_p$  against  $1/T$  we find that at the four highest temperatures, which are the only ones at which the dissociation is considera-

<sup>1</sup> Bray and Connolly, *THIS JOURNAL*, 33, 1485 (1911).

<sup>2</sup> Perman and Atkinson, *Z. physik. Chem.*, 33, 215, 577 (1900).

ble, the points lie on a straight line and the slope of this line multiplied by 4.579 gives at the average temperature of the measurements  $\Delta H_{1250} = 53700$ . Assuming that Br has the same heat capacity as other monatomic gases,  $\Delta \Gamma = 3.5 - 0.004T$ , whence  $\Delta H_0 = 52400$ , and

$$\Delta F^\circ = 52400 - 3.5T \ln T + 0.002T^2 - 9.07T \quad (8)$$

where the value of  $I = -9.07$  was obtained from  $\log K_{1250} = -2.27$  as read from the plot. Since the calculation of  $\Delta H$  from the density measurements is greatly affected by small errors, the value of  $\Delta F^\circ_{298}$  may easily be in error by several thousand calories. We have

$$\Delta F^\circ_{298} = 43900. \quad (9)$$

**Br(l) = Br(g).**—Combining Equations 1 and 2, respectively, with 8 and 9,  $\Delta F^\circ = 31425 + 3.05T \ln T + 0.001T^2 - 48.14T$ ;

$$\Delta F^\circ_{298} = 22328. \quad (10)$$

### Hydrobromic Acid; Bromide Ion; Tribromide Ion; Pentabromide Ion.

$\frac{1}{2}H_2 + \frac{1}{2}Br_2(g) = HBr(g)$ .—The dissociation of gaseous hydrogen bromide has been investigated by von Falckenstein<sup>1</sup> at the temperatures 1024°, 1108° and 1222°. His measurements lead directly to the corresponding three values of  $\log K_p$ , 2.60, 2.44 and 2.27.

In order to calculate from these measurements the free energy of this reaction at other temperatures we must know the thermal quantities involved. The heat capacities of the three gases are given in our former paper<sup>2</sup> and thence we find  $\Delta \Gamma = -0.00145T$ . The heat of the reaction at room temperatures calculated from the measurements of Thomsen is 11900, and from those of Berthelot 12300, average 12100, and  $\Delta H_0 = -12000$ . The complete free energy equation is therefore

$$\Delta F^\circ = -12000 + 0.000725T^2 - 3.5T, \quad (11)$$

where the value of  $I$ ,  $-3.5$ , is the mean of the values obtained at von Falckenstein's three temperatures, namely,  $-3.57$ ,  $-3.46$ , and  $-3.43$ . Hence

$$\frac{1}{2}H_2 + \frac{1}{2}Br_2(g) = HBr(g); \Delta F^\circ_{298} = -12970. \quad (12)$$

While the extrapolation to 25° from von Falckenstein's experiments is made over a wide temperature range, the probable errors in the specific heats and in the heat of reaction are not sufficient to produce an uncertainty of more than 100 to 150 cal. in the value of  $\Delta F^\circ_{298}$ . This calculation therefore is probably at least as reliable as one which we shall now make and which is based upon the measurements by Bodenstein and Geiger<sup>3</sup> of the e. m. f. of the hydrogen, bromine, hydrobromic acid cell. They used two half cells both containing the same concentrated aqueous

<sup>3</sup> Bodenstein and Geiger, *Z. physik. Chem.*, **49**, 70 (1904).

hydrobromic acid. In one was a hydrogen electrode, in the other a bromine electrode, enough bromine being added to the hydrobromic acid so that the vapor pressures of the bromine and hydrobromic acid could be simultaneously determined. Knowing then the vapor pressure of  $\text{Br}_2$ ,  $\text{HBr}$  and  $\text{H}_2$ , the electromotive force should be represented by the equation

$$E = E^\circ - \frac{RT}{F} \ln \frac{[\text{HBr}]}{[\text{H}_2]^{1/2} [\text{Br}_2]^{1/2}}.$$

The three cells in which Bodenstein and Geiger measured the electromotive forces and vapor pressures give for  $E^\circ$  the values 0.557, 0.558 and 0.549 v. at  $30^\circ$ . The differences between these values of  $E^\circ$  may be partly due to experimental error, but they must in part be due to the error in assuming the hydrobromic acid to be the same in the two halves of the cell, even though enough bromine is added on one side to change appreciably the vapor pressure of  $\text{HBr}$ , as shown by the authors themselves. The mean of their values gives  $\Delta F^\circ_{303} = -12760$ , or making the slight correction to  $25^\circ \text{ C.}$ ,  $\Delta F^\circ_{298} = -12740$ . Their value therefore agrees as well as could be expected with the one which we have given above. We shall accept the values obtained in Equations 11 and 12.

Before leaving Equation 11 it may be worth while to make a comment, which, though obvious when stated, has not to our knowledge previously been made. Ordinarily it has been assumed that in a reaction like the dissociation of  $\text{HBr}$  the degree of dissociation would, except for a possible change in the sign of the heat of reaction, increase with the temperature, and that at very high temperatures the dissociation would be complete. This is by no means the case. We have hitherto considered three reactions, namely, the dissociation of  $\text{NO}$ , of  $\text{HI}$  and of  $\text{HBr}$ , in which neither the number of molecules nor the number of atoms within a molecule changes. In such cases, as was first pointed out by Haber, not only is  $\Delta F$  small and the heat of reaction nearly constant, but the value of  $I$  is small and the free energy equation approximates closely to the simplest form  $\Delta F^\circ = \Delta H_0$ . In such a case it is evident, since  $-RT \ln K = \Delta F^\circ = \text{constant}$ , that as the temperature is indefinitely increased  $\ln K$  must approach zero, and therefore  $K$  must approach unity. In other words, the degree of dissociation will approach 50% and not 100% as the temperature is increased. In the actual cases which we have considered there are additional small terms in the free energy equation, but nevertheless it is evident that in any temperature range in which Equation 11 is approximately valid the degree of dissociation of  $\text{HBr}$  cannot exceed 50%, except of course insofar as other reactions enter, such as the dissociation of  $\text{H}_2$  and  $\text{Br}_2$  into their monoatomic forms.

$\frac{1}{2}\text{H}_2 + \text{Br}(l) = \text{HBr}(g)$ .—Combining Equations 1 and 2, respectively, with Equations 11 and 12, we find

$$\Delta F^{\circ} = -6775 + 4.8T \ln T + 0.000725T^2 - 47.10T; \Delta F^{\circ}_{298} = -12592. \quad (13)$$

$\text{Br}(l) + \ominus = \text{Br}^-$ .—The free energy of formation and of dilution of aqueous hydrobromic acid have been exhaustively investigated by Lewis and Storch in the paper to which we have already referred and which will shortly be published. As the final result of this investigation, against the standard hydrogen electrode, at  $25^{\circ}$ , the potential of liquid bromine in the presence of bromide ion at (hypothetical) molal concentration is  $-1.0659$  v., a value which is accurate to within a few tenths of a millivolt. Hence for the above reaction

$$\Delta F^{\circ}_{298} = -nE^{\circ}F' = E^{\circ}F'; \text{ or } \Delta F^{\circ}_{298} = -24594. \quad (14)$$

$\text{Br}^- + \text{Br}_2(\text{aq}) = \text{Br}_3^-$ .—The equilibrium in the formation of tribromide was studied by Jakowkin<sup>1</sup> who determined the partition of bromine between carbon tetrachloride and aqueous solutions of KBr at  $25^{\circ}$ . Assuming that  $\text{KBr}_3$  and KBr are in dilute solution ionized to the same extent at the same concentration, the ratio of  $\text{KBr}_3$  to KBr should be approximately constant. In fact a complete recalculation of Jakowkin's data gives a much better constant than he himself obtained. In this calculation we have used the partition coefficient given above, after recalculating his concentrations in  $\text{CCl}_4$  to mol fractions. The results of Jakowkin, as recalculated, are given in Table II. We have used only his measurements with dilute KBr and dilute  $\text{Br}_2$ . The first column gives the concentration of  $\text{Br}_2$  as such in the aqueous phase, the second the concentration of KBr used, and the third column the values of the constant  $K = (\text{Br}_3^-)/[(\text{Br}^-)(\text{Br}_2)]$ .

TABLE II.

$\text{Br}_2$ .	KBr.	K.
0.00198	0.0625	16.50
0.00377	0.0625	16.15
0.00710	0.0625	16.07
0.00986	0.0625	16.04
0.00145	0.1250	16.32
0.00345	0.1250	16.35
0.00610	0.1250	16.20
0.00880	0.1250	16.05

Dr. Linhart in this laboratory has made calculations based upon Worley's measurements<sup>2</sup> in more concentrated solutions and has shown that, when due allowance is made for the formation of pentabromide, Worley's measurements lead to the same constant as Jakowkin's. Moreover, Jakowkin's measurements are corroborated by the similar investigation of Storch with solutions of HBr. Taking  $K = 16.2$  we find

$$\Delta F^{\circ}_{298} = -1650. \quad (15)$$

<sup>1</sup> Jakowkin, *Z. physik. Chem.*, 20, 19 (1896).

<sup>2</sup> Worley, *J. Chem. Soc.*, 87, 1118 (1905).

$3\text{Br}(l) + \ominus = \text{Br}_3^-$ .—Adding Equations 7, 14 and 15, we find

$$\Delta F_{298}^\circ = -25267. \quad (16)$$

$\text{Br}_3^- + \text{Br}_2(\text{aq}) = \text{Br}_5^-$ .—There can hardly be any doubt that not only tribromide but higher polybromides exist in solution. Nevertheless, since a substance like  $\text{KBr}_5$  is formed in appreciable amounts only when the concentration of bromine is high, and therefore the laws of the dilute solution are not necessarily valid, the calculation of such a constant as  $(\text{Br}_5^-)/(\text{Br}_2)(\text{Br}_3^-)$  is attended with considerable uncertainty. The calculations made by Linhart from the experiments of Worley show very fair constancy in  $K$ , which he takes as 1.2, whence we may obtain as an approximate value

$$\Delta F_{298}^\circ = -110. \quad (17)$$

$5\text{Br}(l) + \ominus = \text{Br}_5^-$ .—Adding Equations 7, 16 and 17,

$$\Delta F_{298}^\circ = -24400. \quad (18)$$

$\text{Br}_2(\text{aq}) + \text{H}_2\text{O}(l) = \text{H}^+ + \text{Br}^- + \text{HBrO}(\text{aq})$ .—From careful measurements of the conductivity, Bray and Connolly<sup>1</sup> have determined the degree of hydrolysis of bromine solutions and found

$$K_{298} = (\text{H}^+)(\text{Br}^-)(\text{HBrO})/(\text{Br}_2) = 5.2 \times 10^{-9}.$$

Hence

$$\Delta F_{298}^\circ = 11310. \quad (19)$$

$\text{Br}(l) \oplus \frac{1}{2}\text{H}_2 + \frac{1}{2}\text{O}_2 = \text{HBrO}(\text{aq})$ .—Owing to our lack of knowledge of the dissociation constant of hypobromous acid it is impossible to determine the free energy of hypobromite ion. We must therefore at present be content with the determination of that of the free acid. Combining Equations 7, 14 and 19 with Equations 9 and 54 of our paper<sup>2</sup> on the free energy of oxygen and hydrogen compounds, we find

$$\Delta F_{298}^\circ = -19739. \quad (20)$$

$\text{Br}(l) + 3\text{H}_2\text{O}(l) + 5\oplus = 6\text{H}^+ + \text{BrO}_3^-$ .—Sammet<sup>3</sup> measured the potential at 25° of a platinum electrode dipping into an aqueous solution of bromic acid saturated with liquid bromine. He used solutions of  $\text{HBrO}_3$  ranging from 0.001  $M$  to 1.0  $M$ . At present only the results in dilute solutions can be used for exact calculations. Thus the potential in the case of the 0.001  $M$   $\text{HBrO}_3$  against the normal calomel electrode was  $-0.929$  v. By the use of the Planck formula he calculated the liquid potential to be 0.031 v. which is probably as nearly correct as the measurements themselves. The potential therefore against the normal calomel electrode, excluding liquid potentials, is  $-0.960$  v., or against the hydrogen electrode is  $-1.238$  v. We have then the equation  $-1.238 =$

<sup>2</sup> Lewis and Randall, *Ibid.*, 36, 1969 (1914).

<sup>3</sup> Sammet, *Z. physik. Chem.*, 53, 678 (1905).

$E^\circ - RT/5F \ln (H^+)^5(BrO_3^-)$ . Taking the degree of dissociation of 0.001 *M*  $HBrO_3$  as 0.97,

$$E^\circ = -1.487; \Delta F^\circ_{298} = 171550. \quad (21)$$

$Br(l) + \frac{3}{2}O_2 + \ominus = BrO_3^-$ .—Combining Equation 21 with Equations 9 and 54 of our paper on oxygen and hydrogen compounds, we find

$$\Delta F^\circ_{298} = 1690. \quad (22)$$

### Summary.

The following table gives the free energy of formation of the several forms of elementary bromine and of the bromine compounds which have been considered in this paper:

Substance.	$\Delta F^\circ_{298}$ .	Equation.	Substance.	$\Delta F^\circ_{298}$ .	Equation.
$Br(l)$ .....	0	..	$HBr(g)$	-12592	13
$Br_2(g)$ .....	755	1, 2	$Br^-$	-24594	14
$Br(s)$ .....	157	3	$Br_3^-$	-25267	16
$Br_2$ (in $CCl_4$ , $N = 1$ ).....	389	5	$Br_5^-$	-24400	18
$Br_2(aq)$ .....	977	7	$HBrO(aq)$	-19739	20
$Br(g)$ .....	[22328]	10	$BrO_3^-$	1690	22

## THE POTENTIAL OF THE MERCURY ELECTRODE AGAINST MERCUROUS ION.

By G. A. LINHART.

Received September 9, 1916.

One of the lines of work in progress in this laboratory is the accurate measurement of the electrode potentials of the chemical elements. The present paper deals with the determination of the electrode potential of mercury against  $Hg_2^{++}$ .

Ogg<sup>1</sup> has shown, in a qualitative way, that the mercurous ion in a water solution of a mercurous salt, is chiefly in the form of  $Hg_2^{++}$ , and to some extent also in the form of  $Hg^+$ . But for obvious reasons (notably hydrolysis and oxidation) mercurous nitrate is not a suitable substance for accurate electrochemical measurements. Therefore, for the present investigation, mercurous perchlorate was chosen, because it was shown by Ley<sup>2</sup> that the extent to which this salt hydrolyzes is extremely small, and that the small amount of hydrolysis products thus formed are soluble in water. An almost neutral solution of this salt can be prepared, not by reducing the mercuric salt in solution by means of metallic mercury, but by treating pure mercurous oxide with a water solution of pure perchloric acid. The details of preparation, as well as the method of measurements, are given in the experimental part of this paper. In the

<sup>1</sup> Ogg, *Z. physik. Chem.*, **27**, 295 (1898).

<sup>2</sup> Ley, *Z. Electrochem.*, **10**, 302 (1904).

table below are given two typical series of a considerable number of e. m. f. measurements obtained from preliminary experiments of concentration cells of mercurous perchlorate in the presence of perchloric acid of the same concentration throughout the cell. The concentration of the perchloric acid was in all cases in large excess as compared with that of the mercurous perchlorate, so that the degree of dissociation of the latter into  $\text{Hg}_2^{++}$  and  $\text{ClO}_4^-$  was practically the same in the two half cells. Therefore, the e. m. f. of concentration cells in the ratio of 1 : 2 should be 0.0089 v. This, however, is not the case as is evident from the results given in Table I.

TABLE I.—PRELIMINARY RESULTS AT 25°.

Series No.	Conc. of $\text{HClO}_4$ .	Conc. of $\text{Hg}_2(\text{ClO}_4)_2$ .		E (volt).
1.....	0.1035	0.00065	0.0013	0.0093
		0.000325	0.00065	0.0095
		0.0001625	0.000325	0.0097
2.....	0.0207 <sup>1</sup>	0.00065	0.0013	0.0091
		0.000325	0.00065	0.0092
		0.0001625	0.000325	0.0092

The deviations of the e. m. f. values from the theoretical (in this case for a 1 : 2 concentration cell,  $E = 0.0089$  volt) seem to indicate some dissociation of the  $\text{Hg}_2^{++}$  ions into  $\text{Hg}^+$  ions. These deviations were, however, found to be probably due to the method of preparing the perchloric acid, namely, adding the theoretical amount of sulfuric acid to a dilute solution of barium perchlorate. The perchloric acid thus prepared contains a trace of dissolved barium sulfate,<sup>2</sup> in this case it probably contained more sulfate ion than barium ion. It is evident that when this acid is added to two solutions of mercurous perchlorate of different strengths both being extremely dilute, the percentage loss of the mercurous ion from the more dilute solution will be considerably greater than from the more concentrated solution. This phenomenon would account for the regular increase in the e. m. f. in the preliminary results given above. The  $E_0$  calculated from these values would therefore be numerically less than if pure perchloric acid had been used. Many precautions therefore had to be taken in order to obtain accurate results.

The imported perchloric acid used in subsequent experiments proved to be very pure, being prepared presumably by distillation of the acid obtained by heating ammonium perchlorate in the presence of aqua regia.

<sup>1</sup> In this series the e. m. fs. of the concentration cells were measured also against the hydrogen electrode and the values obtained are given below:

$\text{Hg}_2(\text{ClO}_4)_2$ .....	0.0013	0.00065	0.000325	0.0001625 <i>M.</i>
—E.....	0.8055	0.7964	0.7872	0.7780 v.

<sup>2</sup> The solubility of barium sulfate in the presence of perchloric acid is apparently quite appreciable, as on addition of either  $\text{SO}_4^{--}$  or  $\text{Ba}^{++}$  a slight precipitate of  $\text{BaSO}_4$  was observed.

### Experimental.

**Apparatus.**—The hydrogen electrode used is of the type developed in this laboratory, and will be described in a subsequent paper by Prof. G. N. Lewis and Dr. R. L. Sebastian. For the other half cell see Fig. 1.

The cells and separatory funnels previously used in the preliminary experiments were subsequently kept in a cleaning mixture, consisting of fairly pure sulfuric acid saturated with chromic acid, for several weeks, then thoroughly washed, steamed, rinsed with conductivity water,<sup>1</sup> and finally dried in an oven and cooled in a desiccator. The rubber stoppers were boiled in dilute alkali, thoroughly washed and dried. Pure mercury was then introduced into each cell to a depth of about half an inch in order to prevent the solution from coming in contact with the platinum wire beneath the mercury in case of accidental tipping of the cell. The end of the separatory funnel, containing the same solution as the corresponding cell, when inserted into the cell, was almost in contact with the surface of the mercury in order to facilitate the renewal of the solution near the mercury surface.

Fig. 1

**Preparation of Substances.**—Starting with pure mercury (twice distilled), pure sodium hydroxide and pure water, pure mercurous oxide was obtained. This was then treated with pure perchloric acid, the excess mercurous oxide filtered out and the solution of mercurous perchlorate thus obtained was shaken with pure mercury and allowed to stand for several days in order that the dispersed mercury could settle out. The solutions were then analyzed<sup>2</sup> and diluted with conductivity water to the desired concentration in specially resistant glass vessels, and then diluted with equal volumes of perchloric acid. These solutions thus prepared were immediately transferred to the cells, treated as described above, and the e. m. f. of each measured against the hydrogen electrode. The acid with which the solutions of the mercurous perchlorate were diluted was exactly twice as concentrated as

<sup>1</sup> Distilled water was redistilled with alkaline permanganate. This kind of water was used in all operations.

<sup>2</sup> 100 cc. of this solution gave, on analysis, 0.2500 g. of mercurous chloride, corresponding to 0.005308 *M* mercurous perchlorate. This solution was diluted and used in the experiments with 0.0118 *M* and 0.0059 *M* HClO<sub>4</sub>. The stock solution used for the other experiments was 0.00550 *M*. Hydrochloric acid was used in the precipitations of the mercurous chloride, giving concordant results with those obtained when sodium chloride was used. Moreover, the filtrate from the sodium chloride precipitations reacted neutral towards litmus paper, showing that there was no excess acid in the mercurous perchlorate, although the original solution of the mercurous perchlorate was slightly acid due to slight hydrolysis.

the acid used in the hydrogen electrode cell and in the connecting vessel forming the liquid junction, so that the concentration of the perchloric acid was the same throughout the cell.

**Electromotive Force Measurements.**—In the first column of Table II is given the number of the series of the e. m. f. measurements; in the second, the concentrations of the perchloric acid in mols per liter of solution; in the third, the concentrations of the mercurous perchlorate in mols per liter of solution; in the fourth and fifth, the observed e. m. fs. of these solutions measured in duplicate against the hydrogen electrode; and in the sixth, the average difference in e. m. f. for a two-fold concentration ratio of the mercurous perchlorate half cells. It may be stated here that the direct measurement of the e. m. fs. of the concentration cells agreed in every case within 0.1 mv. with the differences given in the sixth column.

Av., 0.0089

**Discussion of Results.**—No appreciable change in the e. m. f. of Series 1 and 2 (limit of error being 0.05 mv.) could be observed either at the end of one hour or on renewing the solutions near the mercury surface by means of the separatory funnel. In the remaining series, where the concentrations of the perchloric acid were considerably more dilute, the maximum variation in e. m. f. on renewal of the solution was 0.2 mv.,

<sup>1</sup> (b) and (c) denote, respectively, the first and second renewals of the solutions near the mercury surface by means of the separatory funnels.

the limit of error being 0.1 mv. in Series 3 and 4 and 0.2 mv. in Series 5. The same maximum variations were observed also after the cells remained in the thermostat for 30 minutes.

The absence of any consistent departure of the e. m. f. for a two-fold concentration ratio from the theoretical value, 0.0089 v. is evidence that there is no appreciable dissociation of the  $\text{Hg}_2^{++}$  ion into  $\text{Hg}^+$  ion even with 0.00005 molal mercurous perchlorate in 0.006 molal perchloric acid.

**Calculation of the E. M. Fs. in Hypothetical Molal Concentration of the Reacting Substances.**—The reaction taking place at the electrodes may be represented by the following equations:

Whence,

$$E_o = E_{\text{obs.}} + 0.02957 \log \frac{(\text{H}^+)^2}{(\text{Hg}_2^{++})[\text{H}_2]} \quad (3)$$

or

$$E_o = E_{\text{obs.}} + 0.02957 \log \frac{\gamma_1^2(\text{HClO}_4)^2}{\gamma_2(\text{Hg}_2[\text{ClO}_4]_2)[\text{H}_2]} \quad (4)$$

where  $\gamma_1$  denotes the corrected degree of dissociation of  $\text{HClO}_4$  and  $\gamma_2$  that of  $\text{Hg}_2(\text{ClO}_4)_2$ .

Concerning the activity of bivalent ions<sup>1</sup> in solutions of uni-bivalent salts, little information is at present at hand, especially when the uni-bivalent salt, as in the present case, is mixed with a uni-univalent electrolyte. It has been pointed out by Adams and Rosenstein<sup>2</sup> that in a mixture of a bi-univalent salt and a uni-univalent salt, with the same anion, the degree of dissociation (as measured by conductivity) of the former is equal approximately to the square of that of the latter. If we assume provisionally that this is true also of the corrected degree of dissociation, Equation 4 becomes,

$$E_o = E_{\text{obs.}} + 0.02957 \log \frac{(\text{HClO}_4)^2}{(\text{Hg}_2[\text{ClO}_4]_2)[\text{H}_2]} \quad (5)^3$$

If this assumption, which is tested in Table III, were correct, identical values of  $E_o$  would be obtained. As might have been expected, the assumption fails in the most concentrated solutions, but in the three more dilute solutions  $E_o$  is nearly constant, and the average value (0.7926 v.) may be taken as the normal electrode potential of mercury against  $\text{Hg}_2^{++}$  at hypothetical molal concentration.

<sup>1</sup> Lewis and Lacey, *THIS JOURNAL*, 36, 804 (1914).

<sup>2</sup> Linhart, *Ibid.*, 38, 1272 (1916).

<sup>3</sup> The corrections for the barometric pressure of the hydrogen gas amounted to +0.5 mv. in all but the last series of Table III, for which it was +0.6 mv.

Average of Series 3, 4, and 5.....				0.7926

## Conclusions.

(1) The fair agreement of the  $E_o$  values, with the exception of those with 0.0817  $M$  HClO<sub>4</sub>, seem to justify the adoption for dilute solutions o. the rule, proposed by Adams and Rosenstein with reference to the degree of dissociation of bi-univalent salts.

(2) The best value for the potential of the mercurous electrode is —0.7928 v. (av. of Series 3 and 4).

(3) From the e. m. f. measurements of concentration cells no regular deviations from the theoretical value were observed, from which it may be concluded that there is no appreciable dissociation, of Hg<sub>2</sub><sup>++</sup> into Hg<sup>+</sup> even in very dilute solutions with reference both to the perchloric acid (0.0059  $M$ ) and to the mercurous perchlorate (0.0000531  $M$ ).

Finally, I wish to express my indebtedness, for many helpful suggestions, to Professor G. N. Lewis and Doctor E. Q. Adams.

## THE VANADATES OF BERYLLIUM.

By PAUL H. M.-P. BRINTON.

Received September 8, 1916.

In the course of a general study of vanadates Berzelius<sup>2</sup> prepared what he describes as a yellow, neutral, difficultly soluble, and pulverulent

<sup>1</sup> Averages of  $E_{obs.}$  of Table II.

<sup>2</sup> *Pogg. Ann.*, 22, 58 (1831).

salt, by the addition of ammonium vanadate to a solution of a beryllium salt. He made no analysis of the substance, and assigned no formula. The only other mention of any vanadate of beryllium is made by Tanatar and Kurovski,<sup>1</sup> who by the action of sodium vanadate on beryllium chloride solution obtained a yellow amorphous precipitate which contained 47.28% of  $V_2O_5$ . Another precipitate obtained by using beryllium, nitrate in place of the chloride contained 25.4%  $V_2O_5$  and 46.3%  $BeO$ ; differing from the one before mentioned in being of somewhat lighter color. The compositions of these substances are said to correspond to formulas of the following types:  $xBeCl_2 \cdot yBe_3(VO_4)_2 \cdot zBeO$  and  $xBe(NO_3)_2 \cdot yBe_3(VO_4)_2 \cdot zBeO$ .

During the progress of an investigation<sup>2</sup> of certain general properties of beryllium salts, opportunity was offered for some study of the vanadates of beryllium, and the results of these experiments are here recorded.

A solution of ammonium vanadate, made by dissolving vanadium pentoxide in concentrated ammonium hydroxide and evaporating to small bulk, was added to a dilute solution of beryllium nitrate. The latter was, of course, acid in reaction, owing to hydrolysis, and there was no precipitate on mixing the two solutions. Ammonium hydroxide was added drop by drop until a yellow precipitate formed, and this increased with every drop of the hydroxide. The precipitate, after drying for a week over sulfuric acid in partial vacuum, was analyzed by methods which will be discussed later. The results led to a formula approximately expressed by  $4BeO \cdot V_2O_5 \cdot 6H_2O$ . Subsequent trials in which the conditions of precipitation were varied gave precipitates in which the ratio  $BeO/V_2O_5$  went to about 4.3, while the molecules of water varied from 3.1 to 9.7. It is evident that the products of such precipitations are simply basic mixtures of variable proportions, and do not represent pure compounds.

The ratio 4 for  $BeO/V_2O_5$  differs considerably from that of Tanatar and Kurovski, who obtained a figure of about 13. If they precipitated in the presence of an excess of beryllium salt the variance is easily explained, for my investigations have shown that the ratio of base to acid in such cases can go as high as 60 : 1—in fact, there is no limit to the basicity under these conditions. If the precipitates were obtained in the presence of excess of vanadate the matter is not so easily explained, but in this event it is probable that the difference in composition is due to varying degrees of washing. It was found that the washings from the yellow precipitates, although apparently colorless, none the less contained notable quantities of the vanadate which gave a very distinct yellow color upon concentration by evaporation. From this it is easy to see how the mixtures could become more basic by long-continued washing.

<sup>1</sup> *J. Russ. Phys.-Chem. Soc.*, 41, 813 (1909).

<sup>2</sup> This investigation will be the subject of a later paper.

It was evident that a normal beryllium vanadate was not to be obtained by precipitation with a soluble vanadate, so other means were tried for the preparation of such a compound. With the idea of obtaining an orthovanadate, beryllium hydroxide and vanadium pentoxide were taken in the molecular ratio of 3 : 1. A little of this mixture was boiled with water for an hour, and the yellow solution was filtered from the undissolved residue. Upon cooling the clear yellow filtrate became turbid. Set to evaporate on the water bath, the solution again became clear, and when considerably concentrated it still remained clear after standing in the cold overnight. Evaporation was continued until a deep orange-red, syrupy liquid was obtained, and this, after standing in the cold for two days, set to a solid mass of fascicular crystals. Upon repeating the above experiment with larger quantities of material—6 g. of the mixed oxides, boiled with three successive liters of water—and evaporating to about 40 cc., it took nine days before any separation of crystals took place. At the end of that period the whole had set to a mass of dark yellow crystals, which seemed to get a little darker on standing. The mass was so hard that it was difficult to scratch out a sample with a knife, and it evidently consisted of crystals of two colors, yellow and brown. Upon adding alcohol to some of the crystal mixture the whole surface was converted to a uniform yellow crystal mass.

A rough preliminary analysis of a small portion of the heterogeneous mass indicated that there was probably present a normal metavanadate instead of an orthovanadate, and this metavanadate had either three or four molecules of water of crystallization, as well as a slight excess of beryllium oxide. The analysis was not regarded as very reliable, and it is not worthy of record. It suggested two points, however: that equimolecular weights of the two oxides should be taken to boil together, as that since alcohol was capable of transforming the surface of the heterogeneous mass to fine, yellow crystals, it might be able to precipitate out these yellow crystals from the concentrated syrupy liquid, and these crystals might then be free from basicity.

Equimolecular proportions of beryllium hydroxide and vanadium pentoxide were boiled with water as before, the yellow liquid freed from insoluble residue by filtration, and evaporated to an orange-red syrup. This hot syrup was then poured into a large volume of 95% alcohol. A copious separation of lemon-yellow particles immediately occurred, and after standing twelve hours a thick layer of yellow crystals had settled to the bottom of the dish. Under the microscope the crystals appeared as perfectly homogeneous, yellow, waxy plates. Later attempts in which alcohol was added to a more dilute solution furnished larger crystals of more definite form, and it could then be seen that there were really two sets of crystals; the main mass consisting of particles of about

0.25 mm. average diameter; but scattered among these were a few little flat, tabular crystals, the largest of which did not exceed 0.05 mm. in width or length. These surely did not make up as much as 1% of the total mass. The main crystals are evidently isometric, being cubes modified by an octohedron. The polar angle gives a value of  $54^{\circ} 46'$ , the theoretical value being  $54^{\circ} 44'$ . The cube face in contact with the glass does not show the octohedral modifications. The upper horizontal face is, in nearly all cases, characterized by a quadrangular embayment, or negative development. This feature being developed on only one face of the cube suggests a tetragonal habit, but the values given above for the polar angle seem to prove conclusively that the crystals are isometric. The embayments, then, would appear to result from physical position only, and not from any crystallographic consideration. Thin fragments of these crystals do not polarize light, but the larger tabular crystals, found scattered among the large ones, do polarize light, and seem to show an orthorhombic habit. One of these little crystals was mounted on the goniometer, but, although six faces in the prismatic zone gave signals, they were too irregular to yield satisfactory measurements. For the crystallographic measurements, which were made with a two-circle Goldschmidt goniometer, I am indebted to Prof. F. N. Guild, of the University of Arizona.

Whether or not these very small crystals were the same in substance as the larger ones cannot be said. Making up as small a percentage of the whole as they did, it is certain that they could not have very much effect on the analytical results, and it was physically impossible to isolate enough of the little particles to make an independent analysis of them.

Several batches of the yellow crystals were made at different times, and the following analyses were made on three different lots. The results show clearly that the salt is a normal beryllium metavanadate tetrahydrate, a compound which has not heretofore been prepared.

$\text{Be}(\text{VO}_3)_2 \cdot 4\text{H}_2\text{O}$ .				
	Calculated.	Found.		
BeO.....	9.00	8.44	9.74	9.18
$\text{V}_2\text{O}_5$ .....	65.22	66.60	65.38	66.86
4 $\text{H}_2\text{O}$ .....	25.78	24.96	24.88	23.96

The material represented by the first analysis was crystallized from water, the other two by precipitation with alcohol. The amounts used for analysis in the first two samples were small, and in view of the somewhat unsatisfactory method of separation used, the results are perhaps as concordant as might be expected. The third analysis was made on a good-sized sample, and is in all respects the most reliable. The ratio of  $\text{BeO} : \text{V}_2\text{O}_5$  in this analysis is 1 : 1.002, and this may be taken as con-

clusive proof that we are dealing with a normal metavanadate of beryllium, with four molecules of crystal water, though a little of the latter is evidently lost with comparative ease.

Some difficulty was experienced in finding a method suitable for the exact, quantitative separation of beryllium and vanadium in the scheme for analysis. Attempts to remove the vanadium first, as lead vanadate, were unsuccessful, for it seemed that a concentration of acetic acid sufficient to prevent the co-precipitation of beryllium caused incompleteness in the precipitation of lead vanadate. The method finally adopted was essentially that of Noyes, Bray and Spear.<sup>1</sup> It was, however, necessary to redissolve the first precipitate of basic beryllium carbonate in nitric acid, and to repeat the precipitation under pressure. Occluded sodium salts were removed by again dissolving the basic carbonate in nitric acid, and making final precipitation with ammonium hydroxide. After ignition and weighing, the residue was dissolved in sulfuric acid, and the traces of vanadium determined by titration with permanganate, after reduction by sulfur dioxide. The final filtrate from the beryllium precipitation was treated with sulfuric acid, evaporated to fumes, diluted, reduced by sulfur dioxide, and titrated with potassium permanganate for the determination of the main portion of the vanadium. It should be mentioned that this filtrate was warmed for an hour before the sulfuric acid was added. This treatment usually caused a slight separation of beryllium hydroxide, which was filtered off and added to the main portion. This little precipitate seemed pure white, but if it did contain any vanadium compound this would be corrected for by the determination of the vanadium in the ignited beryllium oxide. The percentage of water of crystallization was taken by difference, having first made sure that there was no alcohol of crystallization.

The approximate solubility of the beryllium metavanadate tetrahydrate was determined by agitation of the fine crystals in a sealed test tube for five days, in a thermostat at 25°. In the filtrate the vanadium was determined by titration, and the solubility thus calculated was found to be one part per thousand of water at this temperature. In hot water the crystals are readily soluble, and on cooling there is a strong tendency toward supersaturation. In pyridine the solubility seems to be of the same order as that in water. The crystals are practically insoluble in chloroform, ether, and absolute alcohol.

The specific gravity of the metavanadate, determined by suspension in methylene iodide diluted with benzene, was found to be 2.273.

The crystals lose water slowly, but continuously, over sulfuric acid, but no definite end point of dehydration could be obtained.

### Summary.

It has been shown that basic mixtures, and not chemical compounds, are obtained by the addition of soluble vanadates to solutions of beryllium salts.

A new compound, beryllium metavanadate tetrahydrate, has been prepared, and its properties described.

TUCSON, ARIZ.

## THE ARSENATES OF LEAD.

[SECOND PAPER.]

### EQUILIBRIUM IN THE SYSTEM $\text{PbO}$ , $\text{As}_2\text{O}_5$ , $\text{H}_2\text{O}$ .

BY C. C. McDONNELL AND C. M. SMITH.

Received October 4, 1916.

In a preceding article<sup>1</sup> we showed that trilead arsenate, although spoken of freely in the literature, is not so easily produced as is ordinarily believed. Double decomposition between soluble lead salts and soluble arsenates rarely gives a product of theoretical composition, and the action of excess ammonia on dilead arsenate leads to the formation of a basic compound, as was first recorded by Tartar and Robinson.<sup>2</sup> These facts suggested that trilead arsenate is relatively unstable and capable of existing only under very limited conditions. In order to clear up this point the following phase rule study was undertaken.

The three component system  $\text{PbO}$ ,  $\text{As}_2\text{O}_5$  and  $\text{H}_2\text{O}$  can easily be investigated as far as mono- and dilead arsenates are concerned, but the system as such cannot be followed beyond dilead arsenate, owing to the insolubility of lead hydroxide. This necessitates the use of some other base to produce alkalinity. Ammonia seemed particularly suitable for this purpose, since it is easily prepared free from carbon dioxide, has practically no solvent action on lead compounds, and does not form double salts under conditions such as obtained in these experiments. Then, too, it is of especial interest since its action on dilead arsenate has long been considered the best means of producing trilead arsenate, as first stated by Berzelius.<sup>3</sup>

The use of ammonia in such a system introduces a fourth component, but by keeping its concentration constant one degree of freedom is destroyed, and the system will behave like a three-component one. (Owing to the low concentrations employed, we are justified in the assumption that the volume changes were nil or insignificant.)

The experiments were carried out in the following manner: Pure ammonia water was prepared (by distilling concentrated C. P. ammonia water over barium hydroxide to remove  $\text{CO}_2$ , and absorbing the evolved

<sup>2</sup> *Ibid.*, 36, 1848 (1914).

<sup>3</sup> *Ann. chim. phys.*, [2] 11, 229 (1819).

vapors in recently boiled and cooled distilled water) and diluted to 0.0338 *N* (arbitrary dilution). A series of 2 g. portions of pure amorphous dilead arsenate,  $\text{PbHAsO}_4$ , were put into flasks, and to them were added varying amounts, from 90 to 180 cc., of the dilute ammonia solution.

All of the mixtures were put into a shaking machine and agitated for seven hours on each of two successive days at  $32^\circ \pm 1^\circ$ . (It was determined that equilibrium had been reached in this time.) After allowing the mixtures to settle, they were filtered on Gooch crucibles containing disks of filter paper and the clear filtrates analyzed. The results showed that only a mere trace of lead went into solution, but a considerable amount of arsenic, indicating that the reaction consisted in the removal of a portion of the arsenic acid from the dilead arsenate to form soluble ammonium arsenate. The course of the reaction could, therefore, be followed by determining the arsenic oxide in solution, the results of which are here tabulated.

Cc. of 0.0338 <i>N</i> $\text{NH}_4\text{OH}$ used.	G. of $\text{As}_2\text{O}_5$ per liter of filtrate.	Total g. of $\text{As}_2\text{O}_5$ dissolved.
90	1.956	0.1760
95	1.925	0.1829
100	1.960	0.1960
105	1.953	0.2051
110	1.960	0.2156
115	1.941	0.2232
120	1.926	0.2311
125	1.902	0.2378
130	1.891	0.2459
135	1.871	0.2526
140	1.809	0.2533
150	1.706	0.2559
160	1.591	0.2546
170	1.503	0.2555
180	1.429	0.2572

The significance of these results is brought out more clearly in the accompanying graph.

The first additions of ammonia have resulted in the formation of a constant solution, as shown by the branch A-B of the graph, which, in a three-component system at constant temperature, indicates the existence of two solid phases. One of these must, of course, be the unchanged dilead arsenate, and the other may easily be determined as follows: The constant solution contains 1.951 g.  $\text{As}_2\text{O}_5$  per liter, and the break B in the graph occurs at 112 cc., making the total dissolved  $\text{As}_2\text{O}_5 = 0.2185$  g. The transposition of 2 g. of dilead arsenate to trilead arsenate requires the solution of 0.2208 g.  $\text{As}_2\text{O}_5$ . The molecular ratio of the residue,  $\text{PbO}/\text{As}_2\text{O}_5$ , figures out as 2.99, showing that trilead arsenate is the second solid phase. Analysis of the residues immediately preceding and following the point B gave 25.65 and 25.31%  $\text{As}_2\text{O}_5$ , respectively,

while the formula  $\text{Pb}_3(\text{AsO}_4)_2$  requires 25.56%, which is additional confirmation that it is trilead arsenate. The constant solution (to the point B) contains 0.00849 mol.  $\text{As}_2\text{O}_5$  per liter, making the molecular ratio  $\text{NH}_4\text{OH}/\text{As}_2\text{O}_5 = 3.98$ , which is practically equivalent to a solution of diammonium hydrogen arsenate,  $(\text{NH}_4)_2\text{HAsO}_4$ .

The portion B-C of the graph shows why trilead arsenate is not ordinarily obtained by double decomposition. If, after all the dilead arsenate was changed to the tri-salt, the latter remained as such on adding more ammonia, the total dissolved  $\text{As}_2\text{O}_5$  would remain constant and the graph become a rectangular hyperbola. But a continued increase is shown in the total  $\text{As}_2\text{O}_5$  dissolved and the branch B-C is a straight line. This indicates the formation of a series of solid solutions, with trilead arsenate as one end member and some basic arsenate as the other. At the point C 0.2553 g. of  $\text{As}_2\text{O}_5$  has been dissolved, leaving in the residue 0.407 g.  $\text{As}_2\text{O}_5$  and 1.286 g.  $\text{PbO}$ , giving a molecular ratio  $\text{PbO}/\text{As}_2\text{O}_5 = 3.253$ .

Beyond the point C, the total dissolved  $\text{As}_2\text{O}_5$  remains practically constant, and the graph then becomes a rectangular hyperbola, showing that this basic arsenate is not further changed within the limits of our experiments. A large excess of ammonia water produces a product only slightly more basic, having a molecular ratio about 3.30.

About 100 g. of trilead arsenate were prepared by treating dilead arsenate with the theoretical amount of  $N/10$  ammonia, as calculated from the foregoing data. Analysis:

	Dried at 110°.	Anhydrous.	Theory for $\text{Pb}_3(\text{AsO}_4)_2$ .
Lead oxide, $\text{PbO}$ .....	73.62%	74.30%	74.44%
Arsenic oxide, $\text{As}_2\text{O}_5$ .....	25.46%	25.70%	25.56%
Water (by ignition).....	0.92%	.....	.....
	100.00%	100.00%	100.00%

The product contains a small amount of water which is not expelled at 110°. This corresponds to slightly less than  $\frac{1}{2}$  molecule. It is an amorphous powder, with a specific gravity,  $15/4$  of 7.00. Crystallized trilead arsenate (anhydrous) prepared by fusion, had a specific gravity  $15/4$  of 7.30.

### Summary.

It has been shown that the action of dilute ammonia on dilead orthoarsenate proceeds as follows:

(1) Transposition to trilead orthoarsenate,  $Pb_3(AsO_4)_2$ , the supernatant solution remaining constant at the  $(NH_4)_2HASO_4$  stage until transformation is complete.

(2) Formation of solid solutions ranging from trilead arsenate to a basic arsenate, beyond which no further change occurs.

## THE REDUCTION OF VANADIC ACID BY HYDRIODIC ACID.

By GRAHAM EDGAR.

Received August 28, 1916.

In a recent paper by Ditz and Bardach<sup>1</sup> experimental results are given which indicate that the reduction of vanadic acid by hydriodic acid at room temperature and at considerable dilution proceeds irregularly, and that the iodine liberated in the course of the reaction corresponds approximately to that calculated for the reaction

or in some instances to an even greater amount. At the same time it is pointed out that tetravalent vanadium is relatively stable towards dilute hydriodic acid. In order to explain their results, Ditz and Bardach offer the hypothesis that the reduction of vanadic acid by hydriodic acid proceeds directly from the pentavalent to the trivalent state, without the formation of tetravalent vanadium as an intermediate product.

The results of Ditz and Bardach conflict with those of several earlier investigators. Numerous statements occur in the literature to the effect that reduction of vanadic acid by dilute hydriodic acid proceeds until the vanadium approximates the *tetravalent* condition,<sup>2</sup> and several investigators have defined conditions under which a quantitative reduction may be expected, and have based methods for the estimation of vanadium

<sup>1</sup> *Z. anorg. Chem.*, **93**, 97 (1915).

<sup>2</sup> Browning, *Am. J. Sci.*, [4] **2**, 185 (1896); Hett and Gilbert, *Z. öffentl. Chem.*, **12**, 265 (1906); Warynski and Mdivani, *Mon. Sci.*, **22**, II, 527 (1908); Perkins, *Am. J. Sci.*, [4] **29**, 540; Rosenheim, *Inaug. Diss. Berlin* (1888).

upon the reaction.<sup>1</sup> The experimental conditions in most cases seem more favorable for reduction than those described by Ditz and Bardach.

Furthermore it is stated by Rutter<sup>2</sup> that trivalent and pentavalent vanadium react with one another readily in acid solution, undergoing mutual oxidation and reduction in the sense of the equation

If this is true, then reduction of vanadic acid by hydriodic acid *must* pass through the tetravalent stage, even if the initial reduction involved the formation of trivalent vanadium, and since tetravalent vanadium is relatively stable towards dilute hydriodic acid,<sup>3</sup> further reduction must proceed with great difficulty.

The conclusions of Ditz and Bardach seem, therefore, to warrant further investigation.

The experiments described by them are essentially as follows: (1) About 0.062 g. of vanadic acid (in solution as ammonium vanadate) was measured into a large bottle fitted with a separatory funnel and a trap valve. To it were added 1000 cc. of water, 75 cc. of conc. HCl, and 1.5 g. of KI. After vigorous shaking the bottle was allowed to stand for a few minutes and then titrated for iodine with dilute  $\text{Na}_2\text{S}_2\text{O}_3$  solution, after the addition of starch. After the first titration the bottle was allowed to stand, and the continually reappearing blue color of "starch-iodide" was removed from time to time by further titration with thiosulfate. After several hours the amount of thiosulfate used corresponded in most cases to somewhat *more* than that calculated on the assumption that the reduction had proceeded according to the equation

(2) A solution containing  $\text{V}_2\text{O}_5$ , HCl and KI in approximately the same concentrations as in the preceding experiments was shaken repeatedly in a separatory funnel with toluene, and the combined toluene extracts were titrated with thiosulfate as before. Here again the amount of thiosulfate used corresponded to a quantity of iodine somewhat greater than that calculated on the assumption that the reduction had proceeded until the vanadium was in the trivalent condition.

An obvious source of possible error in these experiments is that of atmospheric oxidation. This is indeed admitted by Ditz and Bardach, but they do not seem to consider that this error can materially influence the results. In the present paper experiments are described which cover almost the same ground as those of Ditz and Bardach, but the influence

of atmospheric oxidation has been kept as low as possible, and very different results have been obtained in consequence.

### Experimental.

Solutions of sodium vanadate, sodium thiosulfate, and iodine, each approximately 0.05 *N* were prepared and carefully standardized. An apparatus similar to that of Ditz and Bardach was prepared for the preliminary experiments. It consisted of a large bottle (Fig. 1) fitted with a tightly fitting paraffined cork, through which passed a separatory funnel, a trap valve, and a bent glass tube through which a current of carbon dioxide could be passed.

In the first experiment there were placed in the bottle 1000 cc. of distilled water, 75 cc. of conc. HCl, and about 0.1000 g. of  $V_2O_5$  (added as sodium vanadate). The trap was charged with 10 cc. of 5% KI solution. Then a current of carbon dioxide was passed for some time through the solution to remove air from the bottle and to diminish the amount of dissolved oxygen. After the gas had been passed through the liquid for about 30 minutes, 30 cc. of 5% KI were added from the funnel, and the current of  $CO_2$  was discontinued. At the end of an hour's time, starch was added and the solution was titrated with 0.05 *N* (approx.) thiosulfate solution, still without admission of air. This titration required 23.15 cc. of thiosulfate solution (calculated for reduction to *tetravalent* vanadium, 24.20 cc.). After a few minutes the blue color returned, and was discharged by the addition of more thiosulfate. This was repeated three times during the next six hours, resulting in a total consumption of 28.35 cc. of thiosulfate for all titrations. After the last titration the blue color of "starch-iodide" had not returned after *three days'* standing, thus exhibiting no further signs of reduction. At the end of that time the bottle was opened and air admitted, and after a few hours the blue color due to iodine had developed again.

In this experiment the amount of thiosulfate used corresponds to somewhat more than that calculated from the assumption that the reduction proceeds only to the tetravalent condition, but the evidence that this excess was caused largely at least by atmospheric oxidation seemed so strong that a set of experiments was devised to study the reaction under conditions more readily controlled.

For this purpose the apparatus shown in Fig. 2 was constructed. It consisted of a large separatory funnel (about 550 cc.) connected by means of a ground glass connection with a small separatory funnel, and a glass tube through which a gas could be admitted. The figure shows the de-

Fig. 1.

tails clearly. The technique involved in carrying out the experiments in this apparatus was as follows: The desired amounts of sodium vanadate

Fig. 2.

solution, concentrated hydrochloric acid, and distilled water were run into the apparatus through the small separatory funnel, and a current of pure hydrogen gas was then bubbled through the liquid for about twenty minutes in order to remove air as far as possible. At the end of this time the desired amount of 5% potassium iodide solution was run in through the small funnel, and this was followed by 25 cc. of pure carbon bisulfide. All stopcocks were then closed, and the apparatus was shaken vigorously from time to time for perhaps half an hour. The carbon bisulfide was then drawn off through the lower stopcock, while hydrogen was admitted from the upper one. A fresh portion of carbon bisulfide was then admitted through the small separatory funnel, and the shaking was repeated as before.

This process was continued until fresh portions of carbon bisulfide failed to extract any further amount of iodine even after standing for several hours. The time necessary for the reaction to become complete varied with the concentration of the different reagents, but was never less than an hour and a half nor greater than four hours. In all cases the apparatus was allowed to stand for twelve hours after apparent completion of the reaction, in order to make sure that no further separation of iodine took place, and in one case, after six weeks' standing under hydrogen, no further separation of iodine could be observed. The combined carbon bisulfide extracts were carefully titrated for iodine with 0.05 *N* sodium thiosulfate solution. The results of the experiments are given in Tables I and II. In Table I the concentration of reagents are approximately the same as those employed by Ditz and Bardach; in Table II the effect of certain variations in the concentrations has been studied.

The results given in Table I under conditions of concentration of acid and iodide almost identical with those used by Ditz and Bardach, show that the iodine liberated in the reaction corresponds almost exactly with

that calculated for reduction of the vanadium to the *tetravalent* condition, and not to that calculated for reduction to the *trivalent* condition, as found by Ditz and Bardach. Furthermore the color of the solution at the conclusion of the experiment was in every case the pure blue of tetravalent vanadium, and not the green trivalent. Obviously the large amounts of iodine which Ditz and Bardach found to be liberated in their experiments were caused partially by atmospheric oxidation. Further proof of this was given by an experiment carried out with the same concentration of reagents as those in Table I, and with the same technique, except that the air in the apparatus was not removed by hydrogen. In this case the amount of thiosulfate required for titration of the iodine after four hours' repeated extraction with  $\text{CS}_2$  was 21.20 cc., an excess of 50+ % over that found necessary for the titrations given in Table I. Table II contains the results of experiments carried out with the same technique as that employed in the experiments of Table I, but the concentrations of acid have been varied in such a direction as to make the conditions more favorable for reduction than those studied in the previous experiments. The results show that even if the concentration of acid is made three times that employed by Ditz and Bardach, or if the concentration of iodide is increased to four times that used in their experiments, the amount of iodine liberated corresponds closely to that calculated for reduction of the vanadium to the tetravalent condition. Moreover, the solution at the completion of the experiment has the blue color of tetravalent vanadium, as in the experiments of Table I. The only noticeable effect caused by changing the concentrations of acid and iodide was that the time necessary for the reaction to come to completion was materially shortened by an increase in the concentration of either acid or iodide. The effect of the acid was more marked than that of the iodide, possibly because of the fact that carbon bisulfide does not extract the iodine as efficiently from a concentrated iodide solution as from a dilute one, and, therefore, the removal of the iodine from the solution was not so complete as in the experiments in which the acid concentration was high and that of the iodide low.

Some explanation seems necessary for the large increase in the amount of iodine liberated when air is admitted into the apparatus. Blank experiments carried out with dilute hydrochloric acid and potassium iodide, but without the  $\text{V}_2\text{O}_5$ , showed that a little iodine is liberated when the solution is shaken with  $\text{CS}_2$  in the presence of air but the amount is not nearly large enough to explain the results obtained in the presence of pentavalent vanadium under the same conditions. Likewise blank experiments carried out in the presence of tetravalent vanadium (previously prepared by reduction of pentavalent vanadium with sulfur dioxide) failed to show appreciable liberation of iodine after a few hours' extraction

with  $\text{CS}_2$  in the presence of air. Ditz and Bardach, in attempting to account for the fact that they found more iodine liberated than corresponded to reduction of the vanadium to the trivalent condition, offer the following explanation: (1) Pentavalent vanadium is reduced directly to the trivalent condition by dilute hydriodic acid; (2) in the presence of air the trivalent vanadium is oxidized to something (probably not tetravalent vanadium) which reacts further with the hydriodic acid to cause liberation of iodine. This explanation seems cumbersome and unnecessary. In the first place, the results given in this paper show that under the conditions of experimentation the iodine liberated corresponds to that calculated for formation of tetravalent vanadium, and the color of the solution is evidence that tetravalent vanadium is actually formed. There is no evidence that trivalent vanadium is formed, nor does it seem probable from the theoretical standpoint. A simpler and more plausible explanation of the excess of iodine liberated in the presence of air, is that pentavalent vanadium acts as a catalyst in accelerating the oxidation of hydriodic acid by the oxygen of the air, as certain other oxidizing agents are known to do.

Altogether there seems no reason to suppose that the nature of the reaction of hydriodic acid with pentavalent vanadium differs essentially from the similar reactions with the other halogen acids, or that tetravalent vanadium is not the primary product of reduction. This will be discussed further below.

#### The Mechanism of the Reduction of Vanadic Acid by the Halogen Acids.

Numerous investigators have studied the reactions between the halogen acids and vanadic acid, and the apparent conflict between their results has in some cases led to considerable controversy. In view of the fact that even in some recent papers there appears to be some misconception of the mechanism of the reactions, and of the function of the different reacting substances, it may be well to give a brief discussion of the subject from the standpoint of the theory of electronic oxidation and reduction,<sup>1</sup> and to show how some of the conflicting views may be reconciled.

The most logical method of representing the reaction between vanadic acid and the halogen acids is the following:

and similarly for further reduction

where X represents the halogen (Cl, Br or I).

Obviously conditions which favor the progress of Reaction 1 from left to right are: (a) high concentration of the halogen ion; (b) high concentration of the  $\text{VO}^{+++}$  ion; (c) low discharging potential of the halogen

<sup>1</sup> Stieglitz, *Qual. Anal.*, Vol. I, p. 251.

ion; and (d) removal of the product of the reaction, X, from the solution (usually by boiling, by evaporation, by extraction, or by reaction with a metal).

Similar conditions will likewise favor the progress of Reaction 2.

The concentration of the halogen ion can of course be varied at will, and the discharging potential (c) will vary with the particular halogen used, being greatest with chlorine and lowest with iodine.

The concentration of positively charged vanadium ions ( $V^{++\cdot++}$ , or more correctly,  $VO^{++\cdot+}$ ) will depend almost entirely upon the hydrogen ion content of the solution. Just as in the case of any other element whose oxide exhibits amphoteric properties the acidic ionization of vanadic acid will be diminished and its basic ionization increased, by increasing the hydrogen ion content of the solution.

Bearing these four different factors in mind, and their influence on the reaction, the apparent conflict in the results of different investigators is readily explained.

**Reduction by Hydrochloric Acid.**—In this case we have to overcome the high discharging potential of the chlorine ion, and for complete reduction of pentavalent vanadium to tetravalent all of the other factors mentioned above must be favorable. Thus dilute hydrochloric acid is practically without reducing action upon vanadic acid solutions<sup>2</sup> and even the ordinary process of boiling vanadic acid with concentrated hydrochloric acid<sup>3</sup> fails to produce completion of Reaction 1.<sup>4</sup> It is only when the highest concentration of hydrogen ion and halogen ion is maintained<sup>5</sup> or when the solution is repeatedly evaporated to dryness with concentrated acid,<sup>6</sup> that complete reduction can be effected. Even then the results are not always of the highest degree of uniformity.<sup>7</sup> In no case do we have evidence that Reaction 2 takes place even to the slightest extent.

**Reduction by Hydrobromic Acid.**—In this case the discharging potential is much lower than in the case of the chlorine ion, and in consequence reduction takes place more readily. Thus it has been shown that for solutions whose hydrogen ion content is rather high (4–6 molar) the concentration of bromine ion need not be excessive to effect complete reduc-

tion of pentavalent vanadium to the tetravalent condition, provided the bromine is removed from the solution by boiling.<sup>1</sup> If the acid concentration is still higher, Reaction 1 goes to completion with relatively low concentration of bromine ion, even at room temperature.<sup>2</sup> Several accurate volumetric processes for the estimation of vanadium have been based upon this reaction, as there is a rather wide range of conditions under which Reaction 1 goes to completion, and Reaction 2 does not begin to take place. On the other hand, if *all* of the factors influencing reduction are made favorable (for example, by boiling vanadic acid with concentrated hydrobromic acid, in which *both* hydrogen and bromine ion are present in very high concentration) Reaction 2 begins to take place, and a considerable amount of trivalent vanadium may be formed.<sup>3</sup>

**Reduction by Hydriodic Acid.**—It is in this case that much of the difference of opinion in regard to the reaction of vanadic acid with the halogen acids is found. Methods for the quantitative estimation of vanadium have been proposed, based upon the reduction of vanadium from pentavalent to tetravalent condition,<sup>4</sup> from pentavalent to trivalent condition,<sup>5</sup> and from tetravalent to trivalent condition<sup>6</sup> by the action of hydriodic acid under various conditions. On the other hand, numerous investigators have obtained very irregular results with the reaction, and have raised objections to its use for quantitative purposes.<sup>7</sup> This is probably partially due to failure to eliminate the error due to atmospheric oxidation of the acid iodide solutions, and partially to the fact the range of conditions under which Reaction 1 is complete and Reaction 2 not occurring is more limited than in the case of the reduction involving hydrobromic acid. A careful study of the literature shows that if the concentration of hydrogen ion is kept moderate and that of the iodide ion small, reduction of pentavalent vanadium to tetravalent takes place readily, if the iodine set free is removed by boiling,<sup>8</sup> by extraction with a solvent (see above), or by reaction with a metal.<sup>9</sup> Oxidation of the acid iodide solution must be

guarded against and the proper conditions carefully observed, however, if accurate results are to be obtained. Further reduction of the tetravalent vanadium to trivalent (Reaction 2) does not take place appreciably in solutions in which the concentrations of hydrogen and iodide ion are kept low, but it is possible by making these two factors favorable to effect a complete reduction of tetravalent to trivalent vanadium.<sup>1</sup> Naturally, pentavalent vanadium can be reduced to trivalent by the use of high concentrations of acid and iodide,<sup>2</sup> but the evidence does not justify the assumption that the tetravalent condition is not reached as an intermediate stage. The conditions for effecting a quantitative reduction must be more sharply defined than in the case of hydrobromic acid, but there seems to be no evidence that the mechanism of the reaction is different from that occurring in the case of the other halogen acids.

### Summary.

(1) The reaction between vanadic acid and hydriodic acid at room temperature and at considerable dilution has been investigated. Within the limits of concentration covered by this investigation the reaction results in the formation of tetravalent vanadium, and not trivalent. This is contrary to the observations of Ditz and Bardach. A probable source of error in the results of Ditz and Bardach has been pointed out.

(2) The mechanism of the reactions between vanadic acid and the halogen acids, and the influence of various factors upon the equilibrium, has been discussed.

[COMMUNICATION FROM THE JOHN HARRISON LABORATORY OF CHEMISTRY OF THE UNIVERSITY OF PENNSYLVANIA.]

## ANALYSIS OF CERTAIN TUNGSTEN DERIVATIVES.

BY ORLAND R. SWEENEY.

Received September 20, 1916.

The analysis of "complex inorganic acids" and their salt derivatives has been a subject of interest to analysts. Peculiar difficulties have been frequently encountered, and the impression exists that none of the methods proposed for the various separations are satisfactory. In passing, it may be observed that these doubts are particularly strong in connection with the separation of phosphoric and vanadic acids from molybdic and tungstic acids. In this laboratory where, for many years, "complexes" have received attention, numerous opportunities have arisen to test the proposals made from time to time, and as it was given me to inquire more closely

<sup>1</sup> Gooch and Curtis, *Am. J. Sci.*, [4] 17, 41 (1904); Friedheim and Euler, *Ber.*, 28, 2067 (1895); Edgar, *Am. J. Sci.*, [4] 27, 174 (1908).

into some of these problems, I submit personal experiences with certain of these derivatives. I tried first of all to separate arsenic from tungstic acid; the acids being in the form of their sodium salts. Since arsenic acid may be completely volatilized from its salts, if the latter are exposed, at a comparatively low heat, to the action of dry hydrogen chloride gas, it seemed that in a mixture of sodium pyroarsenate and sodium tungstate this course would lead to a prompt and complete elimination of the arsenic acid. Accordingly weighed portions of sodium arsenate and sodium tungstate were exposed in a boat, to a stream of hot hydrogen chloride. The tungstate was immediately attacked, giving variously colored products, depending upon the temperature. It was found, however, that the arsenic, in the presence of the tungstate, was completely expelled only with great difficulty.

Numerous experiments were made to determine the temperature at which a complete separation could be effected. The results showed that the temperature at which it was practical to remove the arsenic acid was dangerously near the point at which the tungstic acid began to volatilize.

Since only a small amount of the tungstic acid volatilized at  $300^{\circ}$  (measured by a thermometer lying at the side of the combustion tube), it was thought best to collect the portion which volatilized, rather than try to regulate the temperature in such a manner as to completely prevent it. By working in this way the arsenic acid was fully removed to a suitable receiver in four hours. The contents of the combustion tube were rinsed into an evaporating dish with dilute ammonia and evaporated to dryness on the water bath. The residue was then digested with 1 : 1 nitric acid, while small quantities of hydrochloric acid were added from time to time. When all action had ceased the watch-glass cover was rinsed off, and the liquid was evaporated. The residue was moistened with nitric acid and evaporated several times to remove all chlorine. The residue, consisting of tungsten trioxide and sodium nitrate, was dissolved in sodium hydroxide, diluted and filtered. A few drops of methy orange were added, and the solution was just neutralized with nitric acid. It was then boiled, cooled, and the tungstic acid precipitated with mercurous nitrate. After standing four hours it was filtered, washed with 2% mercurous nitrate, and ignited and weighed as tungsten trioxide.

The method of evaporating with nitric acid, and then filtering out the tungsten trioxide, always gave low results. The procedure described—which is really an adaptation of Smith and Exner's method of getting pure tungsten trioxide—gave splendid results. In operating with "complex" salt, such as sodium arsenio-tungstate, a weighed portion was brushed into a small tube, open at both ends, and distributed by rolling and tapping. This tube was then placed in a combustion tube and exposed to a stream of dry hydrogen chloride for about an hour. The

temperature, as measured by a thermometer lying at the side of the combustion tube, was about  $200^{\circ}$ . Since, however, the temperature within the tube varied somewhat with the construction of the apparatus, the proper temperature was ascertained by turning the flames gradually higher until the tungstic acid began to volatilize, and condense on the tube, over the sample; a few degrees lower than this seemed to be the proper temperature to use. With this point determined, the wing-top burners were left permanently adjusted, the gas being regulated at the gascock.

After an hour the apparatus was cooled, the inner tube removed, the sample moistened with water, the tube replaced, and the gas passed for one-half hour longer. This precaution was repeated three times.

Then the receiver was disconnected and the contents of the combustion tube were rinsed into it after first withdrawing the inner tube. A second receiver was put in place, the sample again moistened and the operation repeated. Should the contents of the second receiver show the presence of arsenic when treated with hydrogen sulfide, the treatment must be repeated. The following results were obtained:

Sample of arsenio-tungstate.	Percentage $\text{As}_2\text{O}_3$ .	Percentage $\text{WO}_3$ .
0.1028 g.	11.63	71.01
0.1550 g.	11.57	70.83
0.2858 g.	11.77	70.88
0.2090 g.	.....	71.10
0.1409 g.	11.93	70.76
0.2788 g.	11.93	70.91

The method is then satisfactory and does not require a longer time for its execution than many other procedures in general use.

My next thought was to treat an antimonio-tungstate precisely as had been done with the arsenio-tungstate. The following data proved the concordance of results obtained by the method:

Samples.	Percentage $\text{Sb}_2\text{O}_3$ .	Percentage $\text{WO}_3$ .
0.1462 g.	66.87	16.07
0.0799 g.	66.84	16.02
0.1090 g.	66.81	15.96
0.1811 g.	.....	15.90
0.1582 g.	66.85	15.86
0.3040 g.	67.01	16.05

I had the following experience with a sodium vanadio-tungstate: When the dry hydrogen chloride was passed, the vanadium volatilized as a red vapor, condensing to a reddish brown liquid (the oxychloride). The residue was, however, soon reduced to a brownish mass no longer attacked, but on introducing chlorine gas along with the hydrogen chloride the vanadic acid was quite rapidly and completely expelled.<sup>1</sup>

<sup>1</sup> McAdam, *J. Am. Chem. Soc.*, 32, 1603 (1910).

In most satisfactory separations I employed a form of the apparatus pictured in the sketch.

The tube was made in one piece as shown. It consisted of one-inch soft glass tubing, A, to which was sealed a one-half inch exit tube, B. To the exit tube a calcium chloride tube was sealed; this prevented the water from being drawn back into the hot tube. The receiver was a large test tube. A tin box, C, served as an oven. It was provided with a thermometer. By sealing on D, a small separatory funnel, the sample could be moistened without "breaking" the ground-glass joint E. The dimensions should be about as given. Such a piece is easily cleaned, and the vanadium will not diffuse back to the joint. After it is once started it requires no attention.

Chlorine was generated by dropping hydrochloric acid upon potassium permanganate. Hydrogen chloride was generated in the usual manner. The mixed gases were passed through two wash bottles containing sulfuric acid.

In the actual working, weighed portions of the vanadio-tungstate were introduced into the tube by means of a piece of glazed paper. On passing hydrogen chloride, containing a small amount of chlorine, the sample was attacked with the formation of the customary reddish brown volatile liquid. After a time a gentle heat was applied to the oven, and the temperature was gradually increased until it reached  $200^{\circ}$ . A green residue, soluble in water, after evaporation becomes again volatile in hydrogen chloride. If the vanadium condenses in the neck of the tube it should be allowed to distil off slowly in the stream of hot hydrogen chloride.

After about an hour the reduction tube was cooled, and 5 cc. of a 10% sodium hydroxide solution were added.<sup>1</sup> On evaporating in a stream of the gases it was again heated, for one-half hour, at  $200^{\circ}$ . It was then alternately moistened with water and treated with the gas mixture until the red vanadium oxychloride no longer appeared in the cool portion of the exit tube. The rear end of the tube was then rinsed out, a second receiver put in place, and the operation repeated.

The appearance of the red film proved to be a very delicate test for vanadium. When it no longer showed it was always found that the vanadic acid had been completely expelled. The precaution of an extra treatment was, however, observed.

The tungsten was removed from the tube with ammonium hydroxide, and then determined as described under arsenic.

Various methods for estimating the vanadic acid were studied, and it was finally decided that the volumetric method, using potassium permanganate, was best suited to the conditions presented by the hydrogen chloride method.

Experiments were made to prove that there was no loss on evaporating a strong hydrochloric acid solution of vanadium. Such a solution was evaporated, in a retort, the distillate was collected and failed to show the slightest color with hydrogen peroxide.

In the determination of the vanadic acid which had been volatilized, and which it was proposed to estimate with potassium permanganate, I proceeded as follows: The receiver, contents, and exit tube, were rinsed into an evaporating dish, 5 cc. of concentrated sulfuric acid were added, and the solution concentrated, as far as possible, on the water bath. It was then heated, over a low flame, until white fumes of sulfuric acid came off. The contents of the dish were next rinsed into an Erlenmeyer flask, diluted to two hundred cc., heated to boiling, and a stream of sulfur dioxide passed in to completely reduce the vanadium to the vanadyl salt.

<sup>1</sup> This was necessary since the vanadio-tungstic acid contained no sodium or potassium, and, for that reason, a soluble residue resulted on treating with hydrogen chloride.

The boiling was continued and a stream of carbon dioxide was passed to expel the excess of sulfur dioxide, after which the solution was titrated, while still hot, with potassium permanganate, previously standardized with pure vanadium pentoxide, which had been reduced in the same manner.

The following results were obtained:

Vanadio-tungstic acid.	Percentage $V_2O_5$ .	Percentage $WO_3$ .
0.2204 g.	.....	65.47
0.3396 g.	.....	65.31
0.3227 g.	16.17	.....
0.3022 g.	15.92	65.35
0.3127 g.	15.90	.....
0.2460 g.	15.95	65.20
0.2487 g.	15.95	65.38
0.1848 g.	16.09	65.39

This method is so satisfactory that I prefer it to the others. The temperature is easily regulated; cooling can be quickly effected by removing the oven; the danger of loss from creeping is slight, and the volatile constituent is more quickly removed.

The methods mentioned above, for the separation of arsenic, antimonie and vanadic acids from tungstic acid seem to me superior to those ordinarily employed, hence I offer them in the hope that they may be of service to others who are called upon to work with similar combinations.

In this connection, I desire to record a further experience with certain "complexes." It will be recalled that Balke and Smith made the potassium, ammonium and strontium salts of a bismuthico-tungstic acid. These salts had the general formula  $3 M'_2O, 2 Bi_2O_3, 11 WO_3 + xH_2O$ .<sup>1</sup>

I prepared the potassium salt and from it obtained the mercurous salt, light yellow in color, well defined and very stable. Its analysis gave the ratio

A portion of this salt was covered with water and hydrochloric acid added in an amount insufficient to decompose the whole of it. After several hours' contact in the cold, with occasional shaking, the residue was filtered out. The aqueous filtrate was evaporated under reduced pressure and at a low temperature. A greenish oil separated when the water was nearly removed. Finally, hydrochloric acid vapors began to appear. Then, the greenish yellow solid was permitted to dry out in a desiccator over solid sodium hydroxide until the odor of hydrogen chloride was no longer perceptible. From an analysis, I at first thought that the hydrogen chloride had taken the place of the water of crystallization; later behavior seemed to indicate, however, that the acid had replaced the mercury oxide, and that the new substance had a composition corresponding to the formula

<sup>1</sup> THIS JOURNAL, 25, 1233 (1903).

6 HCl, 2 Bi<sub>2</sub>O<sub>3</sub>, 11 WO<sub>3</sub>. This is questionable and purely speculative. A new study of the compound is now in progress.

UNIVERSITY OF PENNSYLVANIA.]

## NEW DERIVATIVES OF TUNGSTEN.

BY J. BENNETT HILL.

Received September 15, 1916.

As early as 1859, Blomstrand<sup>1</sup> reported a series of compounds of molybdenum derived from the dihalides MoCl<sub>2</sub> and MoBr<sub>2</sub>. These dihalides had been obtained by repeated volatilization of the trihalides in a current of carbon dioxide. The nonvolatile product was soluble in alkalis and from this solution hydrates of the type Mo<sub>3</sub>Cl<sub>4</sub>(OH)<sub>2</sub> were precipitated by weak acids. All of these derivatives were yellow in color. They could be dissolved in strong acids, the nitric acid solutions showing no ionized halogen. The hydrochloric acid solution of the chloromolybdenum hydroxide gave on crystallization, Mo<sub>3</sub>Cl<sub>6</sub>·6H<sub>2</sub>O, and on dilution a pale yellow insoluble compound, Mo<sub>3</sub>Cl<sub>6</sub>·3H<sub>2</sub>O. Mixed halogen derivatives, such as Mo<sub>3</sub>Cl<sub>4</sub>Br<sub>2</sub>·6H<sub>2</sub>O and Mo<sub>3</sub>Br<sub>4</sub>Cl<sub>2</sub>·6H<sub>2</sub>O were also obtained. The chemistry and constitution of these compounds was further developed by Atterberg,<sup>2</sup> Liechti and Kempe,<sup>3</sup> Muthmann and Nagel,<sup>4</sup> Rosenheim and Kohn,<sup>5</sup> and Koppel.<sup>6</sup> Muthmann and Nagel determined the molecular weight of molybdenum dichloride dissolved in ethyl alcohol, and found it to correspond to the triple formula Mo<sub>3</sub>Cl<sub>6</sub>. Rosenheim and Kohn prepared a compound, Mo<sub>3</sub>Cl<sub>6</sub>·HCl·4H<sub>2</sub>O, by dissolving Mo<sub>3</sub>Cl<sub>6</sub> in strong hydrochloric acid, evaporating on a water bath and allowing the solution to crystallize. The compound consisted of glistening yellow needles, soluble in hydrochloric acid but was hydrolyzed by pure water. Only three-sevenths of the chlorine in the compound were ionized.

In 1909, Chapin<sup>7</sup> described halide bases of tantalum. He prepared these compounds by a method previously used by Chabrie<sup>8</sup> for obtaining what he called the dichloride of tantalum. It consisted in heating the pentachloride with 3% sodium amalgam in a hard glass tube sealed at one end and evacuated by means of a suction pump. Chapin used the pentabromide of tantalum. The reaction mass, taken up with water and

<sup>8</sup> *Compt. rend.*, **144**, 804 (1907).

hydrobromic acid and evaporated, furnished a crystalline body,  $\text{Ta}_6\text{Br}_{14} \cdot 7\text{H}_2\text{O}$ , dissolving in water to a dark emerald green solution. Chapin further showed that only one-seventh of the bromine in this compound was ionized, indicating the formula  $(\text{Ta}_6\text{Br}_{12})\text{Br}_2 \cdot 7\text{H}_2\text{O}$ . As additional evidence of the correctness of this formula he prepared a number of derivatives of the radical  $\text{Ta}_6\text{Br}_{12}$ , *e. g.*,  $(\text{Ta}_6\text{Br}_{12})\text{Cl}_2 \cdot 7\text{H}_2\text{O}$ ,  $\text{Ta}_6\text{Br}_{12}(\text{OH})_2 \cdot 10\text{H}_2\text{O}$  and others. He determined the molecular weight of the parent bromide in propyl alcohol and found it to correspond to the formula given.

In 1913, Harned<sup>1</sup> reported a similar series of compounds of columbium obtained from the pentachloride by the Chabrie method. He obtained a crystalline body,  $(\text{Cb}_6\text{Cl}_{12})\text{Cl}_2 \cdot 7\text{H}_2\text{O}$ , soluble in water to an olive green solution, a crystalline hydroxide,  $\text{Cb}_6\text{Cl}_{12}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ , and others. Both the columbium and tantalum compounds were characterized by their remarkable tinctorial power, a milligram being sufficient to color 100 cc. of water an intense green.

Harned also obtained a brown compound, insoluble in water, the analysis of which corresponded to the formula  $\text{Cb}_6\text{Cl}_{14} \cdot 9\text{H}_2\text{O}$ . This was prepared by the addition of concentrated hydrochloric acid to the alkaline solution of the green compound  $(\text{Cb}_6\text{Cl}_{12})\text{Cl}_2 \cdot 7\text{H}_2\text{O}$ . The brown derivative, on boiling with water, slowly reverted to the original green. His experiments led him to the conclusion that there was a constitutional difference between the two.

In view of the existence of these compounds of molybdenum, tantalum and columbium, it would seem reasonable to expect that the closely related element, tungsten, would form similar derivatives. Roscoe<sup>2</sup> reported the dichloride, dibromide and diiodide, but a more thorough investigation of them has never been carried out. The present work was undertaken to prepare, if possible, bodies of tungsten similar to those of molybdenum, tantalum and columbium.

To get pure tungsten trioxide from wolframite, the method of purification was that employed by Smith and Exner.<sup>3</sup> The reduction of the pure oxide of tungsten by hydrogen was carried out in a quartz tube, heated to a little over  $1000^\circ$  in a gas-heated furnace constructed of asbestos. The resulting metal with a pale gray color was changed to hexachloride by the process of Smith and Exner and need not be mentioned here. It was found, however, that, while commercial tungsten could be converted to hexachloride at the rate of about 20 g. in two hours, the pure material as obtained above, was only very slowly attacked, seven hours being required to effect the chlorination of 10 g. of metal. Since there was only a trace of oxychlorides formed in the reaction, it was thought that possibly their

<sup>1</sup> THIS JOURNAL, 35, 1078 (1913).

<sup>2</sup> *Ann.*, 162, 360 (1872).

<sup>3</sup> *Chem. News*, 90, 37 (1904).

presence might exert a catalytic action on the chlorination. In an attempt to catalyze the reaction in another way, 0.1 g. of precipitated platinum was sprinkled on the tungsten in the boat. On passing chlorine over the gently heated boat no difference in the speed of the reaction was at first noticed. After a few minutes a glow appeared to run through the mass and, from this point on, the reaction took place as fast as the chlorine could be passed in, the chlorine uniting with the metal with incandescence. By this means 20 g. of tungsten were converted to hexachloride in  $1\frac{1}{2}$  to  $1\frac{3}{4}$  hours. After the tungsten had been swept out, the platinum remained on the bottom of the boat as a brown powder. This was used in the chlorination of the next batch of tungsten and so on repeatedly. Three hundred grams of pure tungsten hexachloride were so obtained.

To reduce the hexachloride in the method outlined by Chabrie and by Chapin, it was mixed in a mortar with a little less than the amount of powdered 3% sodium amalgam calculated to reduce it to the state of dichloride. The mixture was quickly transferred to a Jena tube sealed at one end. The tube, after connecting with a suction pump and evacuating, was gently heated until the reaction had taken place and then heated strongly for about ten minutes. It was allowed to cool in the vacuum, and the contents extracted with hydrochloric acid. On filtering there was obtained a deep reddish brown filtrate and a gray precipitate. Attempts to crystallize the highly colored compound from this solution failed. Its solution was very stable in the air and could be evaporated to dryness with only a trace of decomposition.

Before preparing any quantity of the brown solution the conditions of the reaction were investigated, varying the proportions of the reacting substances and the temperature and duration of heating. As a result the following details were adopted: 15 g. of tungsten hexachloride were ground in a mortar and mixed carefully and quickly with 105 g. of sodium amalgam. The reaction between the two substances is rather vigorous and, unless precautions are taken to prevent it, is liable to take place in the mortar. In view of this, the mortar, as well as both of the reacting substances, were cooled in ice previous to the mixing. In addition to this, not more than ten seconds were allowed to elapse between the time when the amalgam was brought in contact with the hexachloride and the time when the mixture was in the Jena tube with the vacuum on. In spite of these precautions the reaction frequently took place during mixing. When the mixing and transfer to the tube had been successfully accomplished, the reaction was allowed to take place, and the tube then heated just to dull redness and allowed to cool immediately. The contents were extracted with hydrochloric acid (sp. gr. 1.08), and the solution filtered. The brown color so obtained was intense.

A portion of the brown solution was evaporated to dryness and the dry

residue extracted with alcohol. A dark reddish brown solution resulted from which nothing could be crystallized. An extraction with ether gave a yellow solution which on evaporation left a pale yellow amorphous body. This, taken up with a drop of dilute hydrochloric acid and allowed to evaporate, showed under the microscope shining, yellow needles. A somewhat larger portion of the dry residue, treated in a similar way, gave needles as much as a centimeter in length. Experiments with the original brown solution of the reduced mass led to the following method of isolation of the yellow needles: The brown solution was boiled down until considerable sodium chloride had separated out, when it was filtered hot and allowed to cool. There then separated a mixture of sodium chloride and the yellow needles. This was filtered off and washed with concentrated hydrochloric acid until the liquid came through almost colorless. The mixture was spread out on a watch glass and allowed to dry in the air. It was next extracted for about ten minutes under a reflux condenser with ether containing about 5% of ethyl alcohol. The insoluble sodium chloride was filtered out and the ether distilled off from the filtrate, leaving a yellow amorphous mass. This was taken up with fairly strong hydrochloric acid, and boiled when everything dissolved. The clear yellow-colored solution was evaporated to small bulk and allowed to cool, when an abundance of yellow needles separated. These were filtered off, washed with concentrated hydrochloric acid and dried in the air. From 150 g. of tungsten hexachloride, 12 g. of the yellow compound were obtained.

It proved to be readily soluble in alcohol, acetone, glacial acetic acid and in ether containing alcohol, but was almost insoluble in pure anhydrous ether. It was insoluble in benzene, carbon bisulfide, carbon tetrachloride and chloroform. It dissolved in water, but the aqueous solution on standing hydrolyzed, precipitating out first a yellow and then a black compound. The crystals on long exposure to air, or in a desiccator over sulfuric acid, disintegrated, giving a lemon yellow amorphous compound, insoluble in water. The same compound was produced on allowing the solution in dilute hydrochloric acid to stand or on diluting it with water. The resemblance of these two compounds to Rosenheim and Kohn's  $\text{Mo}_2\text{Cl}_6 \cdot \text{HCl} \cdot 4\text{H}_2\text{O}$  and Blomstrand's  $\text{Mo}_2\text{Cl}_6 \cdot 3\text{H}_2\text{O}$  will be at once noticed.

Warm nitric acid effected a complete decomposition of the solution of the yellow needles, a hydrated tungsten trioxide being precipitated in granular form. Potassium hydroxide added to an aqueous solution of the compound gave a clear yellow-colored solution which darkened immediately to a deep brown. From this solution weak acids threw down a black gelatinous precipitate. The same compound was obtained by treating the aqueous solution of the yellow needles with sodium carbonate. The brown alkaline solution on exposure to the air slowly faded in color

to a deep yellow, which with weak acids yielded a yellow gelatinous precipitate.

The determination of tungsten in the yellow needles was obtained by a very simple and direct method. The compound was weighed out in a porcelain crucible, covered with concentrated nitric acid and digested for several hours on a water bath. It was then evaporated to dryness, ignited and weighed as  $\text{WO}_3$ . Results 1 and 2 were obtained by this method; the analyses were made with different preparations of the compound, the results giving evidence both of the accuracy of the method of analysis and of the homogeneity of the product. The third determination was obtained by an altogether different procedure. The aqueous solution of the compound was treated with potassium hydroxide and the deep brown solution acidulated with acetic acid. The black precipitate was filtered off and ignited to trioxide.

The determination of chlorine offered much greater difficulty. It would be fruitless to enumerate the methods attempted. Most of them were valueless for the reason that the silver chloride was contaminated with tungsten. It might be mentioned here that the presence of as little as  $\frac{1}{2}\%$  of tungsten in this precipitate completely alters its character, the silver chloride separating in a granular form rather than curdy. Of the methods attempted the following appeared to be the most satisfactory:

Method 1.—The compound was dissolved in water, treated with ammonia and the solution oxidized with ammonium persulfate. The excess ammonia was boiled off, the tungsten precipitated out as cadmium tungstate and the chlorine determined in the filtrate as silver chloride. Determination 1 was obtained by this method.

Method 2.—The solution of the compound was treated with sodium carbonate and boiled. The black precipitate was filtered out and the silver chloride precipitated in the filtrate. The precipitate showed considerable contamination with tungsten and was dissolved in ammonia and reprecipitated. Determinations 2 and 3 were obtained in this way.

Method 3.—The compound was dissolved in nitric acid (sp. gr. 1.1) and warmed for about two hours when the tungsten completely separated as the hydrated trioxide. This was filtered off and the chlorine determined as silver chloride in the filtrate. The precipitate showed no contamination with tungsten. The results are determinations 4 and 5.

The water was estimated by the method used by Chapin. The material was mixed with dry lead oxide and heated in a boat in a current of pure dry air to about  $300^{\circ}$  for two hours. The water was collected in a weighed calcium chloride tube. The details of manipulation are those outlined by Chapin.

			Mean, 10.18%

It should be noted that the hydrogen of any hydrochloric acid in the molecule of the compound would appear here as water along with the true water of the compound. The theoretical compositions calculated below are figured on this basis and will, therefore, add up to more than 100%.

It was expected that the composition of the compound would correspond to the formula  $W_3Cl_6.HCl_4.H_2O$ , analogous to Rosenheim and Kohn's  $Mo_3Cl_6.HCl_4.H_2O$ . It will be seen on reference to the figures that the observed values do not agree with those calculated for this substance. They agree much better with the calculated percentages for a compound containing another half molecule of water, the doubled formula of which would be  $W_6Cl_{12}.2HCl_9.H_2O$ . The calculated compositions follow:

Per cent.	Calculated for $W_3Cl_6.HCl_4.H_2O$ .	Calculated for $W_6Cl_{12}.2HCl_9.H_2O$ .	Observed.
W.....	63.20	62.55	62.51
Cl.....	28.46	28.16	28.28
H <sub>2</sub> O.....	9.27	10.20	10.18

The doubled formula finds support in its analogy with the tantalum and columbium compounds. It finds a complete analogy in the columbium compound prepared by Harned and formulated by him,  $Cb_6Cl_{14}.9H_2O$ .

Since the compounds of molybdenum, tantalum and columbium ionize only part of their chlorine in aqueous solution, it seemed reasonable to expect that the yellow tungsten compound would behave similarly. Accordingly an attempt was made to determine the amount of chlorine ionized. In view of the fact that the compound is hydrolyzed in pure water or in dilute acids other than hydrochloric, the problem presented considerable difficulty. The first attempt was to dissolve it in potassium hydroxide solution and to add to the deep brown solution acetic acid, throwing out the black gelatinous precipitate. This was filtered off and the chlorine determined in the filtrate. The operation was conducted entirely in the cold. A similar treatment of the molybdenum compound precipitated a hydrated  $Mo_3Cl_4(OH)_2$  leaving the ionized chlorine in the filtrate. The same behavior was expected here. The following result was obtained:

Wt. sample = 0.2009 | AgCl found = 0.2291 | % Cl = 28.21

This corresponds to the total chlorine in the compound, indicating that a complete decomposition had taken place and that the black precipitate contained no chlorine.

A second attempt was based on the fact, previously mentioned, that the brown alkaline solution on standing fades to a brownish yellow, and that from this solution acetic acid precipitates a yellow-colored substance. A sample of the yellow needles was dissolved in alkali and so treated, the chlorine being determined in the filtrate.

Wt. sample = 0.1017 | AgCl found = 0.1182 | % Cl = 28.76.

The result again indicated a complete decomposition of the needles. It would seem probable that if derivatives in which only a part of the chlorine is split off, are formed at all, they are extremely unstable.

In order to provide further evidence in favor of the formula assigned to the yellow compound, a determination of the molecular weight was sought. An attempt was first made to arrive at this by the lowering of the freezing point of glacial acetic acid. It was discovered, however, that the water of crystallization of the compound interfered to such an extent that no result could be obtained by this method. The rise of the boiling point of ethyl alcohol was next attempted. Here the hydrochloric acid in the molecule appeared to interfere, the boiling point falling on solution of the compound rather than rising. A further investigation along these lines was prevented by lack of material.

### Other Related Compounds.

The lemon-yellow-colored amorphous compound has been described. About a gram of this material was prepared from the yellow needles. It was soluble in boiling hydrochloric acid, reverting to the original yellow derivative. It dissolved in alkalis to give the deep brown solution. Analysis gave the following results:

Wt. sample = 0.2003	WO <sub>3</sub> found = 0.1716	% W = 67.95
Wt. sample = $\begin{cases} 0.2074 \\ 0.2007 \\ 0.1063 \end{cases}$	AgCl found = $\begin{cases} 0.2325 \\ 0.2236 \\ 0.1169 \end{cases}$	% Cl = $\begin{cases} 27.73 \\ 27.57 \\ 27.20 \end{cases}$
Wt. sample = 0.2001	H <sub>2</sub> O found = 0.0107	% H <sub>2</sub> O = 5.35

These values do not correspond to any reasonable formula and it is probable that the compound prepared was impure.

An investigation of the mother liquors from the crystallization of the yellow needles led to the isolation of another compound crystallizing in dark brown shining needles. This was prepared by slowly saturating the mother liquor with hydrochloric acid gas and letting it stand for several days. The sodium chloride thrown out contained, besides yellow needles, a small quantity of the brown compound in crystals about 2 mm. long. The mixture was dried and the brown needles picked out. Only a few

milligrams were obtained. They dissolved in water to a clear yellow-colored solution, not decomposed by boiling nitric acid nor by potassium hydroxide. Sodium carbonate threw out a yellow granular precipitate. The tinctorial power of the compound was remarkable, one of the small crystals giving a decided color to 100 cc. of water. This fact makes it probable that the substance is related to the tantalum and columbium compounds. No analysis was obtained owing to the small amount of substance at hand.

### Investigation of the Alkaline Solution of the Yellow Needles.

It has been mentioned that the addition of alkali to an aqueous solution of the yellow needles produced three distinct solutions: first, a yellow-colored solution which changed immediately to a deep brown, which in turn changed slowly on exposure to the air to a less highly colored brownish yellow solution. It was undertaken here to determine the state of oxidation of the tungsten in these three solutions. The deep brown solution was first investigated. To this end a sample of the yellow compound was dissolved in water and treated with a solution of potassium hydroxide. The solution was let stand for about thirty seconds when it had assumed the dark color. An excess of standard iodine was then added, the color fading to a pale yellow. After standing thirty minutes, the solution was made acid with acetic acid and the excess iodine titrated with thiosulfate. The result is No. 1 in the table. It shows that the tungsten is almost completely in the trivalent condition. The determination was repeated, allowing the alkaline solution to stand ten minutes before the addition of the iodine. The result (2 in the table) shows that the tungsten has been completely oxidized to the trivalent state. Since, from the deep brown solution, weak acids threw out the black gelatinous precipitate which redissolved in alkali to give the original solution, the above results would indicate this black compound to be a hydrated  $W_2O_3$  possibly  $W(OH)_3$ .

The same method was applied to the brownish yellow solution obtained by letting the alkaline solution stand exposed to the air for twenty-four hours. The result (3 in the table) shows that the solution contains quadrivalent tungsten and that the yellow hydrate obtained from it by the action of weak acids must be a hydrated  $WO_2$ .

The first yellow alkaline solution contains tungsten of undoubtedly the same state of oxidation as the yellow needles. The rapidity with which it oxidizes made it rather more difficult to investigate than the other two. To avoid this difficulty the iodine solution was added to the potassium hydroxide and the mixture then added to the water solution of the yellow compound. It was let stand thirty minutes, made acid, and titrated as before. The result is No. 4. It indicates bivalent tungsten, which was, of course, to be expected.

### Summary.

1. The action of chlorine on tungsten metal to form hexachloride is catalyzed to a remarkable degree by the presence of a small amount of platinum black.

2. Tungsten forms the compound  $W_6Cl_{12} \cdot 2HCl \cdot 9H_2O$ , resembling the molybdenum derivative  $Mo_3Cl_6 \cdot HCl \cdot 4H_2O$ , prepared by Rosenheim and Kohn.

3. The alkaline solution of the preceding compound oxidizes readily and from the solution stable hydrates of trivalent and quadrivalent tungsten were obtained:

## THE EFFECT OF PRESSURE UPON THE POTENTIAL OF THE HYDROGEN ELECTRODE.

BY N. EDWARD LOOMIS AND S. F. ACREE.

Received August 28, 1916.

In the previous work by the authors,<sup>1</sup> by Desha,<sup>2</sup> Myers,<sup>3</sup> and by Clarke,<sup>4</sup> it was shown how to make hydrogen and calomel electrodes which can be read to a few millionths of a volt. It was further found that by using a large number of hydrogen and calomel electrodes in batteries to reduce errors, by thoroughly saturating the acid solutions and electrodes with hydrogen before connecting the systems, by using a saturated (4.12 *N*) solution of potassium chloride to annul the contact potential as completely as possible, and by using wide connecting tubes and large fresh contact surfaces, and keeping the barometric pressure constant, it is possible to reproduce readings in a given series to close to 0.00001 volt. Recent investigations of our own and by others<sup>5</sup> have shown that these methods must be adhered to closely for work of the highest precision and accuracy.

The two greatest sources of uncertainty in this work are contact potential and the potential of the hydrogen electrode when incompletely saturated, and, because of these, high reproducibility of readings does not mean corresponding high accuracy. We, therefore, devised,<sup>6</sup> in 1910-11,

an automatic pressure regulating device involving a Fues normal barometer and electrical equipment for measuring the e. m. f. while keeping the hydrogen at normal and any other desired pressure while it passes through the system. Because of other work, however, we have not yet been able to take up all the problem outlined of studying the effect of hydrogen pressure on the e. m. f. at different temperatures, of measuring the rate of establishment of the gaseous and electrical equilibrium within the electrodes of different materials having different kinds of surfaces in order to study constant and especially *changing* solutions, and especially the problem of studying the mechanism of the establishment of the equilibrium between the molecules, atoms, and ions of hydrogen in and at the different kinds of electrodes. This last phase of the problem is also being studied by Prof. Edward Bennett and one of us in our investigations on the conductivities of solutions. Especial attention will be given to the well-known facts that between 100° and 180° hydrogen dissolves in palladium as hydrogen atoms<sup>1</sup> up to about 400 mm. and above this pressure chiefly as H<sub>2</sub> to the extent of about 900 volumes. Platinum black<sup>2</sup> dissolves about 100 volumes oxygen and 110 volumes of hydrogen up to 300 mm. and above this pressure up to 4.5 atmospheres. The volume absorbed is practically constant for hydrogen but increases 8.5 volumes for oxygen. This last point may be significant in connection with the fact that the hydrogen-oxygen cell gives only 1.08 volts instead of 1.23. Experiments will be performed at 1–3000 mm. at different temperatures to see whether at the critical pressures discussed above, 300 mm. and 400 mm., there is any break in the e. m. f.-pressure-temperature relation should involve (P — 300) and (P — 400) instead of P.<sup>3</sup> This effect of pressure on the electromotive force must be considered all the more important because of such work as that of Harris<sup>4</sup> in which he found that in hydrogen gas the negative charge is associated with 1, 3 and 6 molecules of hydrogen and that the positive charge is associated with 9 molecules of hydrogen. A discussion of all of these relations will be found in another article.

When the work of Loomis and of Myers was carefully considered the data seemed to fit in best with the barometric corrections deduced from the formula  $E = RT/nF \log n \text{ H}_2/\text{H}'_2$ , in which  $n$  was chosen as unity for the balance of the hydrogen ions. But the corrections were so small, and were so masked by such other errors as contact potential that it was shown that the same average values were obtained whether a barometric correction was applied or not. In view of these uncertainties and the fact that no one else had had occasion to work with the precision requiring

<sup>1</sup> Hoitsema, *Z. physik. Chem.*, **17**, 1 (1895).

<sup>2</sup> *Ibid.*, **19**, 25 (1896).

<sup>3</sup> *Z. physik. Chem.*, **17**, 1 (1895).

<sup>4</sup> *Phil. Mag.*, **31**, 339 (1916).

the solution of this problem, it seemed desirable<sup>1</sup> to get direct evidence on the effect of wider variations of pressure upon the potential of the hydrogen electrode, especially in the chain

upon which most of the work had been done. The experiments described in this article show that the corrections in the data of Loomis and Myers obtained by the use of the above equation are double the values now found, as has been pointed out by Loomis.<sup>2</sup> When the proper corrections are applied to all our data there are no changes in the general averages because, as pointed out before,<sup>3</sup> the average barometric pressure in Baltimore is practically 760 mm. The same average value 0.4272 is obtained for the data of Myers and Clarke as we obtained in the present study of the electromotive force on the hydrogen electrode in 0.1 *N* hydrochloric acid against calomel in 0.1 *N* KCl.

This work, therefore, shows that the absorbed molecular hydrogen in the electrode is proportional to the  $1/2$  power of the hydrogen pressure or that the absorbed molecular gas gives hydrogen atoms in accordance with the equations  $\text{H}_2 = K \times 2\text{H}$ , and  $\text{H}^+ = K' \times \text{H}$ , either condition leading to the equation  $E = RT/2F \log n p_1/p_2$ , as discussed in another paper. Our work, therefore, harmonizes with that of Czepinski,<sup>4</sup> Haber and Foster,<sup>5</sup> Lewis and Rupert,<sup>6</sup> and of Ellis,<sup>7</sup> who recently made one direct measurement of the effect of pressure on the hydrogen electrode.

The method used in obtaining the results given in this paper was to measure the hydrogen electrode in 0.1 *N* hydrochloric acid against the calomel electrode in 0.1 *N* KCl with no intermediate solution, first at barometric pressure and then at increased or decreased pressure. The arrangement of the solutions was such that increase in pressure caused very slight shifting of the solutions. Contact between the two solutions was made in a wide tube as in all our other work and as recommended since by Cummings and Gilchrist,<sup>8</sup> and by Clarke and Lubs.<sup>9</sup> In order to get constant potentials it was found necessary to renew the surface of contact between the two electrolytes at each set of readings. All measurements were made at 25°.

The apparatus used in making the measurements was the same as

<sup>1</sup> *Am. Chem. J.*, **46**, 585, 609, footnote.

<sup>2</sup> *J. Phys. Chem.*, **19**, 663 (1915).

that which has already been described in previous papers from our laboratory.

One experiment is described in detail to illustrate the method in which the measurements were carried out.

8.40 A.M.	E. M. F. experiment started.	8.40 A.M.	E. M. F. experiment started.
9.16	0.42583	Increased pressure to atmospheric + 40 mm.	
9.35	0.42634	10.19	0.42701
9.43	0.42642	10.26	0.42717
9.54	0.42654	10.36	0.42721
9.56	0.42652	10.40	0.42722

Bar. (corrected) = 735 mm.

Pressure = 735 + 40.

Corresponding to an increase in pressure of 40 mm. there is an increase in potential of  $0.42722 - 0.42652 = 0.00070$ .

In calculating the change in potential of the hydrogen electrode from the equation

$$E = \frac{RT}{2F} \log n \frac{p_1}{p_2} = \frac{0.05915}{2} \log_{10} \frac{p_1}{p_2},$$

it has seemed more logical<sup>1</sup> to use for  $p_1$  and  $p_2$  not the total pressures of the system but the partial pressures of the hydrogen, *viz.*, the total pressures minus the vapor pressure of the water solution, practically the same as that of pure water for dilute solutions. There is a difference<sup>2</sup> of only a few hundred thousandths of a volt in the two ways of calculating and our results are not sufficiently accurate to indicate which method of calculation gives the better results.

Applying the equation to this experiment we have

$$E = \frac{0.05915}{2} \log_{10} \frac{775 - 24}{735 - 24} = 0.00070.$$

In this case there is perfect agreement between the measured and theoretical values.

To indicate the steadiness of the electromotive force of the system this same experiment may be followed somewhat further. After the measurement at 775 mm. had been made the pressure upon the system was increased to 789 and then allowed to fall to the original pressure of 735 again. The reading at 789 was 0.42749 at 11.09 A.M. The pressure was released and the subsequent readings were as follows:

Time.....	11.17	11.26	11.34	11.41	11.45	11.48	11.54
E. m. f.....	0.42683	0.42654	0.42647	0.42645	0.42648	0.42651	0.42653

It will be noted that the last two readings are practically identical with those two hours earlier at the same pressure.

The following table summarizes the results which were obtained in eight

<sup>1</sup> Loomis and Acree, *Am. Chem. J.*, **46**, 610 (1911), footnote. Ellis and Clarke and Lubs have now adopted this method.

<sup>2</sup> Loomis and Acree, *Am. Chem. J.*, **46**, 610 (1911), footnote.

teen similar experiments. The readings at different time periods are omitted and only the final e. m. fs. obtained at equilibrium are given.

The first two experiments are to be considered as preliminary ones. The poorer agreement in these is probably due to the fact that fresh surfaces of contact between the two solutions were neglected. The lack of agreement in the fifth from the last is probably due to incomplete saturation or to a change in the potential of the calomel cell, possibly due to shaking, as indicated by the fact that when the pressure was released the electrode failed to come back to its original value by an amount very close to the difference between the theoretical and measured values. In the two final experiments the temperature of the bath varied. But even in these experiments the changes in e. m. f. obtained are much closer to the theory than to double this amount. These experiments marked \* are omitted from the final average. For the remaining determinations the average change in potential per mm. change in pressure is 0.00001751; that calculated is 0.00001746, a variation of 0.29%.

This series of experiments also gave opportunity for further measurements of the potential of the system

The average values of previous measurements of this system by Bjerrum (1) Loomis and Acree (2), and Myers and Acree (3) are 0.4273, 0.4269 and 0.4273, respectively, after correcting for barometric pressure, for the vapor tension of the solution at the hydrogen electrode, and for the present voltage of the Weston cell, and the average is 0.4272. For a more complete summary of these measurements see Loomis and Meacham in an article soon to be published. The following table gives the measured

voltage of five experiments with the above system at 25° with corrections for the potential of the calomel cell, for the barometric pressure, and for the vapor tension of the solution, and the final corrected voltage. The corrections for the potential of the calomel cell were determined as usual in our laboratory by comparing the working electrode with the mean of a large battery containing ten other electrodes. The couplets in the first column give the e. m. f. observed at first under atmospheric conditions and again at this pressure after having subjected the system to the increased pressure.

Average, 0.42723

### Conclusions.

1. Experiments on the influence of the partial pressure of hydrogen on the potential of the hydrogen electrode show that near atmospheric pressure the changes can be expressed by the formula  $E = RT/2F \log n H_2/H'_2$ , in which  $H_2$  and  $H'_2$  are the partial pressures. The average change in potential found is 0.00001751 volt per millimeter which is only 0.3% larger than the value 0.00001746 volt calculated by the use of the above formula.

2. Five experiments on the system

gave the potential  $0.42723 \pm 3$ , which is in very close agreement with the average of our earlier values and with those of Bjerrum, namely, 0.4272.

## STUDIES IN THE MEASUREMENT OF THE ELECTRICAL CONDUCTIVITY OF SOLUTIONS AT DIFFERENT FREQUENCIES.

### V. INVESTIGATIONS ON THE USE OF THE VREELAND OSCILLATOR AND OTHER SOURCES OF CURRENT FOR CONDUCTIVITY MEASUREMENTS.<sup>1</sup>

BY W. A. TAYLOR AND S. F. ACREE.

Received August 26, 1916.

As the measurement of the true electrical conductivities of solutions

<sup>1</sup> Robertson and Acree, *J. Phys. Chem.*, **19**, 381 (1915); Taylor and Curtis, *Phys. Rev.*, **6**, 61 (1915); Taylor, *Science*, **42**, 388 (1915). We are indebted to the Carnegie Institution of Washington for aid in this work.

of electrolytes and of heterogeneous systems, such as woods and other plant tissues and their liquid contents, skin and muscular tissues under different conditions, blood and many colloidal solutions and suspensions is of great importance to chemists, physicists, botanists, zoölogists, geologists, medical men, and others, we have been working during the past few years to develop methods for this purpose with an accuracy of 0.001%. The most important new aspects of the investigation were to determine the nature of the electrode processes, the polarization or capacity phenomena, and the phase relations, by the use of pure resistances, capacities, inductances, the oscillograph and an alternating current potentiometer. Since the ideal condition of being able to measure the true resistance at high frequencies approaching infinity cannot be realized today because of errors from skin effects and inductance and capacity in the resistance coils and leads, and because there are no current detectors giving the necessary precision at such high frequencies, we have tried to find methods for using lower frequencies. In this work it was first necessary to obtain a source of alternating current which has a pure sine wave form of any desired voltage and of constant frequency, which frequency may be varied at will through a wide range. A pure sine wave is required in order to prevent unsymmetrical polarization at the electrodes and to annul the influence of harmonics on the telephone; that is, to obtain complete silence when the fundamental frequency is perfectly balanced by the use of the correct resistance and inductance or capacity in the bridge. Since we have found that the apparent resistance of a given solution in a cell with bright electrodes may vary as much as several per cent. with change in frequency, and that the true electrical resistance can be obtained only by making resistance measurements at several different frequencies and extrapolating the resistance to infinite frequency, or applying the formula  $R_{\infty} = R_f - KL_{ff}$ , it is obvious that we must be able to change the frequency at will, but that it must be constant at any given setting.

In our work we have tested the induction coil,<sup>1</sup> the 60-cycle city current of Madison, a Holzer-Cabot wireless alternating current generator, a General Electric type of large generator, a Siemen's-Halske alternating current generator, the small Vreeland oscillator sold by Leeds & Northrup for work at 500 and 1000 cycles, and the very fine type<sup>2</sup> B Vreeland oscillator which the Western Electric Company sells for work at frequencies varying from 160 to 4200 cycles. Oscillograms of the wave forms of the different machines are given in the figures below. These photographs show the wave form of the voltage, and also that of the current in some

<sup>1</sup> See Leeds and Northrup Catalogue 48, for oscillograms of their induction coils and of their small Vreeland oscillator, and for a description of this latter instrument.

<sup>2</sup> See "The Vreeland Oscillator" issued by the Western Electric Co., for a description of their Vreeland Oscillators, the oscillograms, and general applications of these instruments.

cases. In the case of the Madison city current the wave form of the charging current of a condenser supplied with this voltage is also shown to give an idea of the harmonics present. The writers are greatly indebted to Messrs. Curtis, Fitch and Fearing of the Bureau of Standards and to Professor Edward Bennett and Dr. G. H. Gray of the University of Wisconsin, for assistance in obtaining these oscillograms at various times since 1911.

The induction coil should be discarded when conductivity measurements of any great degree of accuracy are desired. It is especially unfitted for this work because (1) it does not give an alternating but a pulsating current having a large number of over-tones which prevent the operator from obtaining complete silence in the telephone, (2) the range of frequency is comparatively small, and (3) it is impossible to keep the frequency constant. Figs. I and II show the voltage wave form given by our induction coil, which is one of the best types made by Leeds and Northrup. This wave form is not only clearly far from sinusoidal, but is very unsymmetrical. The electromotive force below the axis is considerably larger than that above and the much slower rise to the maximum above is in decided contrast to the sharp break into the axis from below. The unreliability of an induction coil is clearly shown by the fact that although Figs. I and II were made without changing the setting of the induction coil, the difference between the amplitudes of the upper and lower peaks in Fig. I is much larger than in Fig. II. These facts show clearly not only that there is unsymmetrical polarization at the electrodes but that it varies so much from moment to moment when an induction coil is used that it is impossible to have the same current or voltage phases at the telephone terminals and secure silence.

Fig. III gives the oscillogram of the voltage wave of the 60-cycle city current of Madison. It is seen that the wave form is nearly sinusoidal, although the irregularities at the crest of the wave show that some harmonics are present. Fig. IV shows the oscillogram of the charging current of a condenser supplied by this voltage. In the charging current of a condenser the amplitude of any  $n$ th harmonic is  $n$  times as great as in the voltage wave form. Fig. V shows the pure sine charging current of the condenser after these harmonics have been tuned out by the use of the proper inductance and capacity. By tuning out the harmonics a very much better and more accurate minimum can be obtained. In Figs. IV and V,  $e$  denotes the voltage and  $i$  the current curves. Although the frequency is not quite steady a very good bridge balance can be obtained for such low frequencies and this purified source of current was useful in getting resistance, capacity and inductance measurements to compare with those at higher frequencies.

Figs. VI and VII give the oscillograms of a Holzer-Cabot wireless gen-

erator at 248 and 500 cycles, respectively. Although the wave form is very good for a machine of this kind, it is somewhat flat-topped because of the presence of a third harmonic. This prevents complete silence in the telephone when the fundamental is balanced. The greatest disadvantage is that the machine has no attachment for changing or regulating the frequency.

Figs. VIII and IX give the oscillograms of the wave forms obtained from the large General Electric Company generator made for frequencies from 160 to 3000. The first is for the 600-cycle side of the machine and the second for the 3000 side. These are practically sine waves and the freedom from harmonics allows us to obtain a much better minimum than that given by the Holzer-Cabot machine. But the frequency is not absolutely constant and the cost of the machine is very large. The energy output of the machine is so large that an alternating current galvanometer can be used as current detector at low frequencies with high precision.

Curtis in his work on resistances for alternating currents, and Washburn in his fine work on conductivities, and also Schlesinger have already

tested the Siemens-Halske generator and found it excellent. The harmonics can be easily tuned out by the use of inductances and capacities. It can be made to give frequencies from 400 to 1800 but these are not constant unless a special regulating device is attached.

We have found the type B Vreeland oscillator sold by the Western Electric Company to be far the best source of current tried thus far, for the following reasons: (1) It is practically noiseless and can be started and stopped conveniently. (2) By the use of suitable secondary coils, which can be rotated easily, it can be made to give any voltage desired up to about 500; only a very small current can be obtained at this voltage but this is ample for measuring resistances up to 100,000 ohms or more. When a storage battery of constant voltage is used as a source of actuating current the alternating current obtained has a voltage steady enough for alternating current potentiometry. (3) It gives a constant frequency independent of variations in the actuating direct current or in the load and, hence, under even only fairly constant conditions, gives a note of constant pitch and loudness in the telephone, and, of especial importance, allows the cell capacity to be balanced out sharply so that an accurate bridge balance can be obtained. (4) The frequency is regulated by means of a set of mica and paper condensers with a range of 0.001 to 40 microfarads and in this way can be changed easily to any value between 160 and 4200 cycles and kept constant for weeks to within 0.10%. By changing the number of turns in the field coils of the Vreeland oscillator the frequency can be made as low as 30 to 40 without the use of additional condensers. By using extra condensers or inductances and these special field coils the frequency can be lowered to possibly 10; although Vreeland states that the wave form is not perfect at this frequency it is nevertheless good enough for all of our requirements. By the use of quartz bulbs frequencies up to 100,000 for wireless telegraphy can be obtained. An instrument for giving simultaneously any two frequencies within these ranges is much needed and may later be placed on the market. (5) It gives practically a pure sine wave free from harmonics which disturb the operator using the telephone and, hence, it is possible to obtain easily complete silence in the telephone. (6) It can be run by a mercury rectifier, but the wave form is then not so good, because the rectifier voltage is pulsating and not steady. Our unloaded rectifier gives the pulsating voltage wave form 2 in Fig. X, 1 being the zero of voltage in both Figs. X and XI. When loaded with the Vreeland the rectifier gives the voltage wave form 2 in Fig. XI, and the Vreeland gives the voltage wave form 3. This wave form 3 is seen to have a smaller amplitude every second cycle. The Vreeland gives a fine sine wave when run by the current from a good dynamo, especially if any small irregularity, such as that due to the dynamo brushes, is suppressed, and Fig. XII illustrates a study of their dynamo

by Professor Bennett and Dr. Gray. Line 1 is the voltage oscillogram of the Madison 60-cycle city current and is used for reference. Line 2 shows the harmonics in the voltage wave form from the dynamo, and the entire film shows that the harmonics are repeated every six cycles. It was obtained by passing 3.5 amperes through the primary circuit of a 5 : 1 transformer and taking the voltage oscillogram of the secondary circuit. As the oscillograph was set so that the zero of voltage was 12 feet away and the transformer magnified the harmonics 5 times it is seen that the variation of about 1 inch in the oscillogram corresponds to a change of about  $1/750$  in the voltage from this cause. These harmonics can be suppressed by the use of a proper set-up of inductances and capacities. Line 3 illustrates the improvement secured by using an inductance of 1 henry in series with the primary of a second transformer set-up duplicating in every respect the one described above. As lines 1, 2 and 3 were taken simultaneously it is seen that this inductance chokes out the harmonics so nearly completely that there is no doubt that the current from any dynamo could be purified by using inductance and capacity, and hence the inductance and capacity in the Vreeland automatically tend to purify the dynamo current. When 3.5 amperes from a storage battery were passed through the transformer a perfectly straight voltage line, not illustrated, was obtained. The advantage of using such a purified current from a dynamo over that from a storage battery is simply one of less expense and avoidance of the labor of attending to storage batteries. The voltage, however, is not very constant in even the best dynamo. But a storage battery gives the steadiest current and hence the best wave form from the Vreeland, illustrated in 3, Fig. X, and should be used when convenient. Although the usual Type B instrument is made to operate on direct currents of 110 down to 75 volts, an instrument like ours can be ordered to operate from 120 down to 50 volts and thus effect distinct economy when storage cells are used. (7) In order to regulate the frequency we use calibrated tuning forks of 100, 250, 500, 750, 1000, 1500, 2000 and 3000 vibrations, and by changing the capacity the frequency can be fixed by the "beat" method with an accuracy of 0.10% for the lower frequencies and much better for the higher ones. Having calibrated the Vreeland at several frequencies, it is a simple matter to calculate the capacity necessary for any frequency. As such a set of tuning forks is expensive we shall be glad to lend them to anyone. (8) It is thus seen that no other available instrument so nearly meets ideal conditions for alternating current work in physics and chemistry and no investigator who has once used the Vreeland oscillator will be content with anything less satisfactory. Fig. XIII gives the practically pure sine voltage and current wave forms,  $e$  and  $i$ , for 240 cycles from the Type B Vreeland, when the current is passed through a conductivity cell;

a small third harmonic is present and has been studied by H. P. Hastings.

At the suggestion of one of us, Leeds and Northrup arranged with Vreeland to develop a smaller and less expensive instrument giving 500 and 1000 cycles, which they are now selling. After we had tested the first of these and the development of our work had shown the desirability of certain modifications, especially a wider range of frequency, Vreeland consented to the sale of an instrument giving 500, 750, 1000 and 1500 cycles, which are ample for most work on the simple measurement of the conductivities of solutions. Fig. XIV gives the oscillogram of the wave form of the small Vreeland oscillator at 130 cycles. It should be emphasized that this Vreeland was built by Leeds and Northrup to give frequencies of 500 and 1000 and that we had to add extra capacity in order to get the lower frequency. Even under these extreme conditions the wave form for this lower frequency is still very good. The wave form for 500 cycles in Fig. XV is practically a pure sine wave and gives excellent results in conductivity work.

After making the above study on the best source of alternating current for this conductivity work practically all of our measurements have been made with the Type B Vreeland oscillator. The development of the best types of bridges, telephones, inductances, capacities, cells, baths, etc., and the applicability of various types of bridge set-ups in this work will be described in the succeeding articles. Especially will it be shown that the apparent resistance changes with frequency when bright electrodes are used but that by the proper methods and calculations the true electrical conductivity can be obtained.

MADISON, WIS.

## STUDIES IN THE MEASUREMENT OF THE ELECTRICAL CONDUCTIVITY OF SOLUTIONS AT DIFFERENT FREQUENCIES.

### VI. INVESTIGATIONS ON BRIDGE METHODS, RESISTANCES, CELLS, CAPACITIES, INDUCTANCES, PHASE RELATIONS, PRECISION OF MEASUREMENTS, AND A COMPARISON OF THE RESISTANCES OBTAINED BY THE USE OF INDUCTANCE AND CAPACITY BRIDGES.<sup>1</sup>

BY W. A. TAYLOR AND S. F. ACREE.

Received August 28, 1916.

During the last few years, chemists have made decided improvements in the Kohlrausch method of measuring the electrical conductivities of solutions.

<sup>1</sup> We are indebted to the Carnegie Institution of Washington for aid in this work.

A. A. Noyes<sup>1</sup> and his co-workers made great strides by using weighed solutions and fine bomb-cells, and their work probably has an accuracy of 0.10%.

Washburn<sup>2</sup> published the first fine article on a general improvement of the Kohlrausch method in which he described notable advances by the use of tuned telephones, pure resistances, better cells, a 1000 cycle current of sine wave form, better capacities for securing a minimum, and methods of grounding.

Chapman and Hibbard<sup>3</sup> have recently published an excellent bulletin in which they describe similar apparatus and especially the use of an alternating current galvanometer as a detector for the 60-cycle current obtained from a Holtzer-Cabot generator.

Hartley and Barrett<sup>4</sup> showed an apparent change of resistance with change in frequency, and Schlesinger<sup>5</sup> has described some noteworthy improvements.

The general methods here described had their origin in 1908-9 in the repeated observations that the resistance of solutions apparently changed with a change in the frequency of the current from the induction coil. As this source of error was seen to be a possible explanation of the discrepancies in the results obtained by different investigators using different frequencies and different cells it was decided to investigate as deeply as possible the frequency, resistance and capacity relations. Washburn and Chapman and Hibbard used 1000 and 60 cycles, respectively, and considered that the resistances observed are the true electrical resistances, but our work shows the necessity for measurements at different frequencies, if we are to understand clearly all the phenomena involved in the solution and at the electrodes, and to measure the true electrical conductivities. By deliberately magnifying the different sources of error we have been able to understand them and develop methods for their elimination.

In this study we have been greatly aided by Dr. H. L. Curtis of the National Bureau of Standards, and especially by Prof. Edward Bennett, of the University of Wisconsin, and by other colleagues who have made many important suggestions on the interpretation of our results and on the methods, which are well known to electrical engineers and physicists, but not to chemists in general. Most of the data here reported were worked out by Taylor in Washington with the excellent equipment kindly placed at our disposal by the Bureau of Standards.

In this research the writers have tried (1) to solve the ordinary mechan-

ical and electrical difficulties connected with the measurement of the conductivity of electrolytes, (2) to make a fundamental study of the *electrode phenomena* and their bearing on the resistance and capacity of a solution in a conductivity cell at different frequencies and voltages, and (3) to eliminate the importance of these electrode phenomena as far as possible so as to make the *apparent* resistance of a solution in a cell as nearly as possible only the *true electrical resistance* of the solution.

**Source of Current.**—The first requisite for securing a bridge balance when resistances, inductances, and capacities are measured, is a source of alternating current which has a pure sine wave form of any desired voltage, and of constant frequency, which frequency may be varied at will through a wide range. This is necessary to prevent unsymmetrical polarization at the electrodes and to annul the influence of harmonics on the telephone, and to enable us to study the effects of changes in voltage and frequency on the resistances of solutions in the cells. After testing the ordinary "buzzer," the Holtzer-Cabot and General Electric generators and the 60-cycle current of Madison, we have found that the Type A or B Vreeland oscillator sold by the Western Electric Company best suited our requirements for many reasons previously published. We are making measurements at 250 to 3000 cycles per second. Arrangements have now been made with Dr. Vreeland, however, for Leeds and Northrup to sell a small instrument for use at 500, 750, 1000 and 1500 cycles, which are sufficient for most work. We use calibrated tuning forks and the beat method to secure the correct frequency.

**Resistances.**—In order to make measurements with a precision or accuracy of 0.001% with alternating currents, the resistances must be so made as to be free from errors from inductance and capacity at all frequencies used. Curtis<sup>1</sup> has shown that average American and German resistances of 1000 ohms and over, including our own Chapeyron coils, may have errors greater than 0.05% arising from inductance and capacity effects, and has devised coils which are practically free from these defects. These coils have been used in our work. These have been used recently by Washburn and by Chapman and Hibbard. Washburn formerly used platinum strips on glass rods devised by physicists and we are indebted to Professor H. Pfundt for the use of one of his type of platinum film on glass plates. It seems to the writers that the great objection to platinum films on glass or quartz is the high temperature coefficient, the fragility, and the inconvenience in mounting or inclosing them.

**Telephones.**—We have used telephones made by the Western Electric Company which are very sensitive and which can be tuned to the particular frequency of the alternating current employed, in order to get the

<sup>1</sup> Curtis and Grover, *Bull. Bur. Standards*, Vol. 8, No. 3 (1911).

greatest accuracy in bridge settings. The attachment of a stethoscope to the telephone, suggested by Curtis, has been a very great aid. We have also used an alternating current galvanometer at low frequencies.

**Bridge.**—Two well-known types of the Wheatstone bridge were recommended to us by Leeds and Northrup, Curtis, and Bennett, and Mr. H. P. Hastings has begun the use of several others. We have employed throughout the work the substitution method used regularly in the Bureau of Standards and suggested to us by Dr. Curtis, and have compared it with others. The arrangement of the bridges is shown in Figs. I and II, and

Fig. I.

the substitution method used is explained below.  $R_1$  and  $R_2$  are Curtis ratio coils of 100, 500, or 1000 ohms each,  $C$  the cell,  $T$  the telephone,  $S$  the variable resistance in the bridge,  $L$  a variable standard inductance,  $L_1$  a fixed inductance greater than the smallest value of  $L$ ,  $K$  a standard variable condenser,  $K_1$  a variable or fixed condenser with a capacity larger than the lowest value of  $K$  if the bridge cannot be balanced by  $K$ , and  $R$  a set of fine variable Curtis resistances with a range from 10,000 to 0.001 ohm. In making a reading with the bridge shown in Fig. I,  $R$  is set on zero, and, with the cell in circuit,  $S$  and  $L$  are varied until there is no sound in the telephone. The cell is then removed and the bridge again balanced by varying  $L$  and  $R$ . The reading of  $R$  is then the sum of the "apparent" resistances of the cell and of the cell leads and electrodes, whose resistances are known, and the difference between the two inductance readings gives the inductance corresponding to the cell "capacity." It is then necessary simply to regulate the temperature of  $R$  and by this method we eliminate any error due to changes in the other resistances, or in the inductances, arising from changes in room temperature. With good temperature regulation measurements on a cell can be duplicated to one part in 100,000. In making a reading with the bridge shown in Fig. II a similar procedure should be employed, *i. e.*, the bridge is first balanced with the cell and the

the substitution method used is explained below.  $R_1$  and  $R_2$  are Curtis ratio coils of 100, 500, or 1000 ohms each,  $C$  the cell,  $T$  the telephone,  $S$  the variable resistance in the bridge,  $L$  a variable standard inductance,  $L_1$  a fixed inductance greater than the smallest value of  $L$ ,  $K$  a standard variable condenser,  $K_1$  a variable or fixed condenser with a capacity larger than the lowest value of  $K$  if the bridge cannot be balanced by  $K$ , and  $R$  a set of fine variable Curtis resistances with a range from 10,000 to 0.001 ohm. In making a reading with the bridge shown in Fig. I,  $R$  is set on zero, and, with the cell in circuit,  $S$  and  $L$  are varied until there is no sound in the telephone. The cell is then removed and the bridge again balanced by varying

condensers  $K$  and  $K_1$  in circuit. Then the cell is removed and the bridge again balanced by changing  $R$  and  $K$ . The resistance and capacity of the cell are then obtained as above.

The method of grounding the bridge was developed by Curtis and Taylor and other methods and improvements will be described later by Mr. H. P. Hastings.

This bridge set-up in Fig. II, with the exception of the substitution method and the grounding, is the one devised by Kohlrausch and improved with great success first by Washburn and Bell<sup>1</sup> and later by Hibbard and Chapman. These workers, however, did not use Curtis ratio coils but employed the circular Kohlrausch slide wire bridge. It will be shown in a subsequent article that even a mechanically perfect circular Kohlrausch slide wire bridge must be used with very great caution as errors as large as 1% can arise in some bridge set-ups because of the self-induction in the circular slide wire and the capacity between the metal cover and the slide wire.

We have now devised and used extensively a special bridge containing Curtis ratio and dial coils and inclosed Curtis alternating current standards similar to the National Bureau of Standards' fixed resistances for direct currents. These are all immersed in oil at constant temperature and the resistances can be relied upon very accurately. They are furthermore calibrated by direct current against a set of four National Bureau of Standards resistances of the inclosed type. This apparatus was built for us by Leeds and Northrup and it will be described and the measurements reported in the near future in other articles.

**Capacities.**—Our condensers consist of (1) a Western Electric Company box of standard mica units from 0.001 to 1.1 microfarads and paper units up to 41.1 microfarads and (2) a Leeds and Northrup variable air condenser, giving from  $25 \times 10^{-6}$  to  $1500 \times 10^{-6}$  microfarads. We have

<sup>1</sup> THIS JOURNAL, 35, 197 (1913) and Catalog No. 48 of Leeds and Northrup (1915).

Fig. II.

also three other variable air condensers of low range. These standards have either been calibrated by the Bureau of Standards or checked by us against our standards. These measurements were, of course, made at the different frequencies used by us.

Fig. III.

**Inductances.**—Our fixed inductances are wound in a single layer on mahogany spools, as we have found that multiple layers produce changes in resistance and inductance when the frequency is changed. Stranded and braided enameled silk covered wire should be used at high frequencies to prevent errors from "skin effects." Our variable inductances are improved forms of the Ayrton and Perry types on mahogany frames worked out in cooperation with Professor Edward Bennett and are so devised as to be practically free from changes in resistance and inductance arising from changes in frequency. They are arranged with verniers and mechanical devices which allow us to obtain quickly and accurately values from  $10^{-3}$  millihenries upward. They will be

described in detail in separate articles.

**Phase Relations.**—The resistance of a solution in a conductivity cell is made up of the *true resistance* of the solution and certain phenomena which we shall call *electrode effects*. A cell behaves toward an alternating current as if it were made up of a resistance in series with a condenser with a small leak, and it offers an impedance to the harmonically varying current, changes the phase in that bridge arm, and gives an unbalance in the telephone. It is, therefore, impossible to obtain a perfectly sharp minimum in the telephone unless the capacity is accurately balanced by one of the several well-known methods, such as (1) a capacity in parallel with the resistance arm of the bridge, as recommended by Kohlrausch, (2) a capacity in series with the resistance arm of the bridge, (3) an in-

ductance in series with the cell (in R, Fig. I), or (4) an inductance in the opposite side of the bridge (in R<sub>2</sub>, Fig. I). We have used all of these methods and have compared them with others and our results will be given in a later report.

Mr. H. P. Hastings has observed the very interesting and fundamentally important phenomenon that in cells with small bright electrodes a disturbing third harmonic accompanies the low fundamental note from the Vreeland oscillator at low frequencies, and this has also been observed in oscillograph measurements by Dr. G. H. Gray. This harmonic can, of course, be balanced out by an inductance or capacity, and its frequency can be thus calculated. We have devised methods for balancing out the fundamental notes, and the harmonics simultaneously, in order to study the electrode phenomena more carefully. A Vreeland oscillator giving simultaneously two or more frequencies of any desired values is greatly to be desired.

**Cells.**—Our cells are dumb-bell types which we have developed since 1908 and are shown in Figs. III and IV. They are made by Otto Haak, 545 N. 5th Street, Philadelphia. The advantages of these cells are the following: (1) The ground glass joints are not exposed but are under the

Fig. IV.

liquid of the bath and hence prevent evaporation of the solvent and consequent changes of concentration. (2) The electrodes are supported in four places so that they cannot change position and thus change the cell constant. They can be made of Jena 16<sup>III</sup> or 297<sup>III</sup> glass or of quartz. Our criterion of excellent cells is that *whatever the solutions used the ratios of the resistances of any solution in two such cells, or of two solutions in any*

cell, must be constant to within 0.01% at infinite frequency. Only in this way can we be certain that the electrode effects have been practically eliminated and that we are measuring the *true electrical resistance* of the solution with great accuracy. This we have now succeeded in attaining.

**Solutions.**—The solutions should be made up and analyzed by weight methods in resistance glass or quartz containers and transferred by means of apparatus which will be described in a later report, *under the water* of the constant temperature bath into *clean cells* containing air in which the vapor pressure is that of the solution to be measured. In the present work the solutions were not made up with any great degree of accuracy as we were concerned first with developing accurate *methods* for making conductivity measurements and this problem could be solved as well by relative as by absolute measurements of conductivity.

**Precision of Resistance Measurements on Solutions.**—Using the apparatus described and the method outlined above it will be seen from the TABLE I.—DATA SHOWING PRECISION OF RESISTANCE READINGS ON A GIVEN SOLUTION IN A GIVEN CELL.

data given in Table I that readings on a given cell with a given solution can be repeated easily with an average deviation within  $\pm 0.001\%$ .

**Checks on the Resistance of Different Parts of the Same Solution in the Same Cell.**—Resistance measurements were then made on different parts of the same solution in the same cell to see how closely these measurements would check. The following table shows that the maximum variation is about  $0.01\%$ . Each measurement given is the average of a large number of readings for the same portion of the solution. Considering the fact that the electrodes in most of the older cells made in 1908 were not absolutely rigid, that the solutions were poured into the cells, etc., these values check remarkably well.

**Constancy of Resistances of Solutions in Cells Over Short and Long Time Periods.**—Dr. G. H. Gray's oscillograph measurements at 60 and 240 cycles and our conductivity data show that after two cycles the current does not cause an appreciable change in the resistance and capacity of the cell during short time periods such as ten minutes. It seemed desirable in the practical use of the conductivity method to see whether measurable changes occur in longer time intervals. Table III illustrates

some of our characteristic data, each measurement given being the average of a number of readings. These data show that in cells with platinized electrodes the resistances of the solutions do not change appreciably on standing in the cells for 24 hours. On the other hand in cells with bright platinum electrodes there is an increase in the resistance and the change seems to be larger when the resistance is measured at 600 cycles than when measured at 1000 cycles.

**A Comparison of the Resistances Obtained at 600 and 1000 Cycles by the Use of Inductance and Capacity to Balance the Capacity of the Cell.**—As was mentioned above, in order to obtain a perfectly sharp minimum in the telephone, the capacity in the cell must be accurately balanced by some method such as by another capacity in parallel with the resistance arm of the bridge, or by an inductance in series with the cell. Some measurements were made on resistances of solutions in different cells at 600 and 1000 cycles by using both methods of balance to see how closely the two would check. The data are shown in Table IV.

In order to use the substitution method with a condenser in parallel with the resistance arm,  $R_4$ , as in Fig. II, a balance was first made with the cell inserted, the cell was then removed and the substitution resistance,  $R_3$ , balanced against the resistances of the bridge. When this method is used a correction must be made on the substitution resistance according to the following equation worked out for us by Professor Edward Bennett:  $R_3/R_4 = R_1/R_2 - K/C$ , in which  $R_1$  and  $R_2$  are the values of the ratio coils,  $R_3$  the value of the substitution resistance,  $K$  the capacity in parallel with the resistance  $R_4$  which is necessary to balance the capacity of the cell, and  $C$  is the capacity of the cell calculated from the inductance, or by other methods which will be described later. When this correction is made for the three cases given in Table IV the values for the apparent resistances obtained by the use of an inductance and those obtained by the use of a condenser check extremely well. The largest variation is 0.004%, and in this case the data are not very satisfactory, but all of the remaining values check to within about 0.001%, which is not more than the experimental error.

The first part of the table gives the data for 0.2 *N* NaCl in Cell IX with roughened electrodes 2 inches in diameter. The readings were taken in the following order: First, Group 1, then Groups 2, 3, 4, etc. At both 600 and 1000 cycles the uncorrected resistance measured with the condenser is only about 0.002% higher than the one measured with the inductance, and the corrected resistances do not vary more than 0.001%. The second part of the table gives duplicate measurements, (a) and (b), of the data for 0.05 *N* NaCl in Cell I with 1-inch bright electrodes. Measurements were made in this case only at 1000 cycles. Here the uncorrected resistance measured with the condenser is about 0.013% higher than that measured

with the inductance, but the corrected resistances differ only 0.001%. The third part of the table gives the data on 0.025 *N* NaCl in Cell I at 600 and 1000 cycles. In this case there is practically no difference in the uncorrected readings with the condenser and inductance at 1000 but at 600 cycles the uncorrected resistance measured with the condenser is about 0.01% higher than that measured with the inductance. The corrected resistances, however, differ only 0.002% at 600 and 0.004% at 1000 cycles.

It will be seen from the data with both the condenser and the inductance that the apparent resistance decreases when the frequency is raised from 600 to 1000 cycles, which is in conformity with all of our other results. The changes in resistance obtained by using the 2-inch roughened electrodes with inductances or condensers were practically only 0.025%, whether corrected or not, because of the large capacity of these large electrodes. The 1-inch bright electrodes, with much smaller surfaces and capacities, however, showed a change of resistance of 0.0925% when the inductance method was used and 0.095% when we employed the corrected data from the condenser method. If the data are not corrected, however, this difference of 0.0025% experimental error becomes four times that large, namely, 0.010%. All of the above facts, then, show that both the inductance and the condenser methods give practically the same results when the proper corrections are made.

### Conclusions.

(1) We have found that the Vreeland oscillator is the best and most convenient source of alternating current tried for conductivity work because (1) it is practically noiseless and can be started and stopped conveniently; (2) it gives practically a pure sine wave form; (3) it gives a constant frequency independent of the variation in the actuating direct current; and (4) this frequency can be changed easily to anything desired in our work.

(2) Curtis coils on porcelain spools should be used for all resistances above 10 ohms to prevent errors due to inductance and capacity effects.

(3) For greatest accuracy in balancing the bridge one should use a telephone which can be tuned to any desired frequency, and can be attached to a stethoscope, as suggested by Curtis.

(4) A substitution method suggested by Curtis for measuring resistances is advantageous as, by simply regulating the temperature of *R* in Fig. I, it prevents errors due to any changes in the resistances of the bridge

coils, or in the inductance, caused by variations in temperature, and allows the experimenter to read the resistances directly instead of having to make involved calculations.

(5) The bath, if made of metal, and also the bridge, should be grounded to prevent errors from capacity effects.

(6) In order to prevent changes in the resistance of the solutions during measurements the cells should be made (1) with the ground glass joints below the surface of the liquid of the bath to prevent evaporation of the solvent in the cell, (2) with the electrodes well supported by several glass arms and platinum posts to prevent changes in position of the electrodes, and (3) with the leads to the electrodes sealed off at the end in the glass tubes to allow the experimenter to keep these ends clean and to prevent changes in the resistance of the leads.

(7) Solutions should be made up and analyzed by weight methods in clean, resistance glass or quartz containers and transferred *under* the water of the bath into clean cells.

(8) Resistance measurements on a given solution in a given cell can be duplicated to within 0.001%.

(9) Resistance measurements on different parts of the same solution in the same cell, even when no special precautions were taken in filling the cell, checked to within 0.01%.

(10) The resistances of aqueous solutions in cells with platinized electrodes did not change appreciably on standing in the cells 24 hours. Cells with bright electrodes showed changes in resistance from 0.05 to 0.14% in 24 hours.

(11) A comparison of the resistances obtained by the use of (1) an inductance and (2) a condenser to balance the capacity of a cell shows that the values of the resistances obtained by the two methods are practically the same, the variation being only  $\pm 0.001\%$ .

## STUDIES IN THE MEASUREMENT OF THE ELECTRICAL CONDUCTIVITY OF SOLUTIONS AT DIFFERENT FREQUENCIES.

### VII. INVESTIGATIONS ON THE TRUE AND APPARENT RESISTANCES, VOLTAGE, APPARENT CAPACITY, SIZE AND CHARACTER OF ELECTRODES, RATIO OF INDUCTANCE CHANGES TO RESISTANCE CHANGES, AND THE RELATION OF INDUCTION AND CAPACITY TO FREQUENCY.<sup>1</sup>

BY W. A. TAYLOR AND S. F. ACREG.

Received August 28, 1916.

In the preceding papers we have shown that the resistances of solutions of electrolytes can be measured with a precision of 0.001% and an

<sup>1</sup> We are indebted to the Carnegie Institution of Washington for aid in this work.

accuracy of 0.01% by the use of (1) Curtis resistances free from capacity and inductance; (2) a Vreeland oscillator giving a pure sine wave of uniform frequency which can be varied widely; (3) proper grounding and shielding of the electrical apparatus and the bath; (4) a telephone which can be tuned to any desired frequency; (5) cells whose electrodes are fixed and whose ground joints are immersed to prevent evaporation; and (6) the use of different bridge methods which give the same true electrical conductivities of the solutions.

In the present article<sup>1</sup> we will discuss chiefly (1) the relation of the resistances of solutions of electrolytes to the voltage, the frequency of the alternating current, and the area of the electrode surface; (2) the relation between the area of the electrode surface and the magnitude of the apparent "capacity" of the cell; (3) the relation between the electrolytes, electrode material, size and character of electrode surface, and change of inductance and resistance with change in frequency; (4) the measurement of the true electrical conductivity of solutions; (5) the explanation of the apparent "capacity" of the cell; (6) the relation between the inductances necessary to valence the capacity of the cell at different frequencies; and (7) the ratio of the change in resistance to the change in inductance produced by a change in frequency.

### Effect of Change of Voltage on the Apparent Resistance of Solutions of Electrolytes.

The first point to be investigated was the influence of change in voltage on the resistances of solutions in different cells. The bridge was first tested to see whether the resistances changed with change in voltage. It was found that a given resistance in the bridge did not vary as much as 0.001%, with change in voltage from one-eighth to 10 volts. Experiments along this line were carried out with the bridge coils alone, and also with inductances in two adjacent arms of the bridge.

We then took up the study of various solutions and in Table I are given the resistances of different solutions in several cells at a number of voltages. Each measurement given is the average of a number of readings. The range of voltage was from  $\frac{1}{4}$  to 2 v., at which the polarization voltage 1.23 is not reached at the electrodes. Above 4 volts there was in most cases such an appreciable heating effect that it was difficult to make accurate measurements. From an inspection of the data in Table I it is seen that the variation in the resistance is not more than  $\pm 0.001\%$ . This is true only when the cells, solutions and containers are kept scrupulously clean, as the slightest trace of grease or dirt causes a measurable

<sup>1</sup> Part of this work was done by Dr. Taylor at the Bureau of Standards, and we are indebted to Dr. J. L. Curtis for many valuable suggestions. We desire to express our thanks especially to Professor Edward Bennett of the the University of Wisconsin for the coöperation which will appear in joint articles later.

variation in the resistance with change in voltage. Since with unclean cells we have found variations in resistance as large as 0.08% when the voltage is changed from  $\frac{1}{4}$  to 2 v. constancy of resistance and inductance with change in voltage can be used as a very reliable test for cleanliness of cells and containers for the solutions.

TABLE I.—VALUES FOR THE RESISTANCES AND INDUCTANCES OF DIFFERENT SOLUTIONS IN VARIOUS CELLS, MEASURED AT DIFFERENT VOLTAGES.

			Res. $\frac{1}{4}$ v.	Ind. in $\mu$ h.	Res. $\frac{1}{2}$ v.	Ind. in $\mu$ h.	Res. 1 v.	Ind. in $\mu$ h.	Res. 2 v.	Ind. in $\mu$ h.

	0.2	N NaCl..			84.260	380	84.259	380		
Cell V,	0.2	N NaCl..	89.143	40	89.143	40	89.143	40	89.143	40

These data also show that there is no change in the inductance necessary to balance the cell capacity and, therefore, no change in the capacity of the cell with this change in voltage. This would most probably not be true if we did not have a perfectly reversible system, for otherwise more ions would be discharged at one electrode than at the other during a given complete oscillation, and we would, therefore, expect the inductance to change. But even in perfectly reversible systems the constancy of resistance and of capacity, or inductance, with change in voltage below the polarization voltage 1.23 is one of the most important factors which must be considered in interpreting the "electrode phenomena." With a higher voltage at each pulse there is a greater number of electrons discharged, a greater change of concentration at the electrodes, the deposition of more gas ions on the electrodes, and a greater reverse contact potential, and Dr. G. H. Gray has now been able to show by oscillograph measurements that the resistance and capacity do not change with varying electrode potentials below the polarization voltage 1.23, but do change continuously above this point. Experiments to cover all phases of this problem are in progress.

#### Effect of Change of Frequency on the Apparent Resistance of Solutions of Electrolytes.

A study of the effect of change of frequency on the apparent resistance of electrolytes was next taken up. Acree and Robertson had noticed in their work that a change in the buzzer note caused a change in the apparent resistances of solutions in cells with bright electrodes. This point has doubtless been observed by many others and has recently been con-

firmed in conversations with Professor Mathews of the Department of Physical Chemistry in the University of Wisconsin, Dr. E. P. Wightman, and others. This naturally suggested the study of this phase of the problem, which, as far as we know, had never been investigated before 1909. and which is the most important phase of conductivity work.

We have studied solutions of different kinds and concentrations of electrolytes in cells differing in construction, size, and character of electrodes, etc. The frequencies used have been chiefly 600 cycles and 1000 cycles, although 60, 500, 2000 and 3000 were used in a few cases, and Mr. H. P. Hastings has now employed 60, 250, 500, 750, 1000, 1500, 2000 and 3000. In Table

II is given a summary of the values for the resistances of many different solutions in the same cells at 600 and 1000 cycles, and the difference between these two values in per cent. Each resistance given is the average of a number of readings. At the end of the table we have given the resistance and inductance measurements on 0.1 *N* NaCl in Cell IV at frequencies varying from 250 to 3000 cycles. These last measurements were made by Mr. H. P. Hastings.

From an inspection of these data it is seen that there is only a very small change in resistance with change in frequency from 600 cycles to 1000 cycles in the cells with *platinized* electrodes. With these cells it is also possible to get a balance with an accuracy of  $\pm 0.01\%$  without the use of either an inductance or condenser.

In the case of the cells with bright platinum electrodes, which must be used in some cases to prevent the decompositions caused by spongy platinum, there is a decrease in resistance with increase in frequency. This fact is shown particularly well by Mr. Hasting's data at the end of Table II. In this case the change in resistance with change in frequency from 250 to 3000 cycles is about 3.2%.

It is evident from the data that as the concentration of any given solution is decreased, and consequently the resistance is increased, in a given cell with bright electrodes, the change in resistance with change in frequency decreases. It, therefore, follows that the resistance should be made as high as possible and the voltage raised to get a good minimum, since the change in voltage used causes no change in the inductance or resistance. To accomplish this end, the solutions used in a given cell should be as dilute as possible and the electrodes should be at least 1 inch in diameter and 2 inches is preferable. If the resistance is above 10,000 ohms the errors will generally be less than 0.01% when the resistance at 1000 cycles is assumed to be the true resistance. In order to measure concentrated solutions, cells with constructions between the electrodes<sup>1</sup> should be used in order to make the resistance high.

It was also found that as the size of the electrode surface is increased the change in resistance with change in frequency decreases. This is best seen from Table III below, in which each measurement given is the average of a number of readings. We have selected cells and solutions giving as nearly as possible the same resistance so that the values may be comparable.

Table III also shows that as the surface of the electrodes is increased, the inductance necessary to obtain a balance decreases and hence the apparent "capacity" of the cell, acting as a condenser, increases. It is also seen that the higher the apparent capacity the lower the inductance

<sup>1</sup> Ref. to preceding article.

TABLE III.—MEASUREMENTS OF RESISTANCES AND INDUCTANCES ON SOLUTIONS HAVING ABOUT THE SAME RESISTANCES IN CELLS VARYING IN AREA OF ELECTRODE SURFACE.

	Res. at 1000 cycles.*	Ind. in $\mu h$ at 1000 cycles.	Res. at 600 cycles.	Ind. in $\mu h$ at 600 cycles.	Diff. in res. at 600 cycles and 1000 cycles in per cent.
Cell IV, $\frac{1}{2}$ " bright electrodes, 0.1 <i>N</i> NaCl...	277.703	2229	279.785	5849	0.744
Cell II, 1" bright electrodes, 0.05 <i>N</i> NaCl...	310.202	425	310.544	1295	0.110
Cell X, 2" bright electrodes, 2 <i>N</i> NaCl.....	421.200	134	421.489	326	0.068
Cell IX, 2" roughened electrodes, 0.2 <i>N</i> NaCl	282.092	115	282.162	310	0.025
Cell V, $\frac{1}{2}$ " platinized electrodes, 0.05 <i>N</i> NaCl	329.769	25	329.770	85	0.000
Cell III, 1" platinized electrodes, 0.05 <i>N</i> NaCl	290.269	0	290.2697	0	0.000

and hence the smaller the change in resistance with change in frequency. It is, therefore, evident that the electrical "capacity" of the cell should be made as large as possible. This may be done by increasing the surface area of the electrodes. It follows naturally that platinizing the electrodes best accomplishes this end. Spongy platinum may also increase the rapidity of the reversible ionization of molecular gas. We have found that solutions of different salts having about the same resistance in the same cell with platinum electrodes give approximately the same change in resistance with change in frequency from 600 cycles to 1000 cycles. This is shown in Table IV, in which each measurement given is the average of a number of readings.

TABLE IV.—RESISTANCE MEASUREMENTS ON SOLUTIONS OF DIFFERENT ELECTROLYTES HAVING APPROXIMATELY THE SAME RESISTANCES IN THE SAME CELLS.

	Res. at 1000 cycles.	Res. at 600 cycles.	Dif. in res. in per cent.
Cell II, 0.1 <i>N</i> NaCl....	164.024	164.404	0.23
0.03 <i>N</i> HCl....	149.036	149.378	0.23
0.1 <i>N</i> KCl....	146.003	146.360	0.24
Cell I, 0.2 <i>N</i> NaCl....	53.103	53.329	0.42
0.1 <i>N</i> HCl....	58.270	58.531	0.45

While this is true for platinum electrodes it is also apparent that there is a specific relation between the electrolytes, the electrode material, the character of the electrode surface, and the change of capacity and resistance with change in frequency. The above fact is shown in such data as the following in Table V. For this work the electrodes of one cell were plated electrolytically with silver. The oscillograph will also be used in these cases in the study of valve action and passivity.

TABLE V.—DATA SHOWING RELATION BETWEEN ELECTROLYTES, ELECTRODE MATERIAL, CHARACTER OF ELECTRODE SURFACE, AND CHANGE OF CAPACITY AND RESISTANCE WITH CHANGE IN FREQUENCY.

Character of electrode.	Solution.	Ind. in $\mu h$ .	Change in res. with change in frequency from 600 cycles to 1000 cycles.
1" bright platinum.....	0.1 <i>N</i> AgNO <sub>3</sub>	155	0.12%
1" rough, silver plated..	0.1 <i>N</i> AgNO <sub>3</sub>	25	0.012%
1" rough, silver plated...	0.1 <i>N</i> NaCl	95	0.052%

It is seen also that we have here the same relation between the inductance and the change in resistance with change in frequency as was noted above; that is, the lower the inductance and, therefore, the higher the capacity of the cell, the smaller the change in resistance with change in frequency.

**The Measurement of the True Electrical Conductivity of Solutions.**—In order to make accurate conductivity measurements, the cells and methods must be so perfected that the ratio of the resistances for any given solution in two cells, or of two solutions in any cell, must be constant to within 0.01%. This will not be the case unless we can eliminate electrode effects. We, therefore, compared two cells with platinized electrodes, in both of which the electrode effects have been shown to be zero or very small. Cell III has electrodes 1 inch in diameter and Cell V electrodes one-half inch in diameter. 0.2 *N*, 0.1 *N* and 0.05 *N* solutions of NaCl were measured in both cells and the ratios of the resistances calculated. The ratios are given in Table VI below, in which each measurement given is the average of a number of readings.

TABLE VI.—RATIOS OF THE RESISTANCES OF 0.2 *N*, 0.1 *N* AND 0.05 *N* NaCl MEASURED AT 1000 FREQUENCY IN TWO CELLS WITH PLATINIZED ELECTRODES.

	Res. of 0.2 <i>N</i> NaCl	Ratio of res.	Res. of 0.1 <i>N</i> NaCl	Ratio of res.	Res. of 0.05 <i>N</i> NaCl	Ratio of res.
Cell III.....	78.482		149.922		290.269	
Cell V.....	89.156	1.1360	170.285	1.1358	329.770	1.1361

The deviation in the ratio of resistances is only  $\pm 0.013\%$ , which is not much more than the experimental errors. We can, therefore, conclude that one inch *platinized* electrodes give nearly the true electrical resistance of these solutions when the resistance is above 100 ohms.

As it was found that the change in resistance with change in frequency of any solution in a cell with *bright* platinum electrodes becomes smaller and smaller as the frequency increases, we attempted to eliminate the "electrode effects," or polarization, and thus obtain the *true electrical resistance* of the solution, by extrapolating the resistances to infinite frequency. In order to do this measurements were made at three different frequencies, 600, 1000 and 2000 cycles, with two cells, both of which had electrodes 1 inch in diameter. The electrodes in Cell II were bright and in Cell III were platinized. 0.1 *N* and 0.05 *N* solutions of NaCl were used in each cell. We then plotted the results as curves<sup>1</sup> by using the resistances at different frequencies as ordinates and the reciprocal of the frequencies as abscissas. The points where these curves cut the X axis give approximately the values for the resistances at infinite frequency. The data used in plotting the curves are given in Table VII.

<sup>1</sup> The first calculations were made by Taylor and Curtis in *Physical Review*, 6, 61, following the suggestion by one of us.

TABLE VII.—RATIOS OF THE RESISTANCES OF 0.1 N AND 0.05 N NaCl MEASURED AT 60 CYCLES, 600 CYCLES, 1000 CYCLES, AND 2000 CYCLES IN TWO CELLS, ONE OF WHICH HAS BRIGHT AND THE OTHER PLATINIZED ELECTRODES 1 INCH IN DIAMETER, AND THE EXTRAPOLATION OF THESE RESISTANCES TO INFINITE FREQUENCY.

0.05 N NaCl.	319.3 <sup>1</sup>	1.7396	313.491	1.90979	313.158	1.91132	312.895	1.91279	312.665	1.91390
Difference in ratios in $\frac{1}{C_1}$		1.60		0.21		0.13		0.05		0.004

<sup>1</sup> These solutions are different from those used in the remaining measurements and as neither set of solutions was made up at all accurately the resistance measurements for the two sets do not check; nevertheless, these solutions serve well for purposes of comparison of the difference between the ratios for bright and platinized electrodes.

TABLE VIII.—DATA SHOWING  $R_{\infty}$  CALCULATED BY MEANS OF THE EQUATION  $R_{\infty} = R_f - KLf$  AND THE DIFFERENCE BETWEEN THIS VALUE AND THAT OF  $R_{\infty}$  OBTAINED BY EXTRAPOLATING THE RESISTANCE TO INFINITE FREQUENCY.

	$R_{\infty}$ found by extrapolation.	Res. at 500.	Ind. at 500 in mh.	$R'_{\infty}$ calc.	% dif. in $R_{\infty}$ and $R'_{\infty}$ .	Res. at 1000.	Ind. at 1000 in mh.	$R'_{\infty}$ calc.	% dif. in $R_{\infty}$ and $R'_{\infty}$ .
Cell 1 <sub>2</sub> , bright Pt elec., 0.2 N NaCl	147.45	150.98	3.76	147.56	+0.07	149.20	0.99	147.30	-0.10
Cell 1 <sub>2</sub> , bright Pt elec., 0.1 N NaCl	164.30	165.42	1.09	164.42	+0.07	164.90	0.28	164.39	+0.05
Cell 2 <sup>1</sup> , etched Pt elec., 0.1 N NaCl	455.42	455.74	0.38	455.40	-0.004	455.61	0.13	455.37	-0.01
Cell 1 <sup>1</sup> , etched gold elec., 0.2 N NaCl	101.58	102.39	0.84	101.62	+0.04	102.02	0.22	101.62	+0.04

It is seen that the ratios of the resistances of these solutions in the two cells varied 1.62% at 60 cycles, 0.21% at 600, 0.13% at 1000 and 0.05% at 2000. As the resistances in cells with platinized electrodes do not change with change in frequency from 600 to 2000 cycles the resistance at infinite frequency would in all probability be the same as at the lower frequencies. By comparing the ratios for the two cells at infinite frequency the difference is only 0.004%, which is not more than the errors involved in the experiments and the extrapolation. We must, therefore, conclude that cells with bright platinum electrodes give approximately the true electrical conductivity of solutions only at high frequencies approaching infinity.

In order to eliminate the necessity of making resistance measurements at several different frequencies and extrapolating the resistance to infinite frequency to obtain the true electrical resistance of solutions of electrolytes, we have been able to derive an equation by which the resistance at infinite frequency can be calculated approximately from the resistance and inductance measurements at any given frequency. Professor Bennett has developed the full equations for expressing the changes in the apparent resistance and capacity of a system behaving like a cell, namely, a resistance in series with a "leaky" condenser. In his equations the value of  $n$  in the function ( $f^n$ ) varies with frequency and our value ( $f^1$ ) seems to hold approximately for our frequencies from 250 to 3000.

By using the equation  $(R_f - R_\infty)/L_f f = K$ , when  $R_f$  and  $L_f$  are the resistance and inductance (millihenries) measurements, respectively, at any given frequency,  $f$ ,  $R_\infty$  the resistance at infinite frequency, and  $K$  a constant, we have calculated the value of  $K$  and found it to be about 0.00182. In order to obtain this constant we have used several different solutions in various cells. Cells with bright and etched platinum, and etched gold and silver electrodes were used, as with these we obtain the largest values for  $L_f$  and  $R_f - R_\infty$  and thus minimize the errors.

By using this value for  $K$  and substituting the values for  $R_f$ ,  $L_f$ , and  $f$  at 250, 500, 750, 1000, 1500 and 2000 cycles, in the equation  $R_\infty = R_f - KL_f f$  we then calculated the resistance at infinite frequency,  $R_\infty$ , for several different solutions in different cells, many of which were not used in obtaining the constant  $K$ . A few of the data for frequencies of 500 and 1000 are given in Table VIII in this article. The values for  $R'_\infty$  calculated by using the equation differ by only 0.01 to 0.10%, from those for  $R_\infty$  obtained by extrapolation even though  $R_f$  differs from  $R_\infty$  as much as 2.4% in some cases. The average of the values for  $R'_\infty$  by using ALL of the above frequencies for any given cell and solution varied only from  $\pm 0.01$  to  $\pm 0.025\%$  from those obtained for  $R_\infty$  by extrapolating the resistance to infinite frequency and will be reported in detail in another article on the development of these equations. This gives us a

method for determining approximately the true electrical resistance of the solution by measuring the "apparent" resistance and the inductance (or capacity) at any one frequency. The apparent resistance at 1000 cycles will be within 0.01% of the true resistance if the solution used in the given cell is so dilute that the inductance in henries is less than  $0.5 \times 10^{-4}$  times the resistance. It is thus a simple matter to tell approximately how dilute the solution must be in a given cell to give the true resistance within 0.01% at 1000 cycles.

Another way to get the true resistance within 0.01% at 1000 (1500) cycles is to make use of the fact discussed above that the difference between the apparent resistances at 500 and 1000 cycles, or at 750 and 1500 cycles, is exactly the difference between the true resistance and the apparent resistance at 1000 (1500) cycles. For a given cell, therefore, we measure once for all what resistance is needed to make  $R_{500} - R_{1000}$  or  $R_{750} - R_{1500}$  less than 0.01% of  $R_{1000}$  or  $R_{1500}$  and always employ solutions giving about that resistance or more. This procedure avoids the use of standard inductances or capacities.

The change in resistance with change in frequency shown above will make it clear why different careful workers have found different values for the molecular conductivity and ionization of the same carefully prepared solution of the same salt, as some measurements were made at 60 cycles, others at 1000 cycles, etc. In calculating the ionization the equation  $\alpha = \mu_v/\mu_\infty$  is used. In obtaining  $\mu_v$ , cells with small electrodes are ordinarily used and often the resistances are comparatively small. It has been shown above that the error in such cases may be from 3 to 4%. On the other hand, in obtaining  $\mu_\infty$  cells with large electrodes placed close together are ordinarily used and the resistances are usually large. In such cases the error will be small, such as from 0.05 to 0.1%. It is thus seen that large errors may occur in  $\mu_v$  and hence in  $\alpha$ , and that the extent of this error will depend on the resistance and on the frequency used in making the measurement. In all cases  $\alpha$ ,  $\mu_v$  and  $\mu_\infty$  should be extrapolated to infinite frequency to obtain correct values.

#### **The Effect on the Capacity of Deposition of Gas on the Electrodes.**

—When a current passes in one direction in an aqueous solution of a salt, for instance, a metal or hydrogen is deposited at one electrode and an anion or oxygen at the other. These gases can either remain on the plates, thus decreasing their surface and increasing the resistance and inductance, or dissolve in the water, or become ions on the reverse pulse of the current. A study of these points is being made by Mr. H. P. Hastings by saturating the electrodes and the liquid around the electrodes with  $H_2$ ,  $O_2$ , etc., by pumping out the solution before and during electrolysis and by adding nonelectrolytes (and electrolytes) to combine with the gases. Experiments which have been carried out up to this time apparently show that

the changes in resistance and inductance with change in frequency cannot be accounted for by the deposition of neutral gases on the electrodes, but are probably due to a concentration of the ions of the electrolyte and solvent at and on the electrode and hence to an attendant contact potential.

That the changes are not due to gas deposited on the electrodes is shown by the data in Table IX. These measurements were made at 60 cycles because we would expect the greatest changes in capacity to occur at low frequencies. We shall, however, investigate this subject at higher frequencies of 1000, 1500, etc., where settings can be made with much higher accuracy.

TABLE IX.—DATA SHOWING EFFECT ON THE CAPACITY OF DEPOSITION OF GAS ON THE ELECTRODES.

Cell V,  $1/2$ " platinized electrodes.

Solution.	Res. in ohms.	Ind. in $\mu$ h.
0.1 <i>N</i> NaCl, before passing H through cell.....	147.98	5.9
H passed through cell 2 min.....	147.98	5.9
H passed through cell 2 min.....	147.93	5.5
0.05 <i>N</i> NaCl.....	306.4	6.2

H passed through cell 10 min.....	306.5	5.9
H passed through cell 20 min.....	306.5	6.2
H passed through cell and solution 30 min.....	306.0	5.9

If the electrode phenomena are not due to deposited neutral gas it seems likely that they arise from a double layer formed by the deposition of the ions of the solvent and solute on the electrode and by the change in concentration of the electrolyte at the electrode. If this is the case we should expect these changes to be so closely connected with the electrical factors that very definite relations should be found (1) between the inductances and the frequencies, and (2) between the change in resistance and the corresponding change in inductance produced by changes in frequency. That these relationships are very definite is shown in the next two sections.

**Relation between the Inductances Necessary to Balance the Capacity of the Cell at 600 and 1000.**—By a study of both water and alcoholic solutions in nine different cells it was found that the inductance necessary to balance the capacity of the cell is much larger at 600 than at 1000 cycles and that the inductance is nearly inversely proportional to the square of the frequency. This is shown by the data given in Table X. The average of fifty values for the calculated ratio is 2.66 while the value for the ratio of the square of the frequencies is 2.77. As this relation holds true for a "leaky" condenser the cell seems to act as a simple condenser with a leak.

**Ratio of Change in Resistance to Change in Inductance Produced by a Change in Frequency.**—All of the data given above show that as

TABLE X.—DATA GIVING THE RATIO OF INDUCTANCES NECESSARY TO BALANCE THE CAPACITY OF THE CELL.

the frequency of the alternating current approaches infinity, the change of resistance of a given solution in a given cell, and also the inductance necessary to balance the capacity of the cell, approach zero. In Table XI are given the resistances at 1000 cycles, the differences between the inductances in millihenries and the differences between the resistances in ohms at 600 and 1000 cycles, and the ratios of the differences in inductance to the difference in resistance. It will be seen that the ratios are very close to a constant 2.0. A few of the values calculated for different solutions in different cells are given in Table XI below. Many other cells of different types give this same constant, as they should theoretically.

Considering the fact that most of this work was done before the method was finally perfected, the values are remarkably constant. Mr. H. P.

Hastings has now secured much more elaborate data confirming these results at widely different frequencies, resistances, capacities, and inductances, and we have devised some simple equations for developing the theoretical aspects and for correlating these phenomena approximately, especially with the equation  $R_{\infty} = R_f - KL_f f^n$  discussed above.

**Apparent Capacities of Various Solutions in Different Cells.**—In Table XII we have given the values in microfarads for the capacities of several different solutions in different cells at both 600 and 1000 cycles, calculated from the inductance measurements by means of the equation  $C = 1/L\omega^2$ . These data show that the values for the cells with platinized electrodes are very high, and also that the values for the capacities at the two frequencies are nearly the same. It is also seen that the values for the cells with platinized electrodes do not check very satisfactorily and this is due to the fact that  $L$  is very small and thus a small error in  $L$  causes a very large change in  $C$ .

TABLE XII.—CAPACITIES OF DIFFERENT SOLUTIONS IN VARIOUS CELLS AT 600 AND 1000 CYCLES, CALCULATED FROM THE EQUATION  $C = 1/L\omega^2$ .

In Table XIII are given the values for the capacities of several different solutions in various cells calculated from the equation (1)  $C = 1/L\omega^2$ , and (2)  $C^2 - C/L\omega^2 = -1/R_3^2\omega^2$ , which latter equation will be discussed more fully in a later paper. The values calculated for the capacity by the two methods check very well.

The changes of concentration of the electrolyte at the electrode and the deposition of ions on the electrodes both doubtless give rise to the reverse electromotive force which makes the cell act like a condenser and diffusion and neutralization phenomena make the condenser "leak." Professor Bennett has devised equations for treating such phenomena mathematically and a full report on this subject will be given later.

The most important part of our work planned is to study the electrode phenomena and the phase relations. In order to do this we are devising

alternating current potentiometer methods to study the electromotive force and phase changes near the electrodes. We are using some cells with very small movable plate and point electrodes which are brought close together to magnify the electrode effects and are devising other cells with plane parallel electrodes which can be adjusted as close together as desired by interferometer methods, and we can thus make the known distance between the electrodes so small that the ions move from one plate to the other and back at each cycle and make the electrode phenomena play the chief role. Professor Bennett has available a very fine triple oscillograph with a period of 0.0003 second, with which it is possible to detect and measure changes in phase, voltage, current, capacity, and other phenomena in very short-time periods and at different frequencies, and Dr. G. H. Gray has already made important studies which will be reported later in detail.

### Conclusions.

(1) There is no measurable change in the resistance of a solution, or the inductance, with the change in voltage needed, provided the cells, solutions, and containers are kept scrupulously clean. If the cells are not clean, however, there is a change in resistance with change in voltage, and this fact can be used as a very reliable test for cleanliness of cells.

(2) In order to make accurate conductivity measurements the cells and methods must be so perfected that the ratios of the resistances for any given solution in two cells or of two solutions in any cell, must be constant to within 0.01%. This will not be the case unless we can eliminate electrode effects. The ratios of the resistances of 0.2 N, 0.1 N and 0.05 N NaCl in two cells, one with 0.5 and the other with 1 inch *platinized electrodes* did not vary more than 0.01% which is about the experimental error shown to be due to the 0.5 inch electrodes and other causes. Since there is no measurable change in the resistance of a solution with change in frequency around 500 to 2000 cycles in our cells *with platinized*

*electrodes* 1 inch or more in diameter, we can, therefore, conclude that one-inch platinized electrodes give approximately the true electrical resistance of these solutions at such frequencies, and certainly do so at infinite frequencies, if the resistance is above 100 ohms.

(3) In cells with *bright platinum electrodes* there is a change in resistance with change in frequency from 600 to 1000 cycles and higher, and this change depends upon several factors: (1) as the concentration of any given solution is decreased, and, therefore, the resistance increased, the change in resistance with change in frequency is decreased; (2) as the area of the electrode surface is increased the change in resistance with change in frequency is decreased; (3) as the area of the electrode surface is increased the inductance necessary to obtain a balance is decreased, and, hence the apparent "capacity" of the cell is increased. (4) The higher the apparent "capacity" of the cell, and, therefore, the smaller the inductance necessary to balance this capacity, the smaller the change of resistance with change in frequency becomes. As the apparent "capacity" of a cell is increased by increasing the surface, platinized electrodes should give the smallest change in resistance with change in frequency and this is borne out by all our data. (5) Solutions of different salts having about the same resistance in the same cell with bright platinum electrodes give approximately the same change in resistance with change in frequency from 600 cycles to 1000 cycles. (6) There is a specific relation between the electrolyte, the electrode material, the character of the electrode surface and the change of capacity and resistance with change in frequency. This is shown by the fact that for a change in frequency from 600 cycles to 1000 cycles. 0.1 *N*  $\text{AgNO}_3$  in a cell with 1 inch bright platinum electrodes gives a change of 0.12%; 0.1 *N*  $\text{AgNO}_3$  in this cell with the 1-inch electrodes, rough, silver plated, gives a change of 0.012%, and 0.1 *N*  $\text{NaCl}$  in the same cell a change of 0.052%.

By comparing the resistances of 0.1 *N* and 0.05 *N*  $\text{NaCl}$  in two cells, one of which had bright and the other platinized electrodes one inch in diameter, it was seen that the ratio for the cell with bright electrodes was much lower at the lower frequencies than that for the cell with platinized electrodes, but as the frequency was increased the ratio for the cell with bright electrodes approached that for the cell with platinized electrode. Extrapolating the resistance for the cell with bright electrodes to infinite frequency the ratio was found to differ by only 0.004% from that given by the cell with platinized electrodes. It is thus shown that the true electrical resistance of solutions can be measured in cells with bright platinum electrodes only at infinite frequency. We, therefore, recommend for all conductivity work involving an accuracy of 0.01% the use of a Vreeland oscillator, giving three or more frequencies, for example, 500, 750, 1000

and 1500, or 2000 cycles, and the extrapolation of the corresponding resistances to that at infinite frequency.

(4) By substitution in the equation  $(R_f - R_\infty)/L_f f = K$ , where  $R_f$  and  $L_f$  are the resistance and inductance measurements, respectively, at any given frequency  $f$ ,  $R_\infty$  the resistance at infinite frequency, and  $K$  a constant, we can calculate  $R_\infty$  for any given cell and solution. The values found for  $R_\infty$  by this equation differ from those found by extrapolation by only  $\pm 0.01$  to  $\pm 0.025\%$ .

(5) The fact that there is a change in the resistance of electrolytes with change in frequency makes it clear why different workers have found different values for the molecular conductivity and ionization of the same solution, as some measurements were made at 60 cycles, others at 1000 cycles, etc. The resistances or conductivities at *infinite frequency* should be used in all cases.

(6) Saturation of bright and platinized electrodes with hydrogen produces no appreciable change in the "capacity" of the cell at 60 cycles. This and a great deal of other evidence seems to show that the "capacity" does not arise simply from a neutral gas layer deposited on the electrodes and acting as an air condenser. It is probably due to a "double layer" of ions of the electrolyte and of the solvent at and on the electrodes and hence to "contact potential" by these changes of concentration arising from electrolysis.

(7) The ratio between the inductance measurements at 600 and 1000 cycles with various solutions in many different cells is a constant, the value being about 2.66. This shows that the inductance is nearly inversely proportional to the square of the frequency, the ratio for the square of the frequency used being 2.77. As this relation holds true for a leaky condenser the cell seems to act as a resistance in series with a simple condenser with a leak.

(8) As the frequency of the alternating current is increased the change in apparent resistance of a given solution in a given cell, and also the inductance necessary to balance the capacity of the cell, are decreased and both approach zero at infinite frequency. It was found that the ratio of the difference in the inductance in millihenries to the difference in the resistance in ohms between 600 and 1000 is a constant, being about 2.00.

(9) The electrical capacities of the cells acting as leaky condensers have been measured by different consistent bridge methods. The capacities vary with the solution, size of electrode, character of surface, resistance, and other factors, and range from 10 to 1000 microfarads for bright electrodes and from about 500 to 5000 microfarads for platinized electrodes.

### NOMENCLATURE.

$A$	Area of the cross-section between the electrodes.	$\phi_T$	= $\phi$ , Percentage error due to heating of the cell during the measurement.
$a$	= $\phi^3 \frac{ds}{\alpha}$	$R$	Resistance of the cell = that of the resistance box.
$b$	= $I_T^2 t$	$R_B$	Resistance of the slide wire with its extension coils.
$C$	Capacity	$R_T$	Resistance of the telephone.
$C_p$	Capacity equivalent of polarization.	$R_{\min.}$	Minimum resistance which the cell may have.
$c$	= $R_B + 4R_T$	$R_{\max.}$	Maximum resistance which the cell may have.
$d$	Density of the solution.	$r$	Range-ratio for the cell.
$f$	Frequency of the alternating current.	$s$	Specific heat capacity of the liquid in the cell.
$I$	Total current through the Wheatstone bridge network.	$\Delta T$	Rise in temperature of the cell during the passage of the current.
$I_A$	Current through the conductivity cell.	$\Delta T'$	Fluctuation in the temperature of the bath containing the cell.
$I_T$	Audibility current of the telephone.	$t$	Time required to obtain the bridge setting (sec.).
$j$	= $\sqrt{-1}$	$Z$	Impedance of the cell.
$k$	Dielectric constant of the liquid in the cell.	$\alpha$	Temperature coefficient of the conductance of the liquid in the cell.
$K$	Cell constant.	$\beta$	Coefficient of thermal expansion (linear) of the material of which the cell is constructed.
$\bar{L}$	Specific conductance of the solution.	$\gamma$	Coefficient of expansion of platinum.
$l$	Distance between the electrodes of the cell.	$x_C$	Condensive reactance.
$p$	Percentage error due to the uncertainty in determining the correct bridge setting.	$x_L$	Inductive reactance.
$\phi_L$	Percentage error due to lead resistance.		
$\phi_K$	Percentage error in the cell constant.		

**1. Introduction.**—Since the appearance in 1898 of Kohlrausch and Holborn's "Leitvermögen der Elektrolyte," no comprehensive treatment of the theory and practice of conductance measurements in the case of solutions of electrolytes has appeared. During the period which has elapsed since Kohlrausch's pioneer work in this field the advances in experimental methods and apparatus have made possible a very great improvement in the precision attainable in such measurements and have also led to a more perfect understanding of some of the sources of error and the precautions necessary for their elimination.

Briefly stated the problem of improving the accuracy of the Kohlrausch apparatus for measuring the conductivity of electrolytes is simply a problem of selecting the parts of the apparatus and so disposing them with respect to one another that the whole Wheatstone bridge assembly shall approach as nearly as possible the ideal assembly required by the theory of the alternating current bridge. The principle alterations required in the apparatus itself are (1) the substitution of a high frequency generator giving a pure sine wave of a single frequency, in place of the induction coil; (2) the use of a telephone tuned to the frequency employed; (3) the use of resistance units free from inductance and capacity; and (4) a proper and efficient use of the principle of electromagnetic shielding. A number of other minor improvements have also been made but those just stated are the fundamental changes required by theory.

The writer's first successful experiments with an apparatus incorporating all of the first three changes mentioned above were made in the Fall of 1911, and a preliminary paper describing the advantages of the improved apparatus was published in *THIS JOURNAL* in February, 1913. Since then a number of other improvements have been made in the details of construction and arrangement of the cells and the bridge and a description of some of these can be found in Cat. 48 of the Leeds & Northrup Company, which was published in May, 1915.

In developing the improved apparatus the writer has been ably assisted by his students, especially by Dr. J. E. Bell and Mr. Karr Parker with whose assistance most of the experimental work has been carried out. It had been the writer's intention to incorporate the results of the investigations in this laboratory in a monograph which would deal rather exhaustively with the whole subject of the electrical conductivity of solutions, but owing to the transfer of the writer's activities to a new field the project will have to be abandoned. The present series of papers will, therefore, deal only with the theory of the construction, assembly and use of the apparatus as finally perfected.

As an apparatus for accomplishing its purpose it is now perfect, in the respect that the degree of precision attainable in the measurements is governed and limited solely by the accuracy with which the temperature

of the constant temperature bath containing the cell can be controlled. All other sources of error which affect the precision of the measurement are negligible in comparison with this one.

The present paper deals only with the design, construction and use of the conductivity cells. The two following papers will be devoted to a discussion of the telephone as an indicating instrument and to the make-up and arrangement of the bridge assembly, respectively.

**2. The Bridge Assembly.**—With regard to its behavior towards an alternating current, an electrolytic cell together with its lead wires may be considered as a resistance and a capacity in series, shunted by a condenser.<sup>1</sup> In practice, however, the influence of polarization, which has the effect of a capacity in series with the cell, is usually eliminated by employing platinized electrodes or by using a sufficiently high frequency, or both, and hence in nearly all cases this factor may be neglected. Under these circumstances the cell and its connecting wires may be regarded as a resistance shunted by a condenser.<sup>2</sup>

In measuring the conductance of such a cell with the aid of a Kohlrausch slide-wire bridge, one of the arms of the bridge contains a variable

<sup>1</sup> Or according to Wien (*Ann. Phys.*, **58**, 67 (1906)) as a resistance in parallel with a condenser and in series with a capacity. For the cases considered in this paper the two arrangements become identical.

<sup>2</sup> Assuming that its specific inductive reactance is negligible in comparison with its specific condensive reactance (the value of  $x_L$  for a water cell—Type A—exclusive of the platinum leads, is only about 0.0002 microhenry), the specific admittance of an aqueous solution for a frequency of 1000 cycles is practically equal to  $\sqrt{0.197 \cdot 10^{-14} + \bar{L}^2}$  reciprocal ohm. Evidently the admittance does not differ appreciably from the conductance until the latter falls to a very low value. Thus for  $L = 10^{-6}$  (ordinary conductivity water) the admittance differs from the conductance only by 0.1%. The dielectric condensive reactance of the conductivity cell itself is thus ordinarily a *very small* quantity. Practically all of the reactance usually ascribed to the cell is due to the leads which connect it to the bridge. The general expression for the impedance of a non-polarizable cell and its leads is

$$Z = \sqrt{\frac{(R^2 + x_L^2)x_C^2}{(x_C - x_L)^2 + R^2}}$$

Evidently, therefore, the residual reactance may be either inductive or condensive according to the arrangement of the leads. The best arrangement is twisted or twin wire leads and under these circumstances the residual reactance is condensive and the above expression reduces to

$$Z = \frac{Rx_C}{\sqrt{R^2 + x_C^2}}$$

which is an expression of the same form as that for the cell alone. In other words the condensive reactance of the twisted leads can be treated practically as though it were part of the dielectric condensive reactance of the cell. By using leads of the same length and form on both sides of the bridge the residual condensive reactance will ordinarily be on the side of the cell and the variable air condenser will then be connected across the terminals of the variable pure resistance as shown in Fig. 1.

known resistance. We shall assume that this resistance is free from both inductance and capacity and that a variable capacity is employed in parallel with it. These are the ideal conditions and are the ones which should be approximated at least, in practice.

With this understanding the ideal Wheatstone-bridge network may be represented diagrammatically by Fig. 1. A slide-wire having the re-

Fig. 1.—Diagrammatic representation of the ideal Wheatstone-bridge network containing a conductivity cell free from polarization.

sistance  $R_B$  is stretched between the points  $A$  and  $B$ . The sine-wave alternating current  $I$  of a single frequency  $f$  will be considered as entering at  $A$  and dividing as indicated by the arrows. The left arm of the bridge contains the variable resistance  $R$  shunted by the variable capacity  $C$  (an air condenser), the impedance of this arm of the bridge being  $Z$ . The current through this arm of the bridge is  $I_A'$ . The other arm of the bridge contains the cell, of resistance  $R$  and having a condensive reactance<sup>2</sup> equivalent to that which would result from a capacity  $C$  in parallel with the resistance  $R$ . The impedance of this arm of the bridge will be  $Z$  and the current through it will be  $I_A$ . It will be noticed that this arrangement brings the bridge setting *in the center of the wire*, where it should be in all accurate work in which a slide-wire bridge of the type indicated is employed.

A tuned telephone having the resistance  $R_T$  connects the sliding contact with a point between the cell and the resistance box as indicated. By the term "tuned telephone," is meant a telephone which is substantially free from reactance for the frequency employed and whose diaphragm has a natural period of vibration, for its fundamental, which is the same as that of the current.

The resistance of that portion of the bridge wire between the center

of the bridge and the position of the sliding contact will be denoted by  $\Delta R_B$ . This resistance is just sufficient to cause an audible sound in the telephone and the current flowing through the telephone under these conditions will be its "audibility current,"  $I_T$ .

**3. The Distribution of the Current in the Bridge Network.**—With the aid of Kirchhoff's laws, the following expression for the total current  $I$  through the bridge may be readily obtained in the same manner as for direct currents:<sup>3</sup>

$$I = \frac{I_T}{2 \Delta R_B} \left[ \frac{(R_B/2 + Z)^2 + 2R_T(R_B/2 + Z)}{Z} \right] \quad (1)$$

where the impedance  $Z$  is, of course, a complex quantity, which in the present instance is expressed by the equation

$$Z = \frac{-jR}{2\pi fCR - j} \quad (2)$$

If we substitute this expression into Equation 1 and separate the resulting expression into its real and imaginary parts, we find for the real part

$$I = \frac{I_T}{2 \Delta R_B R} \sqrt{\left[ \frac{1/4 R_B^2 + R R_B + \frac{R^2}{\frac{f^2 k^2}{324 \cdot 10^{22} \bar{L}^2} + 1} + 2R_T R + R_T R_B}{\frac{f^2 k^2}{324 \cdot 10^{22} \bar{L}^2} + 1} \right]^2 + \left[ \frac{1/4 R_B^2 + R_T R_B - \frac{R^2}{\frac{f^2 k^2}{324 \cdot 10^{22} \bar{L}^2} + 1}}{\frac{f^2 k^2}{324 \cdot 10^{22} \bar{L}^2} + 1} \right]^2} \quad (3)$$

where  $k$  is the dielectric constant of the liquid in the cell and  $\bar{L}$  is its specific conductance.

An inspection of this equation shows that for good conductors it reduces to

$$I = \frac{I_T}{2 \Delta R_B R} \left[ \left( \frac{R_B}{2} + R \right)^2 + 2R_T \left( \frac{R_B}{2} + R \right) \right]. \quad (4)$$

As the value of  $\bar{L}$  decreases and the resistance of the cell increases, however, the two expressions differ from each other more and more. If we put  $\bar{L} = 10^{-7}$  and  $R = 10^5$ , then if  $f$  is not greater than 1000 cycles and  $k$  is not greater than 80, Equation 3 does not differ from Equation 4 by more than 10% of the value of  $I$ . Within this degree of accuracy, therefore, we may use Equation 4 in place of Equation 3 as long as we are dealing with solutions whose specific conductance does not fall below  $10^{-7}$  reciprocal ohms.

It will be noticed that this range includes all aqueous solutions down to and including the best "conductivity water" that can be prepared and handled in contact with the atmosphere, even under the most favorable

<sup>3</sup> Maxwell, *Electricity and Magnetism*, 1, 477.

conditions.<sup>4</sup> For the large majority of investigators engaged in conductivity measurements with solutions of electrolytes the above range is sufficiently ample to include all the cases which they meet with in practice. For this reason it seems best in the interest of simplicity to restrict the present discussion to liquids whose specific conductances fall within the range mentioned, since the relations obtained will be much simpler if we can employ Equation 4 instead of the more general and more complex Equation 3. Moreover the applications of the general equation to cases which lie without the above range are of more interest in connection with measurements of dielectric constants than in connection with conductance measurements because, when the specific conductance of the material begins to drop below  $10^{-8}$ , it becomes possible in most instances to use the direct current and galvanometer for the conductance measurements and under these conditions Equation 4, of course, becomes rigorously exact for all cases. The author hopes at some future time to discuss the subject of dielectric constant measurements in the light of Equation 3, particularly with reference to the problem of determining the dielectric constant of salt solutions, a problem which was taken up experimentally in this laboratory last year but which will now have to be dropped.

**4. The Theory of Cell Design.**—In the process of determining the correct bridge setting, the portion of the bridge-wire over which the "minimum" extends will evidently have a resistance equal to  $2\Delta R_B$  ohms (see Fig. 1). Within this range *no sound* will be heard in the telephone. The uncertainty in judging the exact center of this minimum will evidently be larger the larger  $2\Delta R_B$  is, but with properly designed apparatus this uncertainty should never amount to as much as one-fourth of the total range, that is, to as much as  $\frac{1}{2}\Delta R_B$ , and this would produce an error of  $p\%$  in the resistance of the cell. We shall, therefore, be conservative, if we write

$$2\Delta R_B = \frac{pR_B}{100} \quad (5)$$

where  $p$  is the allowable percentage error from the bridge setting.

The relation between the Current  $I_A$  and the Current  $I$  (see Fig. 1) is evidently

$$\frac{I_A}{I} = \frac{R_B}{2R + R_B} \quad (6)$$

If we combine Equations 4, 5 and 6 we have

$$I_A = \frac{50I_T(R_B/2 + R + 2R_T)}{pR} \quad (7)$$

For the purposes of the present discussion we shall assume that the

<sup>4</sup> Cf. J. E. Bell, Univ. of Ill. Thesis, 1913, p. 16.

conductivity cell contains two parallel electrodes of approximately equal areas. These electrodes will be  $l$  centimeters apart and the area of the *uniform* cross-section of the solution between them will be  $A$  square centimeters. The electrodes may be either two metal disks closing the ends of a cylindrical tube containing the solution, or they may be two sufficiently large coaxial cylinders. The area of each electrode must be substantially equal to or larger than the effective area of the cross-section of the solution between them. The heat capacity of the solution between the electrodes will be  $Alds$ , where  $d$  is the density of the solution and  $s$  its specific heat capacity.

If during the operation of determining the bridge setting the temperature of the solution between the electrodes rises  $\Delta T^\circ$  because of the current  $I_A$  passing through the cell, the energy thus liberated will be  $Alds\Delta T \cdot 4.2$  Joules. Equating this to the electrical energy, we have

$$Alds\Delta T \cdot 4.2 = I_A^2 \frac{lt}{A\bar{L}} \quad (8)$$

where  $\bar{L}$  is the specific conductance of the solution and  $t$  is the time required to obtain the final correct bridge setting.

If  $\alpha$  is the temperature coefficient of the conductance of the solution in the cell, a rise of  $\Delta T^\circ$  in the temperature during the measurement will produce a percentage error

$$p_T = 100\alpha\Delta T. \quad (9)$$

Now there is no particular advantage to be gained by attempting to make the error from this source less than that arising from the uncertainty in the bridge setting. We shall, therefore, equate these two sources of error.

$$p_T = p. \quad (10)$$

We can now write

$$\Delta T = \frac{p}{100\alpha}. \quad (11)$$

and Equation 8 becomes

$$\frac{Alds p \cdot 4.2}{100\alpha} = I_A^2 \frac{lt}{A\bar{L}}. \quad (12)$$

Combining this with Equation 7 so as to eliminate  $I_A$  and solving for  $A$ , we have the condition

$$A \geq \frac{50 I_T [R_B/2 + R + 2R_T] t^{1/2}}{R \bar{L}^{1/2} \sqrt{\frac{p^3 ds}{\sim 0.042}}} \quad (13)$$

If we put

$$R = \frac{l}{A\bar{L}} \quad (14)$$

in Expression 13 and again solve for  $A$ , we obtain the important condition

$$A^2 \geq \frac{6 \cdot 10^4 I_T^2 l^2 t}{\bar{L} [l \sqrt{p^3 ds/\alpha} - 120 I_T \sqrt{t \bar{L}} (R_B + 4R_T)]^2}. \quad (15)$$

This relation gives the minimum allowable value for the cross-section of the cell, if the two sources of error indicated are not to exceed  $p\%$  each. By solving this equation for  $l$ , we obtain a similar relation giving the maximum allowable value for the distance between the electrodes for the same condition.

For many purposes, however, a more convenient expression is obtained by solving the equation for  $\bar{L}$  giving us

$$\bar{L} = \frac{l^2 p^3 ds/\alpha}{6 \cdot 10^4 I_T^2 t (R_B + 4R_T)^2} \left[ 1 \pm \sqrt{1 - \frac{1.2 \cdot 10^5 I_T^2 t (R_B + 4R_T)}{A l p^3 ds/\alpha}} \right]^2. \quad (16)$$

This equation gives two values for  $\bar{L}$ . These two values represent the limits between which it is safe to use the cell in question if the two sources of error indicated are not to exceed  $p\%$  each. These two limiting values of  $\bar{L}$  determine what we shall call the *ultimate range* of the cell. No conductivity cell should ever be used for solutions with specific conductances which do not lie within the *ultimate range* of the cell as defined by the above equation.

In determining the actual *working range* of a given cell, however, another factor must also be taken into account, and that is the range of resistances within which it is practicable or desirable to make measurements. If  $R_{\max.}$  is the highest and  $R_{\min.}$  the lowest resistance which it is desirable to undertake to measure, then in addition to the above condition, the following must also be fulfilled:

$$\frac{l}{AR_{\max.}} > \bar{L} > \frac{l}{AR_{\min.}} \quad (17)$$

Before proceeding further with the discussion of the use of the principles thus far derived, it will be convenient to simplify the nomenclature somewhat. We shall introduce the following abbreviations:

$$p^3 ds/\alpha = a \quad (18)$$

$$I_T^2 t = b \quad (19)$$

and

$$R_B + 4R_T = c \quad (20)$$

Furthermore, if  $\bar{L}_1$  and  $\bar{L}_2$ , respectively, represent the upper and lower limits of the range of the cell, then the *range ratio*  $r$  will be defined by the expressions

$$\frac{\bar{L}_1}{\bar{L}_2} = r \text{ and } r \leq \frac{R_{\max.}}{R_{\min.}}. \quad (21)$$

Equation 16 can now be written

$$\frac{\bar{r}}{6.10^4 bc^2} = \frac{l^2 a}{\left[ 1 \pm \sqrt{1 - \frac{1.2 \cdot 10^5 bc}{Ala}} \right]^2} \quad (22)$$

and Expression 13 may be written

$$A \geq \frac{122 \cdot b^{\frac{1}{2}} (2R_{\max.} + c)}{R_{\max.} \bar{L}_2^{\frac{1}{2}} a^{\frac{1}{2}}} \quad (23)$$

where  $R_{\max.}$  is the resistance of the cell when filled with a liquid having the specific conductance  $\bar{L}_2$ .

If  $R_{\max.}$  is more than ten times  $c$ , which will practically always be the case when  $R_{\max.}$  is not less than 10,000 ohms,  $c$  may be neglected in comparison with  $R_{\max.}$  and the above expression reduces to the simple form

$$A \geq \frac{244 \cdot b^{\frac{1}{2}}}{\bar{L}_2^{\frac{1}{2}} a^{\frac{1}{2}}} \quad (24)$$

or in words, the minimum allowable value for the cross-section of the cell is determined by the audibility current of the telephone, the specific conductance of the liquid having the maximum desired resistance in the cell, the density, heat capacity and conductance temperature-coefficient of this liquid, and the percentage accuracy demanded in the measurement. It does not, however, depend upon the distance between the electrodes, that distance being fixed (after the value of  $A$  has been decided upon) by means of the equation

$$l = \bar{L}_2 A R_{\max.} \quad (25)$$

Expressions 23 and 25 together, therefore, fix a minimum volume for the cell. There is, however, another relationship involving the product  $Al$  which must also be satisfied. That is the relationship involved in Expression 22 which we will now proceed to examine more closely.

*The Volume Factor of a Conductivity Cell.*—From Equations 19 and 20 we obtain

$$\frac{\bar{L}_1}{\bar{L}_2} = r = \frac{\left[ 1 + \sqrt{1 - \frac{1.2 \cdot 10^5 bc}{Ala}} \right]^2}{\left[ 1 - \sqrt{1 - \frac{1.2 \cdot 10^5 bc}{Ala}} \right]} \quad (26)$$

and if we solve this equation for the product  $Al$ , we obtain the following expression which determines the minimum allowable value for what we shall call the *volume factor* of our cell.

$$Al \geq \frac{(r^{\frac{1}{2}} + 1)^2 \cdot 1.2 \cdot 10^5 bc}{4r^{\frac{1}{2}} a} \quad (27)$$

Since it will not ordinarily be desirable to restrict the range ratio of a cell to a value less than  $10^3$ , Expression 27 can for most purposes be written

$$Al \geq \frac{3 \cdot 10^4 \cdot bcr^{1/2}}{a} \text{ approx.} \quad (28)$$

It will be noticed that for a series of cells having the same range ratios, the minimum allowable value for the volume factor of the cells is the same for all the cells independent of their particular ranges.

Now if a cell is designed in accordance with the principles set forth in Expressions 23 and 25 a minimum value for its volume factor is also determined thereby. It is necessary, therefore, to ascertain whether this minimum is greater or less than the one fixed by Expression 27. If it is always greater, then Expression 27 need not be considered in designing cells, for the condition which it lays down would always be met if Expressions 23 and 25 are satisfied. We shall proceed to discover the conditions under which the minimum volume factor given by Expressions 23 and 25 shall always be greater than the value demanded by Expression 27.

We proceed as follows: From Expressions 23 and 25 we find

$$Al \geq \frac{1.5 \cdot 10^4 \cdot b(2R_{\max.} + c)^2}{R_{\max.} a} \quad (29)$$

The condition desired is, therefore, expressed by the relation

$$\frac{1.5 \cdot 10^4 \cdot b(2R_{\max.} + c)^2}{R_{\max.} a} \geq \frac{(r^{1/2} + 1)^2 3 \cdot 10^4 bc}{ar^{1/2}} \quad (30)$$

Putting  $R_{\max.} = rR_{\min.}$  in this relation and solving it for  $c$ , we find the two alternative conditions

$$c \geq R_{\min.} [r^{1/2} (r + 1) + \sqrt{r(r + 1)^2 - 4r^2}] \quad (31)$$

or

$$c \leq R_{\min.} [r^{1/2} (r + 1) - \sqrt{r(r + 1)^2 - 4r^2}]. \quad (32)$$

Of these two conditions the first one may ordinarily be disregarded because it usually gives values for  $c$  which are very much greater than any which would be met with in practice. Expression 32 then describes the condition which must be fulfilled if Expression 29 is to take precedence over Expression 27 in determining the dimensions of a conductivity cell. In nearly all cases which will be met with in actual practice, it will be found that the above condition will be fulfilled and that hence no attention need be paid to Expression 27 in designing conductivity cells. In a few very special cases, however, account must be taken both of Equation 31 and Equation 27. As an illustration of such an instance we shall at this point consider briefly the problem of designing a conductivity cell which shall have a minimum volume factor.

*To Design a Conductivity Cell Having a Minimum Volume Factor.—*

It is sometimes necessary to determine the conductivity of a liquid of which only a very small quantity is available. This is the case in studies of the conductivity of the sap of plants, for example. In such cases it

is important to employ a cell which requires a minimum amount of liquid to fill it.

To take a concrete example suppose the specific conductances of different samples of a certain group of plant saps lie within the limits  $\bar{L}_1$  and  $\bar{L}_2$  and that it is desired to measure the specific conductances of these saps with an accuracy of  $p\%$ . Let us suppose further that

$$r = \frac{\bar{L}_1}{\bar{L}_2} \gg 10. \quad (33)$$

Applying the criteria in Expressions 31 and 32 we find the two *alternative* conditions

$$6.3 R_{\min.} \geq c \geq 63 R_{\min.} \quad (34)$$

If, as would normally be the case,  $100 \ll R_{\min.} \ll 20$ , we would usually find that neither of these conditions was satisfied. This would mean that the volume factor of our cell would be determined by Equation 27 which in this case would become

$$Al \geq 1.65 \cdot 10^5 bc/a. \quad (35)$$

After having determined the minimum volume factor from this relation, the values of  $A$  and  $l$  would then be separately obtained by combining with the equation

$$l = A\bar{L}_1 R_{\min.} \quad (36)$$

We shall complete this discussion in the numerical form after considering some typical numerical values of  $a$ ,  $b$  and  $c$  (see Sec. 7 below).

**5. The Adjustment of the Total Current through the Bridge for a Conductance Measurement.**—In the theory of cell design presented above, one of the principal features is the entire elimination of any appreciable heating of the cell during the measurement. It is obvious, however, that *any* cell *could be* appreciably heated if a large enough current is employed for the measurement. The regulation of the current through the bridge is, therefore, an important element in the use of the cells.

It will be noticed, however, that the value of  $I$ , the total current through the bridge, does not appear in any of the final equations which control the cell design. Stated in words this means that a knowledge of the actual value of the current through the bridge is unnecessary either for the purpose of designing the cells or for using them afterwards. By looking back to Sec. 4 it will be noticed that at the beginning of the development of our theory a definite restriction was as a matter of fact placed upon the value of  $I$ . This restriction is involved in writing Equation 5 and the rule for adjusting the current through the bridge for the final measurement may, therefore be formulated as follows: Increase the current from the generator until the following condition is fulfilled:

$$\Delta R_B \leq \frac{pR_B}{200} \text{ approx.} \quad (37)$$

where  $p$  is the maximum percentage accuracy which the cell is designed to give with the telephone employed with it, and  $R_B$  is the approximate resistance of the bridge. Or stated in another way,  $p$  may have any desired value, not less than  $100\alpha\Delta T'$ , provided the cell is not used outside of the conductance range fixed by Equation 22.

**6. Summary.**—The results of the foregoing discussion may be summed up as follows:

Given the problem, *To construct a conductivity cell with a range ratio*  
 $r = \frac{R_{\max.}}{R_{\min.}} = \frac{\bar{L}_1}{\bar{L}_2}$ , *where*  $R_{\min.}$  *is the resistance of the cell when filled with*  
*a liquid of specific conductance*  $\bar{L}_1$  *and*  $R_{\max.}$  *is the resistance of the cell when*  
*filled with a liquid of specific conductance*  $\bar{L}_2$ .

The answer is: 1. Determine the minimum allowable value for the area of the cross-section between the electrodes with the aid of Expression 24; 2. Choose any convenient value larger than this; and then, 3. Determine the distance between the electrodes by means of Equation 25.

Stated in other words, *The area of the cross-section between the electrodes of a conductivity cell must not be less than a certain minimum value which is completely fixed and determined by the audibility current of the telephone, the time required to make the bridge setting, the lowest specific conductance which it is desired to include within the range of the cell and the percentage accuracy demanded in the measurements.*

This practically means that conductance cells should be designed to fit the telephone which is to be employed with them. The audibility current of the telephone is the chief controlling factor and every investigator making conductance measurements should determine for himself the audibility current of his telephone because the value of this important quantity is a function both of the construction of the telephone and of the observer's ear. The audibility current can be conveniently determined by methods which will be described in the second paper of this series, which will appear very shortly.

**7. Numerical Values of the Variables which Control the Cell Design.**—Before proceeding to the discussion of the application of the above principles to concrete cases, it will be necessary to assign appropriate numerical values to the variables involved. The factors governing the selection of these values will now be considered.

*The Resistance of the Slide-wire.*—The theoretical and practical principles which govern the selection and arrangement of the resistance or resistances which make up that portion of the Wheatstone bridge included between the points  $A$  and  $B$  of Fig. 1, will be considered in detail in a later paper. For our present purposes, it will be sufficient to note that according to Equation 1, the best value for  $R_B$  is given by the equation

$$R_B = 2\sqrt{Z(Z + 2R_T)} \quad (38)$$

or for aqueous solutions

$$R_B = 2\sqrt{R(R + 2R_T)}. \quad (39)$$

As a matter of fact, except for very small or very large values of  $R$  it is not necessary to pay much attention to fulfilling the condition expressed by this equation because sufficient accuracy can be obtained with a single bridge wire over a wide range of resistances. One of the slide-wire bridges in extensive use at the present time for measuring the conductances of electrolytes has a slide-wire which with its extension coils has a total resistance in the neighborhood of 250 ohms. This is an appropriate value for general use and in the following illustrative calculations we shall accordingly assume

$$R_B = 250 \text{ ohms.} \quad (40)$$

*The Resistance and Sensitivity of the Telephone.*—Theoretically, other things being equal, a high-resistance telephone should be employed for measuring high resistances and a low-resistance telephone for low resistances but practically the sensitivity is at present the only determining factor in the choice of a telephone. A very satisfactory telephone on the market at present has an audibility current<sup>5</sup> not greater than  $2 \cdot 10^{-9}$  ampere and a resistance of 150 ohms. We shall assume these values in the following calculations and write

$$J_T = 2 \cdot 10^{-9} \text{ ampere} \quad (41)$$

and

$$R_T = 150 \text{ ohms.} \quad (42)$$

*Density and Heat Capacity of the Solution.*—In the following calculations we shall assume

$$ds = 1. \quad (43)$$

This assumption will not be far from the truth in the case of aqueous solutions of electrolytes and in cases where this assumption is not sufficiently exact the necessary modifications of the equations will be obvious.

*Time Required to Obtain the Bridge Setting.*—This factor will vary with the observer, the apparatus he is using and a variety of conditions prevailing at the time of observation. Experiments in this laboratory have shown that a trained observer working in quiet surroundings with good apparatus can, if necessary, make the final bridge setting in about five seconds, even when measuring resistances as high as 50,000 ohms. In designing cells, however, it is better where possible to allow a somewhat longer time than this. We have found that a period of 10 seconds is usually ample to make a leisurely bridge setting if good apparatus is employed. We shall accordingly write

$$t = 10 \text{ seconds.} \quad (44)$$

For any given cell the maximum allowable value for  $t$  can be calculated

<sup>5</sup> Determined for the writer's ear.

from Equation 15. It is well to know this maximum value for  $t$  before measurements are begun with a new cell. Moreover if for any reason an observer wishes a longer time than 10 seconds, the design of the cell can, of course, be made to meet his condition. The following numerical calculations are given only as illustrations.

*Maximum and Minimum Values for the Resistance of the Cell.*—To a considerable extent the values of  $R_{\max.}$  and  $R_{\min.}$  may be chosen arbitrarily and the dimensions of the cell made to correspond with the values chosen. In the following illustrative calculations we shall assume

$$R_{\min.} = 100 \text{ ohms.} \quad (45)$$

This value is sufficiently large to make the elimination of errors due to lead resistances and contact resistances comparatively easy. Moreover it will always be practicable to construct the cell to meet this condition even for solutions of the highest specific conductance. For  $R_{\max.}$  we shall employ the value 10,000 ohms as long the dimensions of the cell will conveniently permit, but for cells to be used for poorly conducting liquids we shall include the case  $R_{\max.} = 100,000$  ohms.

*Temperature Coefficient of Conductivity.*—In the following calculations we shall write, for salt solutions,

$$\alpha = 0.02 \quad (46)$$

as an average value. In the case of conductivity water, however, we shall employ  $\alpha = 0.05$ .

*Percentage Accuracy Desired in the Measurement.*—With the apparatus now available for measuring the conductivity of electrolytes, the degree of precision attainable in the measurement is entirely determined and limited by the magnitude of the unavoidable variation of the temperature of the bath containing the cell. All other sources of variable error are now entirely negligible in comparison with this one. If therefore,  $\Delta T'$  represents the temperature range covered by the fluctuations of the "constant temperature" bath containing the cell, it is obvious that the maximum attainable percentage accuracy, that is, the minimum percentage error in the conductivity measurement is given by the equation

$$p_{\min.} = 100\alpha\Delta T' \quad (47)$$

Now there will obviously be no advantage in making the other sources of error much smaller than this one. We shall, therefore write

$$p = p_T = \frac{1}{2}p_{\min.} = 50\alpha\Delta T'. \quad (48)$$

For solutions of electrolytes where  $\alpha = 0.02$  and  $\Delta T'$  is taken as  $0.001^\circ$  this becomes

$$p = \Delta T' = 10^{-3} \quad (49)$$

and for conductivity water where  $\alpha = 0.05$ , it becomes

$$p = \text{approximately } 3 \cdot 10^{-3} \quad (50)$$

which are the values which we shall employ in the following calculations.

It will be noted that the choice of the above values imposes the condition that the rise in the temperature of the solution produced by the current which passes through it during the measurement shall not exceed  $0.0005^\circ$ . This requirement is evidently sufficiently exacting for all practical purposes. A more exacting requirement in this respect would be useless unless the fluctuations of the constant temperature bath could be made considerably less than  $0.001^\circ$ .

Using the above numerical values we have

$$a = p^3 ds/\alpha = 5 \cdot 10^{-8} \text{ (or for conductivity water = } 54 \cdot 10^{-8} \text{) calories per cc.} \quad (51)$$

$$b = I_T^2 t = 4 \cdot 10^{-17} \text{ coulomb-amperes.} \quad (52)$$

$$c = R_B + 4R_T = 850 \text{ ohms} \quad (53)$$

and the set of expressions derived above may be written:

Equation 22

$$\bar{L} = 2.9 \cdot 10^{-2} l^2 \left[ 1 \pm \sqrt{1 - \frac{8.2 \cdot 10^{-2}}{Al}} \right]^2 \quad (54)$$

Expression 24

$$A \geq \frac{6.9 \cdot 10^{-3}}{\bar{L}^{1/2}} \quad (55)$$

or for conductivity water ( $\bar{L} = 10^{-7}$ )

$$A \geq 7.0 \quad (56)$$

Expression 25

$$Al \geq \frac{(r^{1/2} + 1)^2}{r^{1/2}} \cdot 2 \cdot 10^{-2} \quad (57)$$

or for  $r = 10^3$

$$Al \geq 0.665 \quad (58)$$

Furthermore, if we apply the test imposed by Expression 32 using  $r = 10^3$ , we find the condition

$$c \leq 60R_{\min.} \quad (59)$$

a condition which is evidently fulfilled. We must, therefore, employ Expression 24, or in this instance 55, in determining the minimum value for  $A$ . For this purpose it will be most convenient to construct a graph of this equation. Such a graph is shown in Fig. 2, Curve A. The ordinates represent values of  $A$  in square centimeters and the abscissae, corresponding values of  $\bar{L}_2$  expressed as powers of ten. The point corresponding to  $\bar{L}_2 = 10^{-7}$  is that given by Expression 56. The corresponding curve for  $D$ , the diameter of the cross-section of the cell, is shown on the same diagram.

This diagram can also be employed in designing cells for use with a telephone for which  $I_T > 6 \cdot 10^{-8}$ , if  $p < 10^{-2}$  or for which  $I_T > 2 \cdot 10^{-8}$ , if  $p < 10^{-1}$ .

We shall now proceed to illustrate the use of this diagram in designing a set of conductivity cells to cover the whole range of specific conductances between 1 and  $10^{-7}$  reciprocal ohms.

### 8. Types of Conductivity Cells.

*General Features.*—Every conductivity cell designed for accurate work should fulfill the following obvious conditions:

1. It should be so formed that the operation of filling it with the solution to be measured and its subsequent use exposes the solution as little as possible to the action of the atmosphere.

2. The material of which it is constructed should not contaminate the solutions to be used in it.

3. The electrodes should be of such size and weight that when fixed firmly in one position the cell constant will not change with use, and the electrodes should be so placed that the cell constant does not depend upon the height to which the cell is filled. The electrode stems

should be as short as the conditions of manufacture and of filling and washing the cell will permit.

A cell constructed in the form of a pipet<sup>6</sup> probably fulfills the first condition most satisfactorily. Types<sup>7</sup> of pipet cells which have been in use in this laboratory for a number of years are shown in Figs. 3, 4, 5 and 6.

*Type A.*—This type is for use with conductivity water and very dilute solutions. For use with conductivity water the electrodes may be placed vertically since they are so close together that no appreciable number of lines of flow will reach the surface of the liquid, if the precaution is taken to fill the cell up to the level of the arrows A and D. The right-angled

<sup>6</sup> The writer is not aware of the origin of the pipet form for a conductivity cell. Such a cell is pictured and mentioned in Ostwald-Luther's *Handbuch*, 1902 Ed., and a cell of this form was constructed in this country in 1907 by Kraus (THIS JOURNAL, 31, 732 (1909)).

<sup>7</sup> In the case of Type A the figure is drawn so as to exhibit a form of construction which will permit a minimum electrode stem length, which may be desired in some cases for the reasons explained in Sec. 13. If this is not required the body of the cell is most easily made in the globular form shown in THIS JOURNAL, 35, 752 (1913), Fig. 1.

Fig. 2.

turn in the tube above the electrodes is an additional precaution against the escape of lines of flow to the surface of the liquid. The electrodes are constructed of the purest platinum alloyed with enough iridium to render them stiff. Each electrode is in the shape of a disk about 0.15 mm. thick and supported at the center by a rod of the same material about 1.5 mm. in diameter. The end of this rod may be slightly flanged before it is welded on to the disk in order to increase the strength of the joint and insure perfect rigidity after the electrode has been sealed into position. The inside surfaces of both electrodes should be roughened with a sand blast.

For use with dilute solutions the electrodes are lightly platinized and are preferably placed in a horizontal position (Fig. 4).

*Type B.*—This type is for use with moderately good conductors. The electrode specifications are the same as for Type A, except that a lighter weight platinum may be employed. The electrodes should be covered with a sufficiently heavy coating of platinum black to insure the elimination of polarization (see Sec. 14 below) but the coating should not be any heavier than necessary to accomplish this purpose.

*Type C.*—This type is for use with good conductors. The electrode specifications are the same as for Type A except that the electrodes may be made in the shape of a bowl as shown in the figure and the lower electrode should have a circular perforation at least 2 mm. in diameter near the center of the bottom. The diameter of the bowl may be about 5 centimeters and the depth about 7 millimeters. Both electrodes should be heavily platinized. The electrodes may be placed with their convex sides towards each other as shown in the figure, or they may be placed with their concave sides facing each other. The second arrangement makes a somewhat more efficient use of the electrode surface but it is necessary to guard carefully against the inclosure of a bubble of air underneath the upper electrode in this arrangement. A bubble of air below the lower electrode in the arrangement shown in the figure will do much less harm.

**9. A Series of Cells Covering the Complete Conductance Range for Aqueous Solutions.**—*Cell No. 1. For Conductivity Water.*—This cell will have nonplatinized electrodes and will be employed for solutions with specific conductances ranging from  $1.6 \cdot 10^{-7}$  reciprocal ohms up to a value which will be determined by the appearance of a poor minimum due to the influence of polarization. From Fig. 2 we find  $A = 10.4$  square centimeters. For circular electrodes this would correspond to a diameter of 3.65 centimeters. Suppose we choose 4 centimeters as the maximum diameter which we wish to employ for this type of electrode. This would mean an area of 12.6 square centimeters. Suppose moreover that it is undesirable to place these electrodes nearer together than 2 millimeters. If we put  $R_{\max.} = 10^5$  ohms we find from Equation 25,  $\bar{L}_2 = 1.6 \cdot 10^{-7}$ .

In other words such a cell could be used for conductivity water down to a specific conductance of  $1.6 \cdot 10^{-7}$  reciprocal ohms. This is practically the purest water which can be prepared in contact with the atmosphere<sup>4</sup> and hence the above cell would fill all requirements for conductivity water which is to be handled in contact with the atmosphere. The cell would be of Type A, Fig. 3.

Fig. 3.—Water cell. Type A

For measuring conductivities less than  $1.6 \cdot 10^{-7}$  it is convenient to use electrodes in the form of two coaxial cylinders.<sup>8</sup> A pair of such electrodes about 4 centimeters long, .4 centimeters across and 3 millimeters apart could be employed for specific conductances down to  $0.6 \cdot 10^{-7}$  without the resistance rising above  $10^5$  ohms. A study of the conductivities of dilute solutions in water having an initial conductivity of  $0.6 \cdot 10^{-7}$  reciprocal ohms at  $18^\circ$  is now in progress in this laboratory.

*Cell No. 2. For Dilute Solutions.*—This cell will have lightly platinized electrodes and will be designed to cover the range between  $10^{-6}$  and  $10^{-4}$  reciprocal ohms. From Fig. 2 we find  $D \geq 3$  centimeters. We shall choose the value 4 centimeters for the diameter of the electrodes and of the cross-section of the cell. For the distance between the electrodes we shall take 3 millimeters. The cell will be of the same type as No. 1 and when filled with a liquid of specific conductance  $10^{-6}$  reciprocal ohms will have a resistance of 24,000 ohms.

It will be noticed that the ranges of Cells 1 and 2 overlap to a considerable extent. This is desirable in the case of these cells because the upper limit of Cell No. 1 will be determined by the appearance of polarization influences and recourse will then have to be had to Cell No. 2. Needless to say it is advantageous to employ Cell No. 1 as long as possible because contamination of the solution by materials adsorbed by platinum

<sup>8</sup> A form of electrode originated by Pfeiffer [*Wied. Ann.*, 25, 232 (1885)].

Cell No. 3. Range  $10^{-4}$  to  $10^{-2}$ .—This cell will have well platinized electrodes. The diameter of the cross-section of the cell will be 1.5 centimeters and the distance between the electrodes 1.8 centimeters. It will be noticed that these dimensions fulfill the conditions shown by the diagram and give the cell a resistance of  $10^4$  ohms at the lower limit of the above range. The cell will be of Type B, Fig. 5.

*Discussion.*—These four cells will cover the total conductance range between 1 and  $10^{-7}$  reciprocal ohms. It is obvious that a greater number of cells could be employed if desired and that considerable variation in the dimensions is possible within the limits set by the diagram. It will be noted that with the above set of cells it is not necessary to employ a resistance greater than 10,000 ohms until the specific conductance of the

Fig. 5. Type B

liquid falls below  $1.6 \cdot 10^{-6}$  reciprocal ohms. The whole range could be covered with three cells by taking  $R_{\max.} = 10^5$  for each cell. Where it can be done conveniently, however, it is desirable to keep the value of  $R_{\max.}$  not greater than  $10^4$  ohms since there is then less trouble in obtaining a sufficiently close balance of the capacities in the two arms

many cases less sensitive than this, the corresponding values of  $Al$  would be 2.8 cc. and 0.003 cc., respectively.

Evidently these values are so low that there is practically no danger in falling below them in constructing cells for small quantities of liquids unless a larger range ratio than 10 is demanded for the cell. They are so low in fact that the total volume of the cell would in most cases be

Fig. 7.—Scale: 1 inch = 3 inches.  $l = 0.2$  cm.

practically determined by the space necessary to inclose electrodes of sufficient size to eliminate polarization, unless the method described in Sec. 14b were employed for this purpose.

**11. Connecting the Cell to the Bridge.**—In accurate work the conductivity cell should never be directly connected to the lead wires coming from the bridge but instead a pair of mercury cups *dipping into the bath containing the cell* should always be employed as an intermediary, as illustrated in Fig. 8. The reason for this is, of course, to prevent the exchange of heat between the electrodes and the room, along the connecting wires. For the same reason the distance  $B$  in Figs. 3-7 should be long enough to permit the submersion of all of the body and a good part of the connecting tubes of the cell, below the surface of the bath. Insulated

wires with amalgamated ends are used for bridging across between the cell and the intermediate mercury cups as shown in Fig. 8.

Twisted lamp cord No. 11 is, in practically all cases, of ample size<sup>9</sup> for connecting the intermediate mercury cups with the bridge and if the

Fig. 8.

same length of this cord is employed in connecting the bridge with the resistance box, it will never be necessary to determine or apply any correction for lead resistance, as long as the distance between the bridge setting and the center of the bridge is not greater than  $n/10000$  of the total bridge length,  $n$  being given by the expression

$$n = \frac{5000R_{pL}}{R_{pL} + 200R_L} \quad (61)$$

where  $R_L$  is the resistance of each pair of leads.

The resistance of the wires used to bridge across from the cell to the intermediate mercury cups as well as the resistance of the mercury and of the platinum stems of the electrodes are counted as part of the total lead resistance,  $R_L$ , of the cell.

**12. The Temperature Coefficient of the "Cell Constant" of a Conductivity Cell.**—As is well known, the Cell Constant of a conductivity cell changes with the temperature. The rapidity with which it changes, however, varies with the manner in which the cell is constructed and depends upon the nature of the materials which compose it. The nature of this dependence can be deduced as follows:

*Cells of Types A and B.*—For simplicity let us assume that the lines of flow are all perpendicular to the surface of the electrode, that is, we shall neglect the "edge effect," which will be smaller the more tightly the electrodes fit the cell and the smaller  $l$  is. For the Cell Constant of such a cell we will then have

<sup>9</sup> This size of lead wire is calculated as follows: From Equation 61 we find our limiting condition

$$\underline{R} \geq \frac{(5000 - n)R_{\min}p_L}{400nh}$$

where  $\underline{R}$  is the resistance of the wire in ohms per foot, and  $h$  is the distance between the cell and the bridge. Putting  $n = 200$ ,  $R_{\min} = 100$ ,  $h = 2$  ft. and  $p_L = 5 \cdot 10^{-4}$ , we find  $\underline{R} = 15 \cdot 10^{-4}$  ohms per foot = about No. 11 B. & S. copper wire. Similarly for  $h = 1$  ft. and  $p_L = 5 \cdot 10^{-3}$  we find  $\underline{R} = 3 \cdot 10^{-2}$  ohms per foot = about No. 25 B. & S. copper wire, etc., for any conditions which may be demanded.

$$K = \frac{l}{A} \quad (62)$$

and therefore,

$$A \frac{dK}{dt} = \frac{dl}{dt} - \frac{l}{A} \frac{dA}{dt} \quad (63)$$

For the two derivatives of  $l$  and  $A$  we have

$$\frac{dl}{dt} = \beta(l + s) - \gamma s \quad (64)$$

and

$$\frac{dA}{dt} = 2\gamma A \quad (65)$$

respectively, where  $s$  is the total length of the two platinum rods which support the electrodes,  $\gamma$  is the linear coefficient of expansion of platinum and  $\beta$  the coefficient of linear expansion of the material of which the cell is constructed. Combining these two expressions with Equations 62 and 63, we have the desired expression for the temperature coefficient of the Cell Constant, namely,

$$\frac{1}{K} \frac{dK}{dt} = (\beta - 2\gamma) + \frac{s}{l} (\beta - \gamma) \quad (66)$$

from which it is evident that the shorter the electrode stems the smaller will be the temperature coefficient of the cell.

*Cells of Type C.*—If the diameter of the cross-section of the connecting tube is small in comparison with its length, we have approximately

$$\frac{dl}{dt} = l\beta \quad (67)$$

and

$$\frac{dA}{dt} = 2A\beta \quad (68)$$

and hence from Equation 63

$$\frac{1}{K} \frac{dK}{dt} = -\beta \quad (69)$$

*Cells of the Arrhenius Type.*—For this type we have

$$\frac{dl}{dt} = l\beta \quad (70)$$

and

$$\frac{dA}{dt} = 2\gamma A \quad (71)$$

and on combining with Equation 63 we have

$$\frac{1}{K} \frac{dK}{dt} = \beta - 2\gamma \quad (72)$$

*Typical Illustrations.*—The value of  $\gamma$  between  $0^\circ$  and  $100^\circ$  is  $9 \cdot 10^{-8}$ . For  $s$  we may safely put 2 cm. as the maximum value which the requirements of manufacture or of filling and cleaning will ever demand. Using these values Equation 66 may be written

$$\frac{1}{K} \frac{dK}{dt} = (\beta - 18 \cdot 10^{-6}) + \frac{2}{l} (\beta - 9 \cdot 10^{-6}). \quad (73)$$

For materials such as fused quartz where  $\beta < 0.5 \cdot 10^{-6}$ , this reduces to

$$\frac{1}{K} \frac{dK}{dt} = -18 \cdot 10^{-6} (1 + \frac{1}{l}). \quad (74)$$

For Jena Apparatus Glass for which<sup>10</sup>  $\beta = 6 \cdot 10^{-6}$ , it becomes

$$\frac{1}{K} \frac{dK}{dt} = -6 \cdot 10^{-6} (2 + \frac{1}{l}). \quad (75)$$

In Table I are given the values of  $\frac{100}{K} \frac{dK}{dt}$ , the percentage increase in the Cell Constant per degree rise in temperature, for some typical cells constructed of quartz and of Jena Apparatus Glass, respectively. It will be noticed that these coefficients are very small and that they are all negative. By making  $s$  smaller than 2 cm., they could be decreased still further.

It seems reasonable to suppose that the coefficients calculated in this way will usually justify the use of two significant figures in expressing them; that is, the influence of the "edge effect" will in most cases not introduce an error as large as 10% in the calculated coefficient. If this statement is true, then it will be apparent that if the cell constant is known for one temperature, its value at another temperature may be safely calculated by means of the above relationships, from the equation

$$K_2 = K_1 (1 + (t_2 - t_1) \frac{1}{K} \frac{dK}{dt}) \quad (76)$$

provided that  $p_{K_1}$ , the permissible percentage error in  $K_1$ , fulfills the relation

$$p_{K_1} \geq \frac{10(t_2 - t_1) \frac{1}{K} \frac{dK}{dt}}{1 + (t_2 - t_1) \frac{1}{K} \frac{dK}{dt}} \quad (77)$$

it being, of course, also true that  $p_{K_1}$  cannot be less than  $p_{K_1}$ .

A check on the above considerations by means of an experimental study of the variation of Cell Constants with the temperature has not been made.

<sup>10</sup> A value kindly given me by Dr. E. C. Sullivan of the Corning Glass Works.

TABLE I.

Values of  $\frac{100}{K} \frac{dK}{dt}$ , the percentage increase in the cell constant per degree rise in temperature, for different types of cells in which the length of each electrode stem is taken to be 1 cm.

Type of cell. (See Sec. 8.)	$l$ in cms.	100/K $dK/dt$ .	
		Quartz $\beta = 0.44 \cdot 10^{-4}$ .	Jena App. Glass $\beta = 6 \cdot 10^{-4}$ .
A	0.2	—0.0103	—0.0042
A	0.3	0.0067	0.0032

B	< 10	0.0018	0.0012
C	*	0.000044	0.0006
Arrhenius	All values	0.0018	0.0012

\* For all cases where  $l$  is large in comparison with  $D$ , the diameter of the cross-section.

### 13. The Choice of the Material for Constructing a Conductivity Cell.—

The material of which the cell is composed must first of all be practically insoluble in the liquids to be used in the cell. For most aqueous solutions,<sup>11</sup> at temperatures not greater than 100° and at atmospheric pressure, fused quartz and a number of varieties of glass fulfill this condition satisfactorily. Fused quartz and Jena Apparatus Glass are the materials which have been most extensively used in this laboratory for conductivity work and a brief comparison of their relative merits is perhaps worth while.

The quartz is, of course, more resistant to the attack of water than is the glass, but Kohlrausch's investigation of the solubility of Jena Glass<sup>12</sup> demonstrated that it is sufficiently resistant for all purposes where the solutions are to be made up and handled in contact with the atmosphere. This is confirmed by our own experience with it.<sup>4</sup> Conductivity water with a specific conductance of  $0.21 \cdot 10^{-6}$  ohm has been kept in Jena Apparatus Glass for 12 hours without any appreciable change in its conductance and after several weeks' standing the conductance did not rise above  $0.6 \cdot 10^{-6}$  and in this case the contamination undoubtedly came from the atmosphere.

From the standpoint of cost of material and ease of construction the glass is, of course, to be preferred. A tight seal between the glass and the platinum is comparatively easy to make and is not likely to fracture if handled with ordinary care, and good cells can be made by any skilled glass blower. The manufacture of quartz cells, on the other hand, re-

<sup>11</sup> Such cases as solutions of hydrofluoric acid, solutions at very high temperatures and pressures and solutions of strong alkalies and acids, especially when hot, represent special cases which require individual treatment and they are, therefore, not included here.

<sup>12</sup> Kohlrausch, *Ber.*, 26, 2915, 2998 (1893).

quires the services of a skilled quartz worker and the operation of sealing in the platinum electrodes is covered by patents.

From the standpoint of the magnitude of the effect of temperature on the cell constant, quartz is superior to Jena Apparatus Glass for constructing cells of Type C. As shown in Table I, the cell constant of a quartz cell of this type changes only 0.004% for a 100° change in temperature. From the same point of view the glass is superior to the quartz in the case of cells of Types A and B, as shown by the data in the Table. By choosing a glass with the proper coefficient of expansion it is theoretically possible to construct cells of these types in which the cell constant will be practically independent of the temperature. The necessary condition is obtained by equating the right hand member of Equation 66 to zero, giving

$$\beta = \frac{2 + \frac{s}{l}}{1 + \frac{s}{l}} \gamma \quad (78)$$

or putting  $s = 2$  and  $\gamma = 9 \cdot 10^{-6}$

$$\beta = \frac{2 + \frac{2}{l}}{1 + \frac{2}{l}} \gamma. \quad (79)$$

According to the value of  $l$ ,  $\beta$  varies between  $18 \cdot 10^{-6}$  and  $9 \cdot 10^{-6}$ . Glass can be manufactured<sup>13</sup> with almost any coefficient of expansion between  $3 \cdot 10^{-6}$  and  $14 \cdot 10^{-6}$ , so that the above conditions could be met if desired.

Aside, however, from the desirability of having a cell constant with a small temperature coefficient, it is essential that the cell constant shall not exhibit appreciable thermal hysteresis. With respect to this quality, quartz would be superior to any glass and for this reason quartz is to be greatly preferred for all very accurate work at temperatures greatly removed from room temperature. For the same reason glass cells should be very carefully annealed and aged for a period before being put into use.

**14. The Elimination of Polarization.** (a) *By Platinization and Increase of Frequency.*—The elimination of the effects of polarization in conductivity measurements is usually effected by control of the frequency of the current and of the size and the extent and degree of platinization of the electrode surfaces. In all cases where the presence of platinum black is permissible it has been our experience that polarization can always be eliminated, even when using comparatively low frequencies ( $f > 1000$ ) by the usual process of platinizing the electrodes. It sometimes happens, however, that the solution under investigation contains a substance which

<sup>13</sup> Sullivan, *J. Soc. Chem. Ind.*, 35, 513 (1916).

undergoes a slow decomposition or oxidation in contact with platinum black. Under these circumstances, provided the solution is not too concentrated, the effect of polarization may frequently be eliminated by simply increasing the frequency until a sharp minimum is secured.

The effect of uncompensated polarization always manifests itself by the appearance of a poor minimum, silence never being obtained and a different quality of tone usually being apparent on the two sides of the minimum. In eliminating polarization by the customary device of platinizing the electrodes it should be remembered that the heavier the coating of platinum black the more difficult and tedious will the operation of washing the cell be. The platinum black coating should only be of sufficient thickness to accomplish the elimination of polarization in the solutions for which the cell is to be employed. At present this can only be determined by trial since the problem of the degree of platinizing as a function of the frequency of the current and the nature of the solution, its concentration and temperature is one which still awaits systematic investigation.<sup>14</sup>

In eliminating polarization by increase of frequency, the frequency employed should not be greater than necessary to accomplish the desired result owing to disturbances arising from capacity and inductive influences, which disturbances increase with increasing frequency. For frequencies between 1000 and 5000 cycles the sensitivity of the human ear is approximately constant.

For use in investigations in which it is necessary to eliminate polarization by increase of frequency, it is convenient to have available, telephones tuned to one or two of the higher frequencies, say 1800 and 3000 cycles. It is, of course, also necessary to employ a cell designed to fit the telephone at the particular frequency which is to be employed.

As an illustration of the effect of increasing the frequency, some results obtained in connection with a recently completed investigation in this laboratory, may be mentioned. It was necessary to measure the conductance of a 0.002 *N* salt solution containing organic substances which decomposed in contact with platinum black. Using a cell of Type B provided with sand blasted electrodes, the minimum obtained with 1000 cycles was not satisfactory but by increasing the frequency to about 1800 cycles it became perfectly sharp.

In eliminating polarization by increase of frequency it should, of course, be remembered that the presence of polarization is not the only factor which causes a poor minimum and before attributing a poor minimum to this cause, one should make sure that the resistances and the condensive and inductive reactances are properly balanced and symmetrically dis-

<sup>14</sup> A few experiments along this line using a solution of platinum chloride as the electrolyte have been made by Wien (*Ann. Phys.*, 58, 57 (1896)).

tributed in the bridge net work, and that the electromagnetic shielding has been properly carried out. A quick way of deciding whether a poor minimum is due to the incomplete elimination of polarization or not is to substitute in place of the cell in question a second cell<sup>15</sup> having heavily platinized electrodes and filled with a solution which will give it about the same resistance as the original cell. If the minimum does not become perfectly sharp it indicates that causes other than polarization are responsible. A discussion of some of these other causes and their elimination will be taken up in the third paper of this series which will deal with the details of bridge construction and assembly.

In this connection it should also be remembered that not only will the minimum be poor when polarization is present, but the center of that minimum, even if it can be accurately determined, does not represent the correct bridge setting, but differs from it by an amount  $\Delta R'_B$  which in our nomenclature is expressed by the equation<sup>16</sup>

$$\Delta R'_B = \frac{1/2 R_B}{(2\pi f C_p R)^2} \quad (80)$$

where  $C_p$  is the capacity equivalent of the polarization. As  $f$  increases  $C_p$  also increases and hence  $\Delta R'$  rapidly decreases. The elimination of polarization is thus not merely for the purpose of bettering the minimum but also for the purpose of obtaining a correct bridge reading.

(b) *By Compensation and Increase of Frequency.*—For the measurement of the specific resistance of a good conductor in which for any reason the presence of platinum black is not allowable, the method of merely increasing the frequency ceases to be practicable owing to the lack of sensitivity of the telephone for the very high frequencies which would be required. In such a case, however, a method originally suggested by Kohlrausch and later developed and used by Wien is available. This method is based upon the electrical compensation of the polarization.

In so far as polarization acts like a pure condensive reactance in series with the cell it should be possible theoretically to eliminate it either by the insertion of a variable pure inductance in series with the cell, as was early suggested by Kohlrausch; or by the insertion of a variable capacity in series with the resistance box, as in the dielectric-constant method of Nernst.<sup>17</sup> Since the second method is impracticable for good conductors, owing to the magnitude of the capacity required, Wien took up the experimental study<sup>18</sup> of the first method, and he soon discovered that the

<sup>15</sup> A cell with heavily platinized readily adjustable electrodes would be convenient for this test.

<sup>16</sup> For the deduction and discussion of this equation and a number of experiments illustrating the magnitude of  $\Delta R'$  for different frequencies see Wien, *Wied. Ann.*, **47**, 627 (1892).

<sup>17</sup> Nernst, *Z. physik. Chem.*, **14**, 622 (1894).

<sup>18</sup> Wien, *Loc. cit.*, 1896, p. 37. See also Neumann, *Ibid* **67**, 499 (1899).

effect of polarization is not solely that of a pure condensive reactance but that an increase in effective resistance accompanies it. In other words the compensation of the condensive reactance arising from the polarization, while it improved the minimum, did not give the correct bridge setting but gave a value which corresponded to an apparent increase in the resistance of the cell. This apparent increase in resistance he found to be the smaller, the larger the electrodes and the higher the frequency, and he suggested the very plausible hypothesis that it arises from the incomplete reversal of the electrode reaction. Such a failure of the electrode reaction to reverse itself would mean the consumption of energy and in an alternating current circuit this would play the same role as ohmic resistance. Moreover, it would become less and less as the frequency increased.<sup>19</sup>

By Wien's device, therefore, of electrically compensating for the condensive reactance of the polarization and increasing the frequency so as to eliminate as far as possible the energy loss, arising probably from the incomplete reversal of the electrode reactions, he was able to secure very satisfactory measurements of good conducting solutions with un-platinized electrodes. These results of Wien have been recently reproduced with modern apparatus at the Bureau of Standards by Curtis and Taylor<sup>20</sup> who found that the above method applied to 0.1 *N* and 0.05 *N* solutions of NaCl gave, within 0.02%, the same ratio of specific conductances as was obtained with platinized electrodes.<sup>21</sup>

In concluding this discussion of the conductivity cell, it seems worth while to call attention to the need of a new determination of the absolute specific conductance of some solution. For the purpose of obtaining cell constants we are at present dependent upon Kohlrausch's determination of the specific conductance of potassium chloride solutions. It is doubtful if his values are as accurate as 0.05%. With modern apparatus the accuracy with which these values can be determined is limited only by the accuracy with which the salt could be purified and the solutions made up. It is to be hoped that some institution, such as our National Bureau of Standards for example, will before long undertake the repetition of Kohlrausch's measurements of the specific conductance of the material best suited for use as a standard in determining cell constants.

In conclusion I wish to acknowledge the assistance of Mr. H. J. Weiland and Mr. J. M. Braham in checking the algebra and arithmetic involved in the calculations given in this paper. Most of these calculations have

<sup>19</sup> In this connection the thought naturally occurs that the efficiency of platinum black in eliminating polarization in conductivity measurements is not due solely to the increase in the area of the electrode but arises in part from its catalytic powers.

<sup>20</sup> Curtis and Taylor, *Phys. Rev.*, 6, 64 (1915).

<sup>21</sup> A third method for diminishing the influence of polarization has been described by Wolcott, *Ann. Phys.*, 12, 1653 (1903).

been checked by both men and it is believed that the values given are correct.

URBANA, ILLINOIS.

## REVIEW: THE PREPARATION OF CONDUCTIVITY WATER.<sup>1</sup>

By JAMES KENDALL.

Received June 30, 1916.

Water so nearly corresponds to the universal solvent sought by the alchemists that it is a matter of extreme difficulty, whatever methods of purification are adopted, to obtain a sample which may be shown to be practically free from all conducting impurities. Still more onerous is the task of preserving such a specimen when once prepared, since solution from the containing vessel inevitably introduces some contamination. The final and practical object—to maintain the sample at its original purity while actually in use in conductivity determinations—borders closely upon the unattainable.

By repeated distillations *in vacuo* Kohlrausch and Heydweiller,<sup>2</sup> working in Strasbourg,<sup>3</sup> succeeded in obtaining, in a glass conductivity cell, water with a specific conductivity of  $0.043 \times 10^{-6}$  reciprocal ohms at 18°, or  $0.015 \times 10^{-6}$  reciprocal ohms at 0°.<sup>4</sup> These values are certainly very near to those which would be given by perfectly pure water at the corresponding temperatures. This has been proved by the employment of several distinct indirect methods for determining the ionization constant of water.<sup>5</sup> Kohlrausch and Heydweiller themselves estimate the specific conductivity of absolutely pure water at 18° to be  $0.0384 \times 10^{-6}$  reciprocal ohms.<sup>6</sup>

If it were possible to reproduce this work conveniently and, after obtaining in quantity water of such extreme purity, to employ it in actual conductivity work, then it is obvious that we should never need to apply to our results any water correction at all.<sup>7</sup> In order to do this, however,

<sup>1</sup> Nearly all chemists have occasion at some time to employ especially pure water in their investigations, and find that the usual methods often fail to give the anticipated results. It is difficult to collect from the references in the literature (since the work is generally only incidental) satisfactory suggestions in such a case. Perhaps the most frequent mistake made is to persist in the attempt to prepare water beyond the laboratory's limit of purity. In the following pages the previous work on the subject is summarized and the utmost degree of purity attainable under ordinary conditions indicated.

<sup>2</sup> Kohlrausch and Heydweiller, *Z. physik. Chem.*, **14**, 326 (1894).

<sup>3</sup> After each reference which follows, the place where the investigation was carried out will be indicated. The difficulty in obtaining good conductivity water varies considerably in different localities, as will be seen below.

<sup>4</sup> One millimeter of this water at 0° possessed a resistance equal to that of forty million kilometers of copper wire of the same sectional area, or a length of wire capable of encircling the earth a thousand times.

<sup>5</sup> Landolt-Börnstein, *Tabellen*, **1912**, p. 1187.

<sup>6</sup> This is often incorrectly quoted as the *experimental value* of Kohlrausch and Heydweiller. The results are also usually given without conversion from the Siemens units in which they were published to the units now employed.

<sup>7</sup> A general discussion of the water correction in conductivity determinations will

it would be essential to carry out all the manipulations (preparation of solutions and measurement of conductivities) in evacuated vessels. This is a feat which has been frequently attempted but, owing to the extraordinary experimental difficulties involved, not yet successfully concluded.

The necessity for carrying out the whole of the work *in vacuo* arises from the fact that water, on exposure to the atmosphere, immediately loses its purity. Thus Kohlrausch and Heydweiller<sup>1</sup> give the following values from their experiments with two separate specimens:

Original spec. cond. of water *in vacuo* . . . . .  $0.05 \times 10^{-8}$  to  $0.11 \times 10^{-8}$

Spec. cond. after 20 min. exposure to air . . . . .  $0.34 \times 10^{-8}$  to  $0.40 \times 10^{-8}$

Spec. cond. after long exposure to air . . . . .  $0.66 \times 10^{-8}$  to  $0.65 \times 10^{-8}$

The final values obtained for different samples in equilibrium with the atmosphere were practically constant at  $0.65$  to  $0.70 \times 10^{-6}$  reciprocal ohms at  $18^\circ$ . Subsequent investigators have recorded uniformly similar results; it is impossible to maintain, for more than a short interval of time, any sample of water in contact with air at a much lower value. All existent conductivity data have consequently been obtained with the use of water of this order of purity.

While, therefore, Kohlrausch and Heydweiller accomplished the preparation of small quantities of exceedingly pure water, the main problem—the preparation of pure water in large quantity for actual conductivity determinations—was left unsolved. In later experimental work, indeed, Kohlrausch and Maltby,<sup>2</sup> recognizing the futility of preparing extremely pure water which would be sure to become contaminated before use, did not attempt any further refinements of method, but employed water which was obtained in bulk from Kahlbaum in Berlin with a specific conductivity of  $0.8$  to  $1.0 \times 10^{-6}$  reciprocal ohms at  $18^\circ$ . The water correction for such a sample at high dilutions is considerable.<sup>3</sup>

The endeavors of subsequent investigators have been almost entirely directed towards the facile preparation of large quantities of water of as low a specific conductivity as is possible *in contact with air*. The uncertain water correction consequent upon the employment of such water for conductivity work at high dilutions has come to be regarded as an unavoidable evil. The main investigations of this nature, the methods followed and the results obtained are summarized below.

Walker and Cormack,<sup>4</sup> in Dundee, prepared water of specific conductivity  $0.75 \times 10^{-6}$  at  $18^\circ$  by three successive distillations—with alkali, with phosphoric acid, and without the addition of any chemical. No lower permanent value, it was shown, could be obtained for water in contact with air.

Kohlrausch,<sup>5</sup> in Berlin, found that the specific conductivity of water at  $18^\circ$  was lowered from  $0.9 \times 10^{-6}$  to  $0.5 \times 10^{-6}$  by long standing in an appear in a subsequent communication, to which this and a former article (Kendall, *THIS JOURNAL*, 38, 1480 (1916)) are preliminary.

<sup>1</sup> Kohlrausch and Heydweiller, *Ann. Physik*, 53, 209 (1894).

atmosphere free from carbon dioxide. When  $\text{CO}_2$ -free air was passed through such water in the conductivity cell, the specific conductivity fell further to  $0.2\text{--}0.3 \times 10^{-6}$  but reverted soon to the higher value if the water was again exposed to the atmosphere.

Bousfield,<sup>1</sup> at Hendon (near London), prepared water of specific conductivity  $1.0 \times 10^{-6}$  at  $18^\circ$  by a process of continuous fractional distillation. The most favorable results were obtained by addition of a trace of  $\text{KHSO}_4$  to keep back ammonia and basic impurities. Later improvements<sup>2</sup> gave water of specific conductivity  $0.8 \times 10^{-6}$  in one distillation from tap-water without the use of any chemicals.

Hartley, Campbell and Poole<sup>3</sup> have described an apparatus which supplies water of specific conductivity  $0.75 \times 10^{-6}$  (at  $18^\circ$ ) in a single distillation from Oxford tap-water. Bourdillon,<sup>4</sup> also working at Oxford, has improved greatly upon this and has obtained water of specific conductivity less than  $0.2 \times 10^{-6}$  (part of the yield being as low as  $0.09 \times 10^{-6}$ ) by a single distillation into an air-tight cell. So long as the water was kept in this cell, its specific conductivity increased only slowly (for example, from  $0.12 \times 10^{-6}$  to  $0.4\text{--}0.45 \times 10^{-6}$  in 2–3 weeks), but if the cell was not air-tight the conductivity rose rapidly.

Paul,<sup>5</sup> in Munich, has also recently described a method of obtaining water of specific conductivity  $0.8 \times 10^{-6}$  at  $18^\circ$  by one distillation.

In this country the chief conductivity work at high dilutions has been carried out at the Massachusetts Institute of Technology by A. A. Noyes and his coworkers. Noyes and Coolidge<sup>6</sup> have described a very efficient still for the preparation of high-grade conductivity water. Washburn,<sup>7</sup> using this still at Urbana, has obtained water of specific conductivity  $0.4 \times 10^{-6}$  at  $0^\circ$  and  $0.6 \times 10^{-6}$  at  $25^\circ$  by distillation from an alkaline permanganate solution. The purest water employed by Goodwin and Haskell,<sup>8</sup> at Boston, in their work on hydrochloric and nitric acids at high dilutions, possessed a specific conductivity of  $0.8 \times 10^{-6}$  at  $18^\circ$ .

### Experimental.

The general results of previous workers indicate that, while it is a comparatively easy matter to obtain water of specific conductivity  $0.7\text{--}0.8 \times 10^{-6}$  at the ordinary temperature ( $18^\circ$ ), special apparatus and stringent precautions are necessary to effect any further purification. The significance of the constancy of the values obtained for water in contact with air by different observers working in different laboratories and using different methods has been discussed in a preceding paper.<sup>9</sup>

Sufficient attention does not seem to have been called to the fact that

<sup>1</sup> Bousfield, *J. Chem. Soc.*, **87**, 740 (1905).

<sup>6</sup> Noyes and Coolidge, *Proc. Am. Acad.*, **39**, 190 (1908).

<sup>7</sup> Washburn and MacInnes, *THIS JOURNAL*, **33**, 1688 (1911); Washburn and Williams, *Ibid.*, **35**, 751 (1913); The above are average results. The specific conductivity at  $25^\circ$  increased from an initial value of  $0.19 \times 10^{-6}$  to a final value of  $0.60 \times 10^{-6}$  on exposure to air.

<sup>8</sup> Goodwin and Haskell, *Phys. Rev.*, **19**, 271. (1904).

<sup>9</sup> Kendall, *THIS JOURNAL*, **38**, 1480 (1916).

a method for the preparation of conductivity water which answers extremely well in one laboratory may not work at all in another. The reason lies presumably in the difference in the nature of the impurities present in different water supplies.<sup>1</sup>

While engaged in conductivity determinations at Edinburgh, in 1911-12, the present author found that several of the standard methods (*e. g.*, distillation from alkaline permanganate or repeated distillation without chemicals) failed to give water below  $1.2 \times 10^{-6}$  at  $25^\circ$  in spite of all precautions taken. The Edinburgh water supply was at that time notoriously contaminated with objectionable impurities,<sup>2</sup> the atmospheric conditions in the city are also not of the best.<sup>3</sup> Professor Walker suggested the addition of Nessler's solution to the water under distillation as a method for the simultaneous elimination of the two volatile conducting impurities most to be apprehended—ammonia and carbon dioxide. It was found that one distillation from tap-water to which a few cc. of Nessler's solution had been added provided water of specific conductivity  $0.9 \times 10^{-6}$  at  $25^\circ$ .

This distillation was carried out in the open air with Jena glass vessels and a block-tin condenser, specially modified to ensure thorough washing of the steam on the way to the receiver. By redistillation in silica vessels (connected with a ground-on silica hood),<sup>4</sup> no chemicals being added and the distillate being collected hot, water of specific conductivity  $0.2-0.6 \times 10^{-6}$  at  $25^\circ$  was obtained. Such low values could be observed, however, only when the distillate was tested at once, for its specific conductivity increased rapidly on standing until values of  $0.8-0.9 \times 10^{-6}$  at  $25^\circ$  were attained. The following series of measurements upon a sample of water transferred to a conductivity cell immediately after collection will illustrate this.<sup>5</sup>

Time after transference to cell.....	0.5 min.	2 min.	10 min.	1 hr.	2 hrs.	6 hrs.
Specific conductivity $\times 10^{-6}$ .....	0.22	0.30	0.39	0.55	0.69	0.80

On longer standing no appreciable change occurred; even after the water had remained in the cell for three weeks the specific conductivity was only  $0.85 \times 10^{-6}$ .

The same method of purification was subsequently employed successfully in other laboratories—in Stockholm, Petrograd and New York City.<sup>6</sup> It may therefore be recommended as an easy and general method for the preparation of high-grade conductivity water.

<sup>1</sup> Ostwald found that his measurements upon dilute solutions of acids, made in Riga, were in error owing to the presence of ammonia in the conductivity water employed. In Leipzig this difficulty vanished (*Z. physik. Chem.*, **2**, 280 (1888)).

<sup>2</sup> The purely scientific results obtained from a consequent examination of the water supply are to be found in a paper by Walker and Kay, *J. Soc. Chem. Ind.*, **31**, 1013 (1912).

<sup>3</sup> As its familiar name, "Auld Reekie," testifies.

<sup>4</sup> A still of this type can now be obtained from the Thermal Syndicate, Ltd., New York City.

<sup>5</sup> Specific conductivities have been reduced to  $25^\circ$  throughout to give comparable results.

<sup>6</sup> Results are tabulated in the preceding paper (Table XI). It may be noted that at Petrograd, also, other methods of water purification failed.

The results obtained throughout have been in entire agreement with those of previous investigators in confirming the conclusions of Kohlrausch. Water in contact with air possesses a specific conductivity of at least  $0.7-0.8 \times 10^{-6}$  at  $18^\circ$ , and the correction for this in conductivity determinations at high dilutions must be considerable. The elimination of the water correction by the preparation of perfectly pure water is therefore doomed to remain impracticable unless the whole work is carried out in air-tight vessels. In this connection, present investigations by Washburn at Urbana and by Hartley at Oxford may be mentioned. Hartley and Bassett<sup>1</sup> have already described an "intermediate" type of apparatus for use with very dilute solutions—successive small quantities of solute being added to a large volume (300 cc.) of solvent contained in a special cell which protects it from contamination with the air. The cells designed by Washburn<sup>2</sup> are simpler and serve the same purpose.

#### The Carbonic Acid Concentration of "Pure Water."

In the preceding article<sup>3</sup> it has been shown that the purest distilled water of the laboratory is, in point of fact, a saturated solution of carbonic acid under the partial pressure of the carbon dioxide in the atmosphere, and contains no other conducting impurities in appreciable amount. Some additional evidence from the work of other observers as to the validity of the above conclusion may be considered here.

Caldwell,<sup>4</sup> in an examination of the Letts and Blake method for the determination of  $\text{CO}_2$  in air, made the following observations: "To ordinary distilled water more than sufficient KOH was added to make it alkaline. It was then distilled, and portions of the distillate examined from time to time. They were at first alkaline, no doubt from ammonia, but then became acid, and eventually of a *constant* degree of acidity. This degree of acidity was found to correspond with the amount of carbonic anhydride in the laboratory in which the water was distilled." Solubility measurements follow which confirm these statements.<sup>5</sup>

A recent paper by Fales and Nelson<sup>6</sup> also affords interesting results. According to theory, the hydrogen-ion concentration of *pure* water at  $25^\circ$  is a little less than  $10^{-7}$  normal. The purest distilled water of the laboratory<sup>7</sup> gave a hydrogen-ion concentration of  $10^{-6.8}$ . A saturated solution of carbonic acid under atmospheric conditions at  $25^\circ$  possesses a calculated ionic concentration of  $2.05 \times 10^{-6}$  (see the table on p. 2465). The hydrogen-ion concentration of such a solution,  $10^{-5.7}$ , is clearly in very close agreement with the observed value.

<sup>1</sup> Hartley and Bassett, *J. Chem. Soc.*, **103**, 789 (1913).

<sup>2</sup> "The Measurement of Conductivity of Electrolytes," Leeds and Northrup Co., Catalogue 48.

<sup>3</sup> Kendall, *Loc. cit.*

<sup>4</sup> Letts and Blake, *Proc. Roy. Soc. Dublin*, **9**, 222-3 (1900).

<sup>5</sup> The calculations as carried out by Caldwell are not accurate, since it is assumed that Henry's law in its simple form can be applied (see Kendall, *Loc. cit.*, page 1493). The true calculated values are in slightly better agreement with the observed.

<sup>6</sup> Fales and Nelson, *THIS JOURNAL*, **37**, 2782 (1915).

<sup>7</sup> The author's method of distillation from Nessler's solution was employed. It may be noted that the hydrogen-ion concentration of the indicator used (*p*-nitrophenol) would, under the conditions of experiment, be almost entirely suppressed in the presence of the stronger carbonic acid.

The results of the previous communication may be summarized in the following table:

SYSTEM: CO <sub>2</sub> -H <sub>2</sub> O (ATMOSPHERIC CONDITIONS).				
Temp.	Conc. of satd. soln. (mols per liter).	Ionization constant of H <sub>2</sub> CO <sub>3</sub> .	Conc. of ionized solute.	Spec. cond. of satd. solution.
0°.....	$2.94 \times 10^{-6}$	$2.24 \times 10^{-7}$	$2.46 \times 10^{-6}$	$0.65 \times 10^{-6}$
18°.....	$1.67 \times 10^{-6}$	$3.12 \times 10^{-7}$	$2.13 \times 10^{-6}$	$0.75 \times 10^{-6}$
25°.....	$1.40 \times 10^{-6}$	$3.50 \times 10^{-7}$	$2.05 \times 10^{-6}$	$0.80 \times 10^{-6}$

The agreement of the values given in the last column with those directly obtained by conductivity measurements is evident from Table XI of the preceding paper. Their agreement with the general results of other observers may be seen on examination of the values given in the review of previous work above. The fact that pure distilled water is a saturated solution of carbonic acid may therefore now be regarded as definitely established. If due precautions are taken, no other conducting impurity (such as ammonia from the original water supply or dissolved salts from the containing vessel), can be present in appreciable amount.<sup>1</sup>

It will be impossible to obtain *permanent* conductivity values for water in contact with air lower than those given in the above table. Many investigators have certainly employed "purer water" (*i. e.*, water of lower conductivity) in their measurements, but it is questionable whether any increase in accuracy has been gained thereby. Such water (prepared by passing CO<sub>2</sub>-free air through good distilled water) will be *unsaturated* with respect to the carbon dioxide content of the atmosphere, and will therefore slowly absorb CO<sub>2</sub> and consequently change in conductivity during the necessary manipulations. It is preferable to use a stable sample of water for which we can make an *exact* correction,<sup>2</sup> than to strive after a purer but unstable sample for which the correction is smaller but unknown.

This conclusion may be emphasized by a quotation from Kohlrausch:<sup>3</sup> "The purer the water, the more the difficulties of keeping it constant accumulate. Vessels with quite tight stopcocks would be necessary, if the employment of a purer water than that existing in contact with air (specific conductivity =  $0.8 \times 10^{-6}$  [at 18°] in the most favorable circumstances) is not to entail more dangers than advantages."

### Summary.

The results of previous work upon the preparation of conductivity water have been collected and discussed. A method has been described for obtaining a standard product of specific conductivity  $0.9 \times 10^{-6}$  at 25° by one distillation from tap-water. This method has been found to afford satisfactory results in four different laboratories.

It has been shown that the above specific conductivity value is the same as that given by a saturated solution of carbonic acid under atmospheric conditions. A permanent lower value for water in contact with air is not possible, since slow absorption of CO<sub>2</sub> must take place—unless airtight vessels are employed—until equilibrium is attained.

<sup>1</sup> If other impurities are present, then the observed conductivity will be in excess of that indicated above.

<sup>2</sup> As will be shown in a following paper.

<sup>3</sup> Kohlrausch, *Z. physik. Chem.*, 42, 200 (1902). See also Kohlrausch and Holborn, "Leitvermögen der Elektrolyte," pages 111-112 (Leipzig, 1898).

It is, indeed, quite unnecessary in conductivity work to invite the troubles involved in the preparation of purer water than the saturated  $\text{H}_2\text{CO}_3$  solution. The aim should rather be to exclude all other conducting impurities except  $\text{H}_2\text{CO}_3$ , and make for this an *exact* correction. The application of such a correction to electrolytes of different types at very high dilutions will be discussed in a succeeding article.

## THE HYDROLYSIS OF HEXAHYDROPYRIMIDINE.

BY GERALD E. K. BRANCH.

Received August 30, 1916.

### Introduction.

The study of the catalytic action of hydrogen ion has been recently extended to many cases in which the hydrogen ion decreases instead of increasing the speed of the reactions. The most notable of these investigations have been carried on by Biddle and his co-workers.

It appears that it is by no means uncommon for hydrogen ion to have a retarding effect. In fact in the case of additions to a nitrogen-carbon linkage, it might be expected from theoretical grounds that  $\text{H}^+$  should act as a negative catalyst when there is a tautomeric change involving the nitrogen atom. An example of such a reaction was found by Titherley and Branch<sup>1</sup> in the hydrolysis<sup>2</sup> of hexahydropyrimidine. It was there shown that this substance is tautomeric with methylene- $\alpha,\gamma$ -diaminopropane and that its hydrolysis to formaldehyde and trimethylenediamine is negatively catalyzed by hydrogen ion. Although they did not study this reaction quantitatively, they suggested that the effect of hydrogen ion was due to its favoring the less readily hydrolyzable ring form, a suggestion which has been verified by the author.

When an allelotropic mixture undergoes a reaction which is slow enough to allow equilibrium to be maintained between the isomers, any change in conditions which affects this equilibrium must have a corresponding influence on the reaction. In cases which involve a tautomeric shift about a nitrogen atom the isomers will show very different tendencies to form ions of the type of ammonium ion. The ability to add by virtue of a change of valence of the nitrogen varies inversely with the ability to add at the carbon nitrogen bond. Thus pyridine is a weaker base than piperidine but stronger than imines, just as benzene shows greater powers of addition than cyclohexane, but less than ethylenes.

<sup>1</sup> *J. Chem. Soc.*, 103, 330 (1913).

<sup>2</sup> In this paper hydrolysis is assumed to be preceded by an addition. For the argument, however, it is only necessary that it be a reaction which takes place more readily at a double than at a single bond.

In an allelotropic mixture between the substances  $\text{HA}-\text{CH}=\text{NR}$  and  $\text{A}=\text{HC}-\text{NHR}$  and their hydrogen ion compounds  $\text{H}-\text{A}-\text{CH}=\text{N}^+\text{HR}$  and  $\text{A}=\text{HC}-\text{N}^+\text{H}_2\text{R}$ , where A and R represent any groups, the following equilibria are established:  $\text{HA}-\text{CH}=\text{NR} \rightleftharpoons \text{A}=\text{HC}-\text{NHR}$ ,  $\text{HA}-\text{CH}=\text{N}^+\text{HR} \rightleftharpoons \text{A}=\text{HC}-\text{N}^+\text{H}_2\text{R}$ ,  $\text{HA}-\text{CH}=\text{NR} + \text{H}^+ \rightleftharpoons \text{HA}-\text{CH}=\text{N}^+\text{HR}$ , and  $\text{A}=\text{HC}-\text{NHR} + \text{H}^+ \rightleftharpoons \text{A}=\text{HC}-\text{N}^+\text{H}_2\text{R}$ , and from the laws of equilibrium there will be the following relationships among the concentrations of the substances:

$$\frac{(\text{A}=\text{HC}-\text{NHR})}{(\text{HA}-\text{CH}=\text{NR})} = k_1, \quad \frac{(\text{A}=\text{HC}-\text{N}^+\text{H}_2\text{R})}{(\text{HA}-\text{CH}=\text{N}^+\text{HR})} = k_2,$$

$$\frac{(\text{HA}-\text{CH}=\text{N}^+\text{HR})}{(\text{HA}-\text{CH}=\text{NR})x(\text{H}^+)} = k_3 \quad \text{and} \quad \frac{(\text{A}=\text{HC}-\text{N}^+\text{H}_2\text{R})}{(\text{A}=\text{HC}-\text{NHR})x(\text{H}^+)} = k_4$$

Hence  $k_1 = \frac{k_3}{k_4} k_2$ , and since it has been shown above that  $k_4$  is greater than  $k_3$ , it follows that  $k_2$  is greater than  $k_1$ . Since an increase in concentration of hydrogen ion must favor the ionic forms, it decreases the proportion in which the double bond is situated between carbon and nitrogen, and consequently retards any additions taking place at the carbon-nitrogen linkage, insofar as its action is due to its effect on the equilibrium between the tautomers.

In the case of hexahydropyrimidine the tautomerism is between

Hydrogen ion, according to the rules given above, will greatly favor the former, while only the latter, in virtue of its double bond, will hydrolyze at an appreciable rate. This case is further complicated by the fact that methylene- $\alpha,\gamma$ -diaminopropane undergoes polymerization.<sup>1</sup> Acid solutions will contain chiefly hexahydropyrimidine as its disalt, but there will also be some monosalt of methylene- $\alpha,\gamma$ -diaminopropane and its polymers. It is only these latter substances which are directly acted on during hydrolysis, but as they are removed the hexahydropyrimidine reforms them until it also has disappeared. It will be shown later that the rates of the hydrolysis under different conditions of hydrogen ion concentration and temperature agree with this representation of its mechanism.

### The Nature of the Relation.

It has been shown by Titherley and Branch that when the hydrochloride of methylene- $\alpha,\gamma$ -diaminopropane is allowed to stand with an excess of mineral acid, and afterwards titrated with alkali, using methyl orange

<sup>1</sup> Titherley and Branch, *J. Chem. Soc.*, 103, 332 (1913).

as the indicator, a slow change takes place, which results in the neutralization of an equivalent of acid, and that the rate of the change is an inverse function of the acid concentration.

They suggested two reactions which might account for this phenomenon, namely,

and expressed the opinion that it was due to a combination of these two causes. They obtained evidence that both of these reactions could take place, and positive evidence that the phenomenon was at least in part due to the latter. However, they obtained no evidence that the former was not an almost immediate reaction, and hence could not account for the slow neutralization, and owing to its reversal its effect could not be observed by the above experiment.

That this reaction is, in fact, too fast to account for a slow change is shown by the following experiment. A solution of the hydrochloride of methylene- $\alpha,\gamma$ -diaminopropane was added to a solution containing methylviolet and enough hydrochloric acid to give a green color. The color immediately changed to a blue, corresponding to the neutralization of an amount of acid equivalent to the hydrochloride added, according to Equation I.

There was no noticeable further change of color after standing for more than an hour.

#### Experimental Method.

Solutions of trimethylene diamine, formaldehyde, and hydrochloric acid were mixed in equimolecular proportions. The resulting mixture is chiefly a solution of the hydrochloride of methylene- $\alpha,\gamma$ -diaminopropane, in equilibrium with small quantities of  $\text{CH}_2\text{O}$  and  $\text{NH}_2.\text{CH}_2.\text{CH}_2.\text{CH}_2.\text{NH}_2$ ,  $\text{HCl}$ , and also some other products of the union of the two latter substances.

Measured volumes of this solution and standardized  $\text{HCl}$  were mixed and immersed in a thermostat. After an interval of from five to ten minutes<sup>1</sup> 20 cc. portions were withdrawn, from time to time, run into a mixture of ice and salt, and titrated, as rapidly as possible, with a 0.1 *N* solution of  $\text{NaOH}$ , using methyl orange as the indicator.

A peculiar phenomenon was observed during this titration. The solu-

<sup>1</sup> Rough estimates of the methylene- $\alpha,\gamma$ -diaminopropane in the original solution, made by calculating the amount hydrolyzed in this interval, give about 90% of a quantitative yield.

tion just becomes yellow, then changes back to pink; on further standing the solution again becomes yellow, even (although more slowly) when the solution is kept in a freezing mixture.

There are four possible explanations. Firstly, the reaction

may be slow enough at this temperature,  $-5^\circ$  to  $-10^\circ$  to be noticeable. Secondly, the hydrolysis of  $\text{NH}_3^+\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_3^+$  may be slow. Thirdly,<sup>1</sup>  $\text{CH}_2\text{O}$  may form a compound with  $\text{H}^+$  which decomposes at a noticeable rate. Fourthly,  $\text{CH}_2\text{O}$  may have combined with  $\text{NH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2$  in the original condensation to form traces of compounds more readily hydrolyzable than  $\text{CH}_2=\text{NCH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ . If this were the case, during hydrolysis these substances would be reduced to concentrations which are no longer in equilibrium with the  $\text{CH}_2=\text{NCH}_2\text{CH}_2\text{CH}_2\text{NH}_2$  in a neutral solution, and must reform, on neutralization, by the union of  $\text{CH}_2\text{O}$  with  $\text{NH}_3^+\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_3^+$  or  $\text{CH}_2=\text{NCH}_2\text{CH}_2\text{CH}_2\text{NH}_3^+$ , to give  $\text{H}^+$ . Further hydrolysis would then take place, reducing the  $\text{H}^+$  concentration, until a state of equilibrium is reached.

The first explanation is untenable, as the formation of acid becomes more marked as the hexahydropyrimidine is used up by hydrolysis. The second and third explanations can be shown to be unsound by the fact that neither solutions of  $\text{CH}_2\text{O}$  nor of  $\text{NH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ , when allowed to stand with excess of  $\text{HCl}$  and rapidly neutralized in the presence of ice and salt, become acid to methyl orange on standing. The last hypothesis is the only one which agrees with all the facts observed. In solutions in which all the hexahydropyrimidine has been hydrolyzed the acid formed after neutralization is permanent, also when solutions of  $\text{CH}_2\text{O}$  and  $\text{+H}_3\text{NCH}_2\text{CH}_2\text{CH}_2\text{NH}_3^+$  are mixed, there is a gradual formation of a small amount of  $\text{H}^+$ , which is permanent. In these cases the  $\text{H}^+$  is probably chiefly produced by the reaction  $\text{CH}_2\text{O} + \text{+H}_3\text{NCH}_2\text{CH}_2\text{CH}_2\text{NH}_3^+ \rightleftharpoons \text{CH}_2=\text{NCH}_2\text{CH}_2\text{CH}_2\text{NH}_3^+ + \text{H}^+$ .

For these reasons the first appearance of yellow was taken as the end point, and the titration was performed as rapidly as possible, and the solution vigorously agitated during the process. Naturally, accurate determinations cannot be made under these circumstances, but the measurements made after the reaction had been allowed to go to completion gave results within 5% of the theoretical amount of total amine.

The results at  $25^\circ$  are given in Table I. The first column gives the times from the first titration. The second column gives the concentration of acid as given by the titration. The last figure in this column gives the actual excess of acid above that necessary to form

<sup>1</sup> This explanation was suggested to the author by Dr. E. Q. Adams.

The third column gives the concentration of hexahydropyrimidine, and is obtained by subtracting the final from the actual acid titer. The significance of the fourth column will be discussed later. All concentrations are expressed in mols per liter.

### Discussion of Results.

According to the mechanism suggested in this paper for the hydrolysis of hexahydropyrimidine, the rate of the reaction should depend on the concentrations of the various derivatives of its open chain tautomer, and should be given by the equation

$$\frac{dx}{dt} = k_1 y_1 + k_2 y_2 + k_3 y_3 + \dots \quad (I)$$

where  $x$  represents the concentration of trimethylene diamine formed, and  $\gamma_1, \gamma_2$ , etc., represent the concentrations of the derivatives of methylene- $\alpha, \gamma$ -diaminopropane.

In dilute solutions, these substances will be present chiefly as their ions, which will be in equilibrium with the ion of hexahydropyrimidine according to the equations

etc. Such an equilibrium as

may well be neglected, not only on account of the dilute nature of the solution, but also because owing to the similarity of

and of

such an equilibrium will be very similar to the corresponding equilibrium involving the fully ionized forms, and the rates of hydrolysis of

practically the same as that of

According to the laws of equilibrium, the concentrations of the various substances present will be related by the equations

$$\frac{\gamma_1(\text{H}^+)}{a} = k_{e1}, \quad \frac{\gamma_2(\text{H}^+)^2}{a^2} = k_{e2}, \quad \text{etc.}, \quad (2)$$

where  $\gamma_1$  is the concentration of  $\text{CH}_2 = \text{N}.\text{CH}_2.\text{CH}_2.\text{CH}_2.\text{NH}_3^+$ ,  $\gamma_2$  the concentration of  $(\text{CH}_2 = \text{N}.\text{CH}_2.\text{CH}_2.\text{CH}_2.\text{NH}_3^+)_2$ , and  $a$  the concentration of  $\text{NH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{N}^+\text{H}_2\text{CH}_2$ .

Since in solutions whose concentrations of  $\text{H}^+$  are of the same order of magnitude as in those actually used there is but little diminution of  $\text{H}^+$  during the reaction, we have the following approximate relationships:  $a = (c_1 - x)\alpha_1$ , and  $(\text{H}^+) = c_2\alpha_2$ , where  $c_1$  is the initial concentration of hexahydropyrimidine in all its forms,  $\alpha_1$  the degree of ionization of its dihydrochloride,  $c_2$  the final concentration of  $\text{HCl}$ , and  $\alpha_2$  the degree of ionization of the  $\text{HCl}$ . Substituting in Equations 2 we get

$$\frac{\gamma_1 c_2 \alpha_2}{(c_1 - x)\alpha_1} = k_{e1}, \quad \frac{\gamma_2 (c_2 \alpha_2)^2}{\{(c_1 - x)\alpha_1\}^2} = k_{e2}, \quad \text{etc.}$$

For dilute solutions the approximate forms

$$\frac{y_1 c_2}{c_1 - x} = k_{e1}, \quad \frac{y_2 c_2^2}{(c_1 - x)^2} = k_{e2}, \text{ etc.}, \quad (3)$$

will introduce errors no greater than experimental. By combining Equations 1 and 3 we get the relationship

$$\frac{dx}{dt} = K_1 \frac{c - x}{c_2} + K_2 \frac{(c - x)^2}{c_2} + \dots \quad (4)$$

Neglecting all but the first two terms on the right-hand side of this equation (which corresponds to neglecting all polymers of methylene- $\alpha, \gamma$ -diaminopropane higher than dimolecular) and integrating gives

$$\frac{c_2}{K_1/K_2 t} \log \frac{c_1(c_1 - x + c_2 K_1/K_2)}{(c_1 - x)(c_1 + c_2 K_1/K_2)} = K_2.$$

The experimental results, substituted into this equation, give values for  $K_2$  constant within experimental error, for all values of  $K_1/K_2$  between  $1/2$  and  $1/4$ .  $K_2$  has therefore been calculated in this paper by assuming  $K_1/K_2 = 1/3$ .

The results at  $25^\circ$  have been collected in Table II, in which the first value obtained in each experiment has been neglected, except in the case of Experiment 2.

TABLE II.— $K_1/K_2 = 1/3$ . Temperature =  $25^\circ$ .

### The Effect of Change of Temperature.

A study of the effect of the change of temperature on the rate of the reaction gives further corroboration of the mechanism suggested for the hydrolysis of hexahydropyrimidine. According to this theory, change of temperature should have an abnormally large effect on the rate, for not only will there be the usual increase of reaction rate with tempera-

ture, but there will be an increase in the concentrations of the substances actually undergoing hydrolysis, for the reactions

and

since they involve neutralization, are presumably exothermic. Also, since the heat of the latter reaction is probably the greater, it might be expected that the ratio  $K_1/K_2$  will decrease with rise of temperature. Unfortunately, this latter point cannot be decided from the data given in this paper, as the value  $K_1/K_2$  has not been obtained with sufficient accuracy. It has been shown, however, that the reaction has a high temperature coefficient. The mean value of  $K_2$  was found to be  $3.67 \times 10^{-3}$  at  $25^\circ$  and  $1.46 \times 10^{-3}$  at  $18.4^\circ$ , when  $K_1/K_2$  is assumed to be equal in both cases.

The results obtained at  $18.4^\circ$  are given in Tables III.

### The Effect of Alcohol and of Sodium Chloride.

Alcohol was found to accelerate the rate of this reaction. Dr. Lewis suggested to me that if alcohol, which is less electrophyllic than water, increased the rate, the addition of sodium chloride would probably have the reverse effect. This surmise proved to be correct when the concentrations of salt were high. However, low concentrations of salt increase the rate of hydrolysis. The results of one experiment in the presence of alcohol and four experiments in varying concentrations of sodium chloride are given in Table IV. In each case  $K_2$  has been calculated by the equation used in the previous experiments, and the same value for  $K_1/K_2$  assumed.

### Summary.

The effect of hydrogen ion on addition reactions of any allelotropic mixture, involving a tautomeric shift about a nitrogen atom, is discussed. It is pointed out that in such cases hydrogen ion may be expected to act as a negative catalyst.

The rate of hydrolysis of hexahydropyrimidine was measured under varying concentrations of hydrogen ion, and at two temperatures. Both the effect of hydrogen ion and of temperature on the rate of this reaction were found to be in agreement with this theory.

Alcohol was found to increase the rate of hydrolysis of hexahydropyrimidine.

Sodium chloride in low concentrations was found to increase the rate of this reaction, while in higher concentrations it acts as a negative catalyst.

### [CONTRIBUTION FROM THE SCHOOL OF CHEMISTRY OF THE UNIVERSITY OF MINNESOTA.] THE SILVER SALT OF TRIODOPHENOL AND ITS CATALYTIC DECOMPOSITIONS.

By G. H. WOOLLETT.

Received August 21, 1916.

In the course of further study of the catalytic decomposition of silver salts described by Hunter,<sup>1</sup> *et al.*, it became necessary to investigate the

<sup>1</sup> THIS JOURNAL, 38, 1761 (1916).

behavior of the silver salt of triiodophenol. On account of its symmetrical nature, it was expected that this salt would give a smooth catalytic decomposition, comparable to that of the salt of tribromophenol, giving

silver iodide, and a residue  $\text{---} \begin{array}{c} \text{H} \quad \text{I} \\ \diagdown \quad \diagup \\ \text{C} \quad \text{C} \\ \diagup \quad \diagdown \\ \text{H} \quad \text{I} \end{array} \text{---O---}$  which should then polym-

erize as did those already studied. Further, the result of this polymerization could not fail to be of interest, in comparison with the colored compound, of like empirical composition, already studied by several chemists, and now known as tetraiododiphenylenequinone.

This had been originally obtained by the action of iodine and sodium carbonate on phenol, by Lautemann<sup>1</sup> who believed it to be an aromatic oxide and called it diiodophenylene oxide. Kammerer and Benzinger<sup>2</sup> ascribed it to the formula of a tetraiododiphenoquinone,

$\text{O} = \begin{array}{c} \text{I} \quad \text{H} \\ \diagdown \quad \diagup \\ \text{C} \quad \text{C} \\ \diagup \quad \diagdown \\ \text{I} \quad \text{H} \end{array} = \begin{array}{c} \text{H} \quad \text{I} \\ \diagdown \quad \diagup \\ \text{C} \quad \text{C} \\ \diagup \quad \diagdown \\ \text{H} \quad \text{I} \end{array} = \text{O}$  and this formula has since been retained.

It is proposed to show in a later communication that this formula also is erroneous.

On making very pure samples of the silver salt, it was discovered that it was possible to obtain from it at will either a white amorphous product exactly like those described in the paper already cited, or a red substance, which was easily shown to be identical with Lautemann's red substance.

The present preliminary paper will contain a description of the properties of the silver salt, and of the conditions under which each of the above transformations occurs.

**The Silver Salt of Triiodophenol.**—The phenol was made by the following method, which is based on that of Körner:<sup>3</sup> One-fifth gram molecule of phenol and the amounts of iodine and iodic acid required by the equation

were each dissolved separately in a slight excess of 2 *N* potassium hydroxide solution. The three solutions were then mixed in a three-liter bottle with glass stopper, and diluted to two liters. To the solution dilute hydrochloric acid was slowly added, with good stirring. Iodine was liberated and at first very rapidly taken up, with formation of a white precipitate. After a while the color of free iodine remained for several minutes at a time. When this point was reached, the reaction mixture was rapidly made distinctly acid and placed on the shaking machine for two hours. The precipitate was then chiefly triiodophenol, colored with iodine, giv-

<sup>1</sup> *Ann.*, **120**, 309 (1861).

<sup>2</sup> *Ber.*, **11**, 557 (1878).

<sup>3</sup> *Ann.*, **137**, 214 (1878).

ing it a brown color. Dilute bisulfite solution was now added till the iodine color disappeared, and the precipitate was filtered off. It was a light pink, owing to the presence of a little of "Lautemann's red." This is formed by the action of free iodine on the alkaline solution.

The precipitate was dissolved in dilute alkali and filtered from the insoluble red substance. The mixture of triiodophenol with diiodophenol was reprecipitated from the filtrate by acetic acid, filtered, and washed. It was again dissolved in dilute alkali, treated with bone black without heating, and reprecipitated. It weighed about 80 g. It was purified by repeated solution in about 1500 cc. of alcohol and addition of an equal amount of water, until it gave the proper melting point, 156°. Less careful treatment yielded only products of much lower melting points. Our phenol agreed in every respect with the description of Körner.

From this very pure phenol a sample of silver salt was prepared in the usual way by precipitation from a solution of the potassium salt.

It was washed very carefully, dried on a porous plate, in the dark, then at 70° in a drying oven for nearly an hour, and finally over  $\text{CaCl}_2$  *in vacuo*. The sample was a full lemon yellow, with no appearance of change at any time during the procedure. It was analyzed for both silver and iodine by the method of Carius.

For Ag, subst., 0.1831 g.,  $\text{AgI}$  0.0737 g.; for I, subst., 0.1114 g.;  $\text{AgI}$ , 0.1355 g.

Calc. for  $\text{C}_6\text{H}_2\text{I}_3\text{OAg}$ : Ag, 18.65%; I, 65.82%. Found: Ag, 18.55; I, 65.72.

Since this salt is described by Hantzsch<sup>1</sup> as white in color, several attempts were made to obtain a colorless variety, without success. To see if the color might be due to an impurity, a sample of yellow salt was reduced by zinc and sulfuric acid, and the phenol so obtained was used to make another sample of silver salt, which was again yellow. On acidification of an ammoniacal solution, the yellow salt reappeared. Finally, silver nitrate was added to a glacial acetic acid solution of triiodophenol, when a yellow precipitate fell, which was collected, washed, and analyzed. It was low in silver, as was to be expected from its method of manufacture.

Subst., 0.1580 g.,  $\text{AgI}$ , 0.0587 g. Calc.: Ag, 18.65. Found: Ag, 17.08.

**Formation of the White Oxide from the Silver Salt.**—On treating the silver salt with cold ethyl iodide, most of it was converted into the normal ether triiodophenetole. However, the formation of a small amount of amorphous substance could be demonstrated. If the tendency of the silver salt to decompose was increased by heating, the desired catalytic decomposition occurred, as in the following experiment:

Three grams of good silver salt, in small lumps and powder, were heated about five minutes on the water bath, in an Erlenmeyer flask. Ten cc. of cold ethyl iodide were then poured on the salt. A vigorous reaction at

<sup>1</sup> *Ber.*, 40, 4875 (1905).

once resulted, in every respect analogous to those observed with the salt of tribromophenol and other phenols, except that the color was grass green instead of blue. The color lasted for about fifteen minutes. The silver iodide was filtered off, and on addition of ethyl alcohol to the filtrate, there resulted a slightly pink precipitate. A single solution in bromoform and reprecipitation removed the color, giving a white, amorphous powder, of properties similar to those of the polydibromophenylene oxide of Hunter, except for a less degree of solubility—for instance, it is almost insoluble in chloroform. It was carefully dried and analyzed.

Calc. for  $(C_6H_2I_2O)_n$ : I, 73.82%. Found: I, 73.60, 73.80. Carius subst., 0.1394, 0.1063; AgI, 0.1902, 0.1452.

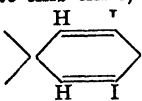

If both the salt and the ethyl iodide were heated before mixing, the action was very vigorous indeed, but gave the same white oxide. The pink color in the crude oxide was apparently due to the formation of a small amount of "Lautemann's red."

**"Lautemann's Red" from the Silver Salt.**—It was noticed that on long exposure to sunlight, the silver salt became red, suggesting the possibility of a second type of decomposition. Comparison with Lautemann's<sup>1</sup> method of making the red substance led to its preparation in the following manner:

A sample of the silver salt was ground up and suspended in water, and then treated with a single drop of a solution of iodine in potassium iodide. As the mixture was shaken, the silver salt became a dark purple in color, the solution still seeming to contain iodine. The colored solid residue was filtered off, dried, and extracted with carbon bisulfide. From this ligroin precipitated a dark red substance, entirely amorphous, and agreeing in every respect with samples made by the method of Lautemann. It was washed with alcohol, dried, and analyzed.

Subst., 0.1078; AgI, 0.1462. Calc. for  $(C_6H_2I_2O)_n$ : I, 73.82%. Found: 73.28.

That this formation of Lautemann's red instead of white amorphous substance is not due simply to the presence of iodine was easily shown by suspending dry salt in benzene, and adding a slight amount of iodine. This led to a formation of a white amorphous solid, only faintly tinged with pink, showing that iodine can also cause the formation of the white oxide. The question of the relation between the white and the red polymers of the unsaturated residues is being studied in this laboratory. It is perhaps worth pointing out, at this time, the possibility of a quinoid form

of the unsaturated residue,  = O although any effect that could be due to such a form, could also result by a simple shifting of val-

<sup>1</sup> *Loc. cit.*

ences without atomic rearrangement, after polymerization of the benzenoid form.

### Summary.

The silver salt of triiodophenol has been prepared in a very pure state, but the colorless form described by Hantzsch has not been obtained, all the samples found being yellow.

This salt, when warmed, gives with ethyl iodide a reaction exactly like that shown by the silver salt of tribromophenol, yielding silver iodide and an unsaturated residue which polymerizes to a white oxide.

The salt, when treated with a very little iodine in water, gives instead of the white oxide, the red substance first described by Lautemann.

## STUDIES OF TRIMETHYLENE OXIDE.

### I. PREPARATION AND CHARACTERIZATION.

By C. G. DERICK AND D. W. BISSELL.<sup>1</sup>

Received September 9, 1916.

I. Introduction. II. Preparation and Purification of Trimethylene Oxide. III. Properties of Trimethylene Oxide. IV. Proof of the Atomic Linking Structure. V. Experimental Part.

#### I. Introduction.

The use of ethylene oxide and its homologs in organic synthesis has been well established in the field of amino alcohols, and more recently their value in the Grignard reaction has been demonstrated by the work of Grignard,<sup>2</sup> Blaise,<sup>3</sup> and Henry.<sup>4</sup> In the study of the scale of influence of substitution, by the senior author and his students,<sup>5</sup> it is necessary to synthesize substituted monobasic paraffin acids, in which the substituents are further removed from the carboxyl group than the delta position. It seemed probable that trimethylene oxide would be of great value in effecting these syntheses. With this in mind the only reported synthesis of this substance was studied.

<sup>1</sup> Presented at the Urbana meeting of the American Chemical Society, 1916. From a thesis, submitted in partial fulfillment of the requirements for the degree of Master of Science at the University of Illinois.

<sup>3</sup> *Compt. rend.*, 134, 552 (1902).

<sup>4</sup> *Chem. Zentr.*, II, 445 (1907).

<sup>5</sup> THIS JOURNAL, 33, 1167 (1911); 38, 400 (1916).

The synthesis of trimethylene oxide by the action of a very concentrated solution of potassium hydroxide upon trimethylene chlorohydrin reported by Reboul<sup>1</sup> was repeated. The yield was very poor and the product very impure, as Section II will show. At best a yield of only 5% of the pure product could be obtained, even after many repetitions. These experiments suggest that Reboul never obtained the pure substance and accordingly the following study was undertaken.

## II. Preparation and Purification of Trimethylene Oxide.

Trimethylene oxide is best prepared by the action of potassium hydroxide containing 8% water upon gamma chloropropyl acetate at 100–110°. The desired products are condensed in a freezing mixture of hydrochloric acid and ice.

In order to purify the oxide it is necessary to know the different collisions of molecules that result in chemical reaction under the conditions of the experiment. They are as follows:

The physical properties of the substances resulting from the reactions show that this method of preparation gives trimethylene oxide contaminated with allyl alcohol, allyl chloride and water, but not with the higher boiling polymers.

To remove the unsaturated compounds, the distillate was carefully treated with liquid bromine until the reddish brown color was permanent. A subsequent distillation from the water bath removed the high boiling brominated compound. After drying the distillate over anhydrous sodium sulfate and redistilling the pure product was obtained. The yield of the pure product boiling from 48–50° (uncorr. at 750 mm.)<sup>2</sup> was 22.5% of the theoretical amount calculated from gamma chloropropyl acetate.

<sup>1</sup> *Ann. chim.*, [5] 14, 496 (1878).

### III. Properties of Trimethylene Oxide.

Since the properties of trimethylene oxide found by the authors differ decidedly from those reported by Reboul, a tabular comparison is given below:

Physical property.	Authors.	Reboul.
Boiling point.....	47.8° (corr. 760 mm.)	About 50°
Density.....	0.8930	.....
Molecular weight.....	57.9	.....
Index of refraction ( $N_D^{25}$ by Abbé).....	1.3897 $\pm$ 0.0008	.....
Color.....	Colorless	Colorless
Odor.....	Pleasant—aromatic	Penetrating
Solubility in water.....	Completely miscible	Completely miscible
Chemical property.		
Action of bromine.....	None, except after long standing	Vigorous

Since Reboul did not obtain enough of his product to study it further, a few of the chemical properties of trimethylene oxide were compared to those of ethylene oxide. This latter oxide has been thoroughly studied by Wurtz,<sup>1</sup> Grignard,<sup>2</sup> and others. The following table will show the relation of the chemical properties of the two homologs:

Chemical property.	Trimethylene oxide (Authors).	Ethylene oxide.
Action of bromine.....	Very slow	Forms red crystalline compound
Action of $PCl_5$ .....	Vigorous—forms trimethylene chloride	Vigorous—forms ethylene chloride
Action of Grignard reagent	Reacts to synthesize higher alcohols	Reacts to synthesize higher alcohols
Action of $FeCl_3$ solution..	Gives brown ppt.	Gives red-brown ppt.
Action of acetyl chloride..	Vigorous—forms gamma chloropropyl acetate	.....

The physical properties given above demonstrate that a pure monomolecular form of trimethylene oxide was obtained by the authors, but not by Reboul. The chemical properties show that it is an oxide, and further that the impurities in Reboul's product were the unsaturated compounds discussed in Section II. These products were removed by the authors when the crude distillate was treated with bromine. With this definitely established, the excellent analysis of such a volatile product, reported by Reboul, must be attributed to a happy compensation of errors, since one of the main impurities is allyl alcohol, an *isomer* of trimethylene oxide, and the other is allyl chloride. Allyl chloride boils at 47° while the oxide boils at 47.8°, so it is obvious that Reboul could not have freed his product from the chloride by simple distillation, his method of purification. Moreover, the product obtained by the authors,

<sup>1</sup> *Ann. chim.*, [3] 55, 427 (1859).

<sup>2</sup> *Compt. rend.*, 126, 1260 (1903).

after carefully repeating Reboul's experiment, always possessed three evidences of impurities, namely: reactivity toward liquid bromine, test for chlorine, and a sharp, unpleasant odor.

#### IV. Proof of the Atomic Linking Structure.

Trimethylene oxide was treated with phosphorus pentachloride, when a vigorous reaction took place forming trimethylene chloride. The latter was identified by its boiling point, insolubility in cold, concentrated sulfuric acid, and qualitative elementary analysis.

Like ethylene oxide, trimethylene oxide when treated with a magnesium alkyl halide reacts to cleave the ring, giving straight chain compounds. This reaction offers further proof of the structure of trimethylene oxide for, when the oxide is treated with magnesium propyl bromide in ether solution, a reaction takes place producing hexanol-1 as follows:

which on heating gives

The product hexanol-1 was identified by its boiling point, that of its acetate, and the characteristic odor of hexanol-1.

#### V. Experimental Part.

*Preparation of Trimethylene Chlorohydrin by the Chlorohydrin Method.*

**Preparation of the Chlorohydrin by the Action of Hydrogen Chloride upon Trimethylene Glycol.**—Dry hydrogen chloride was prepared by dropping concentrated sulfuric acid upon 37% hydrochloric acid, and drying the evolved gas by passing it through concentrated sulfuric acid. The gas was passed into trimethylene *chlorohydrin* which was kept at a temperature of 100°. At the end of three hours, the product was distilled, the fraction boiling between 150° and 175° containing the chlorohydrin. This was redistilled, and from 130 g. of glycol, 25 g. of trimethylene chlorohydrin boiling at 160–164° were obtained. A large amount of the glycol was recovered unchanged. This method was used by Reboul.

**Action of Sulfur Chloride on Trimethylene Glycol.**—Carius<sup>1</sup> prepared the chlorohydrin of ethylene glycol by the action of sulfur chloride on glycol. The procedure in preparing trimethylene chlorohydrin by this method was as follows:

In a liter flask was placed 250 g. of trimethylene glycol and 450 g. of sulfur chloride. After the mixture had been thoroughly shaken it became warm and there was a lively evolution of sulfur dioxide, while sulfur was precipitated. Without heating, but with occasional shaking, the

<sup>1</sup> *Ann.*, 124, 257 (1862).

lively reaction continued for an hour. When the spontaneous action had ceased, the mixture was heated on the water bath for six hours, using a reflux condenser, and was finally heated for half an hour over the free flame. By this time sulfur dioxide had ceased to be evolved. The cessation of the evolution of sulfur dioxide is adopted as a criterion of the completion of the reaction. The contents of the flask were then cooled and ether added. After removing the ether solution the crystallized sulfur was washed with ether, and the ether extracts combined, and shaken with a saturated solution of sodium carbonate to remove sulfur dioxide. The two liquid layers were then separated and the ether layer dried over anhydrous sodium sulfate. After distilling off the ether, the crude trimethylene chlorohydrin was distilled. The portion boiling  $140-180^{\circ}$  was redistilled and a yield of 160 g. of trimethylene chlorohydrin boiling at  $160-164^{\circ}$  was obtained, this being about 60% of theory. The chlorohydrin is a colorless oil, slightly soluble in water, and has an agreeable odor.

*Preparation of Trimethylene Oxide by the Action of Potassium Hydroxide upon Trimethylene Chlorohydrin.*

The method of Reboul<sup>1</sup> was followed rather closely. A 500 cc. flask was fitted with a dropping funnel, and a thermometer so arranged that the bulb of the thermometer was in the reacting mixture. The side neck was connected with the two U-tubes in series, both immersed in a freezing mixture of hydrochloric acid and ice. In the flask were placed 100 g. of potassium hydroxide and 10 g. of water. The temperature of the mixture was brought to  $130^{\circ}$  where it was maintained throughout the experiment. 50 g. of trimethylene chlorohydrin were added drop by drop through the dropping funnel over a period of 45 minutes. As each drop of the chlorohydrin struck the hot potassium hydroxide, a lively action resulted, and a vapor was evolved which condensed mainly in the first receiver.

**Purification of Trimethylene Oxide.**—After all the chlorohydrin had been added the generating flask was allowed to cool and water was added to dissolve the potassium hydroxide and potassium chloride. The residue was then extracted with ether and the ether extract worked up for high boiling products. The treatment of this residue will be discussed later.

The product which condensed in the receivers was a colorless mobile liquid, soluble in water and having a sharp odor. It was observed that the substance at this stage is very reactive toward liquid bromine. Bromine was added drop by drop to the ice-cold distillate until a permanent bromine color remained. At first the bromine acted instantly and violently, the solution being immediately decolorized. When the permanent

<sup>1</sup> *Ann.*, [5] 14, 496 (1878).

color had been obtained, water was added until the water layer was four times greater in volume than the oily layer. The two layers were then thoroughly mixed by shaking, and the heavy bromide allowed to separate out. This was drawn off and the aqueous layer saturated with potassium carbonate. The solution separated into two layers, the lighter containing the trimethylene oxide. The potassium carbonate solution was drawn off and the crude oxide dried over anhydrous sodium sulfate, and distilled from the water bath. The distillate was redistilled and gave 2 g. of pure trimethylene oxide boiling at 48–49° (uncorr.). It was noticed that the sharp, unpleasant odor of the crude distillate had entirely vanished, and that the odor was now sweet and aromatic.

Several modifications of this method of preparing trimethylene oxide have been tried. An experiment was run in which the temperature of the flask was kept at 160–180°, and the result was a preponderance of unsaturated products and very little trimethylene oxide. The next modification was to use a more dilute solution of potassium hydroxide. Instead of 10 cc. of water to 100 g. of potassium hydroxide, 20 cc. were used. The yield of distillate was very much lessened in this case. Another experiment was run using alcohol as a solvent. Again it was found that mainly unsaturated products were formed. Moreover a considerable quantity of ethyl alcohol distilled over with the low boiling products and the complete separation of the oxide was extremely difficult.

While the chlorohydrin method gave some trimethylene oxide, the quantity was so small that the process could hardly be called a feasible one. In all, seven runs were made, and the average yield was only 5–6% of theory.

*Preparation of Trimethylene Oxide by the Action of Gamma Chloropropyl Acetate upon Potassium Hydroxide.*

**Preparation of Gamma Chloropropyl Acetate.**—A flask having a capacity of 1500 cc. was connected with an upright condenser fitted at the top with a dropping funnel and an outlet tube leading into an absorption apparatus filled with water. In the generating flask was placed 300 g. of trimethylene chlorohydrin. Through the dropping funnel was added slowly 250 g. of acetyl chloride. The hydrogen chloride liberated was absorbed in the absorption train. After all the acetyl chloride had been added the contents of the flask were boiled gently until there was no further evolution of hydrogen chloride. The crude ester was then redistilled, yielding 375 g. of gamma chloropropyl acetate boiling at 160–166°.

**Preparation of Trimethylene Oxide.**—The same apparatus in which the oxide was made by the chlorohydrin method was used in this experiment. 150 g. of solid potassium hydroxide were placed in the 500 cc. generating flask. To this was added 12 cc. of water and the temperature

brought to  $100^{\circ}$ , the bulb of the thermometer being immersed in the potassium hydroxide mixture. Through the dropping funnel was then added slowly, 75 g. of gamma chloropropyl acetate. A lively reaction took place at once, and no further heating was necessary throughout the experiment. The heat evolved by the reaction kept the temperature of the mixture at  $100-110^{\circ}$ . Continued shaking was necessary throughout the experiment to maintain a thorough mixture of the reacting substances. In an hour all the ester had been added, and the mixture was then heated for ten minutes at  $120^{\circ}$ . At this time a marked *odor of the unsaturated compounds*, referred to above, was noticed, and the heating was discontinued. The experiment was duplicated and the products of the two reactions combined. The total weight of the crude distillate from 150 g. of ester was 29 g. It was noticeable that this distillate did not possess nearly so strongly the sharp odor of allyl compounds as did the crude product obtained by the chlorohydrin method, although this odor could still be detected. The whole was placed in a small flask kept cold by immersion in a freezing mixture. Bromine was then added slowly, a much smaller quantity being required to produce the permanent color than in any of the previous experiments. When no more bromine was acted on in the cold, the product was distilled from the water bath and the distillate condensed in a receiver immersed in a freezing mixture. The distillate was colored slightly yellow from the excess bromine. Anhydrous sodium sulfate was added and the products was allowed to stand for 24 hours in a glass-stoppered bottle. At the end of that time the color had disappeared. The crude trimethylene oxide was distilled, giving 14 g. of pure trimethylene oxide boiling at  $48-50^{\circ}$  (uncorr.). This is 22.5% of the amount predicted by theory.

*Study of the Chemical Properties of Trimethylene Oxide.*

**Synthesis of Hexanol-1.**—Magnesium propyl bromide was prepared by the action of 4.3 g. of magnesium ribbon upon 24 g. of propyl bromide in absolute ether. To this was added 10 g. of trimethylene oxide in 25 cc. of absolute ether. This was added slowly, to prevent too rapid reaction. When all had been added, the mixture was refluxed for an hour, using an upright condenser. The water was then drawn from the condenser and the ether evaporated. As the last traces of ether were evaporated the mass became porous and metallic looking. Suddenly a violent reaction took place, evolving a good deal of heat and leaving the residue somewhat charred and in the form of a hard cake. Water was then added to the cooled mixture, causing a slight heating. When the product was distilled with steam, about 2 cc. of an oil were obtained which had an odor much like that of hexanol-1. The volume was not great enough, however, to permit of purification by redistillation.

In order to determine a means of preventing this violent decomposi-

tion, a modification of this method was tried. Half the above quantities were used and the magnesium propyl bromide was prepared in the same manner as before. To the ether solution was added 5 g. of trimethylene oxide in 10 cc. of ether, and the mixture refluxed as before. Instead of distilling off the ether at this point, 100 cc. of dry benzene were added to the mixture, and the ether evaporated from this leaving the benzene as the solvent for the reacting substances. While the ether was being evaporated a thermometer was suspended in the upright condenser. When the temperature of the distilling vapors had reached  $70^{\circ}$ , the mixture was refluxed under the water cooler for four hours. The complex which had been precipitated as a gray solid, on the addition of the trimethylene oxide, became pasty under this treatment. No change of color, however, was noticeable. The mixture was now cooled and water added, without visible evidence of heat effect. As the gray mass went into solution a white precipitate formed at the bottom of the flask, and the liquid portion separated into two layers. The precipitate was dissolved in 30% sulfuric acid and the mixture distilled with steam. The distillate collected in two layers, and after separation, the oil was dried over anhydrous sodium sulfate and redistilled. After the benzene had passed over, 5 cc. of a liquid distilling constant at  $155^{\circ}$  were obtained. This was identified as hexanol-1.

**Action of Phosphorus Pentachloride.**—When trimethylene oxide was treated with phosphorus pentachloride, a violent reaction took place and an oil insoluble in water and in cold concentrated sulfuric acid was formed. The liquid was identical in its properties with trimethylene chloride.

**Action of Acetyl Chloride.**—Acetyl chloride reacts violently with trimethylene oxide to form gamma chloropropyl acetate.

*Physical Properties of Trimethylene Oxide.*

**Determination of the Boiling Point.**—The boiling point of trimethylene oxide was determined by the equilibrium method. The following table shows the readings of the thermometer, together with those readings corrected for emergent stem, for calibration and for variation of the atmospheric pressure from 760 mm.:

Readings.....	47.35	47.45	47.40	47.50
B. p. 760 mm.....	47.77	47.87	47.82	47.92

**Determination of the Specific Gravity.**—The specific gravity of trimethylene oxide was determined in an ordinary specific gravity bottle. The determinations were made at  $25^{\circ}$ . Densities are compared to water at  $4^{\circ}$ .

Wt. bulb with oxide, g.	Wt. bulb empty, g.	Volume of bulb, cc.	Wt. of oxide, g.	Sp. gr. of oxide.
10.6760	6.0086	5.2272	4.6674	0.8930
10.6770	6.0086	5.2272	4.6684	0.8931

**Determination of the Index of Refraction.**—The index of refraction of trimethylene oxide was determined by the Abbé refractometer using ordinary (white) light. The following readings were taken:

$n_D^{20}$  . . . . 1.3900, 1.3895, 1.3899, 1.3899, 1.3897, 1.3892, 1.3901, 1.3895, 1.3898, 1.3899.

**Determination of the Molecular Weight.**—The molecular weight of trimethylene oxide was determined by the method of Victor Meyer. Three determinations were made with the following results: 61.5; 56.8; 55.5. The calculated molecular weight is 58.

**Residues from the Preparation of Trimethylene Oxide (Chlorohydrin Method).**—After the trimethylene oxide had been driven from the generating flask, the residues were cooled and the water solutions extracted with ether. The ether solution was dried over anhydrous sodium sulfate, and the ether distilled over. The residue was subjected to fractional distillation. A considerable quantity of the liquid distilled over below  $100^\circ$ . This portion was treated with bromine and found to add that substance quantitatively. From  $100$  to  $150^\circ$  little distilled over, but from  $150$  to  $190^\circ$  there was an increased quantity of distillate. It was this portion that Reboul considered to be the unchanged chlorohydrin. But it was found that this fraction also reacted vigorously and completely with bromine to form heavy oils, while the chlorohydrin under similar conditions will not react at all. From  $200^\circ$  under ordinary pressure to  $270^\circ$  under 30 mm. several fractions were obtained, all of which formed heavy bromides with bromine. The latter fractions were viscous oils which seemed to have minute crystals in the liquid. However, they did not crystallize further on standing for three months.

URBANA, ILL.

[CONTRIBUTIONS FROM THE CHEMICAL LABORATORY OF CORNELL UNIVERSITY.]

## THE NITRATION PRODUCTS OF PHENOLTETRACHLOROPHTHALEIN AND SOME OF THEIR DERIVATIVES.

BY W. R. ORNDORFF AND J. J. KENNEDY.

Received September 8, 1916.

The investigation of the nitration products of phenoltetrachlorophthalein and their derivatives was undertaken to study the effect of introducing negative groups into the phthalein molecule.

The phenol used in this investigation was a pure crystallized product. This was distilled, the first fraction being rejected, and only that distilling between  $180^\circ$  and  $181^\circ$  was used. This product was perfectly colorless and melted sharply at  $42^\circ$ . Commercial tetrachlorophthalic acid was purified by the method described by Delbridge.<sup>1</sup> The purity of the acid

<sup>1</sup> *Am. Chem. J.*, 41, 414 (1909).

used was checked by determining its molecular weight by titration<sup>1</sup> with standard alkali.

**Phenoltetrachlorophthalein.**—This compound was made by the method of Orndorff and Black,<sup>2</sup> the only difference being that tetrachlorophthalic acid was used instead of the corresponding amount of tetrachlorophthalic anhydride. The yield of the phthalein was the same and the same amount of tetrachlorofluoran was formed. The pure phenoltetrachlorophthalein<sup>3</sup> was found to melt<sup>4</sup> sharply at 316–317°, with decomposition. The product, dried in an electric oven<sup>5</sup> at 120°, gave the following results on analysis:<sup>6</sup>

Subst., I, 0.2249; II, 0.2021; cc. 0.1 *N* AgNO<sub>3</sub>, I, 19.78; II, 17.71.

Calc. for C<sub>20</sub>H<sub>10</sub>Cl<sub>4</sub>O<sub>4</sub>: Cl, 31.11%. Found: I, 31.19; II, 31.07.

**Phenoltetrachlorophthalein Dibenzoate.**—This compound was not made by Orndorff and Black. It was prepared to determine if the phenoltetrachlorophthalein was not a mixture of two isomers. According to theory, three products are possible in the condensation of phenol with tetrachlorophthalic acid.

The compound represented by Formula III is tetrachlorofluoran, easily separated from the phthalein, owing to its insolubility in aqueous alkali. The greater amount of the product formed probably has the structure represented by Formula I in which the methane carbon atom is in the para position to each of the hydroxyl groups. However, the compound, represented by Formula II, in which one hydroxyl is ortho and the other para to the methane carbon atom, presents another possibility. If phenoltetrachlorophthalein is a mixture of these two phthaleins, then two dibenzoates should be formed. With this idea in view, the

<sup>1</sup> *Am. Chem. J.*, 41, 399 (1909).

<sup>2</sup> *Ibid.*, 41, 360 (1909).

<sup>3</sup> Phenoltetrachlorophthalein is described by Orndorff and Black as not melting at 300°.

<sup>4</sup> All melting points described in this article are uncorrected and were determined with carefully standardized thermometers using an electrically heated Thiele apparatus.

<sup>5</sup> *Am. Chem. J.*, 48, 477 (1912).

<sup>6</sup> All the chlorine determinations were made by the lime method. *Am. Chem. J.*, 41, 393 (1909). International atomic weights for 1916 are used in this article.

benzoyl derivative of phenoltetrachlorophthalein was made and carefully studied. Ten grams of phenoltetrachlorophthalein were heated to boiling with 70 g. of pure benzoyl chloride when all the phthalein went into solution. The boiling was continued for ten minutes and the contents of the flask poured into alcohol. The benzoate, after repeated washing with boiling water, was obtained in a nearly colorless, amorphous condition. It was then boiled with 95% alcohol, to remove the last traces of benzoyl chloride. The yield was practically quantitative, 98% of the calculated amount being obtained. The benzoate was crystallized several times from a *boiling* mixture of acetone and ethyl alcohol and obtained as a colorless, crystalline product, melting at  $213^{\circ}$ . Analyses showed that this product, was the pure anhydrous dibenzoate. On heating for an hour at  $120^{\circ}$  there was no loss in weight.

Subst., I, 0.2052; II, 0.2304; cc. 0.1  $N$   $AgNO_3$ , I, 12.37; II, 13.85.

Calc. for  $C_{24}H_{18}O_6Cl_4$ : Cl, 21.36%. Found: I, 21.38; II, 21.31.

Some of the product melting at  $213^{\circ}$  was then recrystallized from a mixture of acetone and ethyl alcohol *in the cold*. It now appeared in the form of flocks melting at about  $165^{\circ}$ . Another portion of the anhydrous material recrystallized slowly from benzene in the cold was obtained in white flocks, melting at about  $155^{\circ}$ . The compound from benzene lost a molecule of water,

Subst., I, 0.3144; II, 0.4235, loss (water) at  $130^{\circ}$ ; I, 0.0074; II, 0.0102.

Calc. for  $C_{24}H_{18}O_6Cl_4$ :  $H_2O$ , 2.64%. Found: I, 2.35; II, 2.40,

and no benzene could be detected in the vapors given off. This molecule of water is not lost when the product is placed in an evacuated desiccator over phosphorus pentoxide for several days, and is probably not water of crystallization (page 2500). The product from acetone, however, lost only about one-third of a molecule of water, showing that it was undoubtedly a mixture of the anhydrous material, and the hydrate. After water was driven off both products melted at  $213^{\circ}$  and analyses showed them to be the pure anhydrous dibenzoate.

The dibenzoate of phenoltetrachlorophthalein is readily soluble in acetone, benzene, and ethyl acetate; nearly insoluble in ethyl alcohol, methyl alcohol and ether. It is insoluble in 10% alkali in the cold. On warming, partial saponification slowly takes place.

As the entire amount of the anhydrous dibenzoate had a constant melting point of  $213^{\circ}$ , and in the course of fractional crystallization no indication of an isomer presented itself, it is highly probable that phenoltetrachlorophthalein is not a mixture of two isomers and is correctly represented by Formula I (page 2487).

As Orndorff and Hitch<sup>1</sup> had found that tetrachlorofluorescein gave only a monobenzoate by the Baumann-Schotten reaction, an attempt was made

<sup>1</sup> *J. Am. Chem. Soc.*, 36, 692 (1914).

to obtain the monobenzoate of phenoltetrachlorophthalein, by this method using 10 g. of phenoltetrachlorophthalein, 9 g. potassium hydroxide and 10 g. of benzoyl chloride. The product after purification was found to melt at  $213^{\circ}$  and an analysis showed conclusively that it was the dibenzoate.

Subst., 0.2456, cc. 0.1  $N$   $\text{AgNO}_3$ , 14.75.

Calc. for  $\text{C}_{34}\text{H}_{18}\text{O}_6\text{Cl}_4$ : Cl, 21.36. Found: 21.30.

**Dinitrophenoltetrachlorophthalein** was made as follows: Ninety-six grams of phenoltetrachlorophthalein were heated with a mixture of 1500 g. of glacial acetic acid and 147 g. of sulfuric acid (sp. gr. 1.84) about one hour at  $80^{\circ}$ . The mixture was then cooled to  $20^{\circ}$ , and 49 g. of nitric acid (sp. gr. 1.42) gradually added. The temperature was raised to  $50^{\circ}$  by immersing the flask in hot water, complete solution of the phthalein resulting. Extreme care had to be taken at this point not to allow the temperature to rise above  $50^{\circ}$ , otherwise higher nitration products were formed in sufficient quantity to make the purification of the dinitro compound extremely difficult. The solution was then cooled to room temperature and stirred for 24 hours until no unchanged phenoltetrachlorophthalein could be detected. The nitration product, which crystallized out, was filtered off and washed several times with small amounts of alcohol to remove impurities which imparted to the alcohol an orange color. The yellow dinitro product was then fractionally crystallized from acetone. All fractions finally showed a constant melting point of  $240^{\circ}$ . A small portion crystallized from glacial acetic acid also melted sharply at  $240^{\circ}$ . By adding water to the original nitrating solution, a small amount of dinitro product separated as a light yellow flocculent precipitate. This was purified as described above. The yield of the purified product was about 80%. Fractions crystallized from both acetone and glacial acetic acid lost no weight on heating. The material dried at  $130^{\circ}$ , gave the following results on analysis:<sup>1</sup>

Subst., I, 0.2672; II, 0.2135; cc. 0.1  $N$   $\text{AgNO}_3$ ; I, 19.57; II, 15.70.

Calc. for  $\text{C}_{20}\text{H}_8\text{Cl}_4\text{O}_8\text{N}_2$ : Cl, 25.98%. Found: I, 25.97; II, 26.08.

Subst., I, 0.3494; II, 0.3587; cc. 0.1  $N$   $\text{HCl}$ ; I, 13.00; II, 13.25.

Calc. for  $\text{C}_{20}\text{H}_8\text{Cl}_4\text{O}_8\text{N}_2$ : N, 5.13%. Found: I, 5.21; II, 5.15.

Dinitrophenoltetrachlorophthalein is light yellow in color and dissolves in caustic alkalis and alkali carbonates, with a light yellow color, more concentrated solutions having an orange color. It is insoluble in alkali bicarbonates. It is somewhat soluble in glacial acetic acid and ethyl acetate, more readily soluble in acetone. It is comparatively insoluble in ether, ethyl alcohol, methyl alcohol, and benzene.

An attempt was made to obtain a hydrate, or a carbinol acid of the dinitro

<sup>1</sup> In this work, all determinations of nitrogen were made by first reducing the nitro compounds by means of zinc dust and concentrated sulfuric acid, and then proceeding as in the Kjeldahl-Gunning method.

tro product by dissolving it in potassium hydroxide solution and precipitating with hydrochloric acid. On heating, the product lost no weight even at  $200^{\circ}$  and an analysis showed that it was the anhydrous dinitrophenoltetrachlorophthalein.

Subst., 0.2357; cc. 0.1  $N$   $AgNO_3$ , 17.19.

Calc. for  $C_{20}H_8Cl_4O_8N_2$ : Cl, 25.98. Found: 25.86.

All attempts to prepare dinitrophenoltetrachlorophthalein by the condensation of orthonitrophenol and tetrachlorophthalic anhydride, using such condensing agents as sulfuric acid (sp. gr. 1.84), fuming sulfuric acid (containing 15% of free sulfur trioxide) and freshly fused zinc chloride, were without success.

**Action of Dry Ammonia on Dinitrophenoltetrachlorophthalein.**—When treated with dry ammonia, the dinitro product gradually changed from light yellow to dark brown. Three molecules of ammonia were absorbed in a few hours. It, however, continued to gain weight slowly for four days when it absorbed four molecules of ammonia. When the salt was exposed to the air, the ammonia was gradually given off and the product returned to approximately the original weight. The small amount of ammonia which remained was readily driven off by heating at  $80^{\circ}$ .

Subst., I, 0.5182; II, 0.7526; gain in wt., I, 0.0625; II, 0.0942.

Calc. for  $C_{20}H_8Cl_4O_8N_2 \cdot 4NH_3$ :  $NH_3$ , 11.10%. Found: I, 10.76; II, 11.12.

**Dinitrophenoltetrachlorophthalein Dibenzoate.**—Five grams of dinitrophenoltetrachlorophthalein were boiled with 35 g. of benzoyl chloride for a half hour. The dark brown solution was poured into ethyl alcohol when the benzoate separated as a dark brown oil. After considerable shaking, the oil solidified. It was recrystallized from benzene by the addition of ethyl alcohol, and obtained colorless with a sharp melting point of  $205^{\circ}$ . A fraction crystallized from acetone showed no change in melting point. This product was the hydrate (page 2500). Loss in weight determinations at  $120^{\circ}$  were made with fractions crystallized from a mixture of benzene and ethyl alcohol and also from acetone. In each case the vapors from the drying tube were conducted into a wash bottle containing water, but neither acetone nor ethyl alcohol could be detected in the water.

Subst., I, 0.9985; II, 0.4729; loss (water) at  $120^{\circ}$ , I, 0.0240; II, 0.0113.

Calc. for  $C_{24}H_{16}Cl_4O_{10}N_2 \cdot H_2O$ , 2.33%. Found: I, 2.40; II, 2.39.

The molecule of water is not lost on standing for days in an evacuated desiccator over phosphorus pentoxide. The product is, therefore, a hydrate. The anhydrous dibenzoate also melted sharply at  $205^{\circ}$  and gave the following results on analysis:

Subst., I, 0.2326; II, 0.2286; cc. 0.1  $N$   $AgNO_3$ ; I, 12.31; II, 12.03.

Calc. for  $C_{24}H_{16}Cl_4O_{10}N_2$ : Cl, 18.81. Found: I, 18.77; II, 18.66.

Dinitrophenoltetrachlorophthalein dibenzoate is readily soluble in benzene, acetone and ethyl acetate. It is comparatively insoluble in methyl

alcohol, ethyl alcohol, and ether. In hot 10% sodium hydroxide solution, the product is slowly, but only partially, saponified, the solution becoming orange in color.

By benzoylating dinitrophenoltetrachlorophthalein according to the Baumann-Schotten reaction, the same dibenzoate was obtained. The material melted sharply at  $205^{\circ}$  and, after drying to constant weight at  $120^{\circ}$ , gave the following result on analysis:

Subst., 0.2646, cc. 0.1  $N$   $\text{AgNO}_3$ , 14.18.

Calc. for  $\text{C}_{24}\text{H}_{12}\text{Cl}_4\text{O}_{10}\text{N}_2$ : Cl, 18.81%. Found: 19.01.

Hence, dinitrophenoltetrachlorophthalein, like phenoltetrachlorophthalein, does not give a monobenzoate by the Baumann-Schotten reaction.

**Dinitrophenoltetrachlorophthalein Diacetate.**—Ten grams of dinitrophenoltetrachlorophthalein were boiled for half an hour with 70 g. of pure acetic anhydride. The acetate was then extracted a few times with small amounts of boiling alcohol, in which it is practically insoluble. After crystallizing from benzene, pale yellow crystals were obtained melting at  $136^{\circ}$ . The air-dried product lost no weight on standing for several days in an evacuated desiccator over phosphorus pentoxide. The following results were obtained on analysis:

Subst., I, 0.2684; II, 0.2519; cc. 0.1  $N$   $\text{AgNO}_3$ ; I, 16.24; II, 15.25.

Calc. for  $\text{C}_{24}\text{H}_{12}\text{Cl}_4\text{O}_{10}\text{N}_2$ : Cl, 22.52%; for  $\text{C}_{24}\text{H}_{12}\text{Cl}_4\text{O}_{10}\text{N}_2 \cdot 2\text{H}_2\text{O}$ : Cl, 21.30%. Found: I, 21.46; II, 21.47.

On heating some of the air-dried substance in the electric oven to constant weight at  $105^{\circ}$ , one molecule of water is lost.

Subst., I, 0.4131; II, 0.4188; loss (water); I, 0.0114; II, 0.0120.

Calc. for  $\text{C}_{24}\text{H}_{12}\text{Cl}_4\text{O}_{10}\text{N}_2$ :  $\text{H}_2\text{O}$ , 2.78%. Found: I, 2.76; II, 2.86.

When the temperature was raised to  $140^{\circ}$ , the product melted and after heating five hours another molecule of water was lost.

Subst., I, 0.4131; II, 0.4188; loss (water); I, 0.0230; II, 0.0234.

Calc. for  $\text{C}_{24}\text{H}_{12}\text{Cl}_4\text{O}_{10}\text{N}_2$ :  $2\text{H}_2\text{O}$ , 5.41%. Found: I, 5.56; II, 5.59.

In the above determinations no benzene could be detected in the vapors from the material. The anhydrous material thus obtained gave the following results on analysis:

Subst., I, 0.3707; II, 0.4206; cc. 0.1  $N$   $\text{AgNO}_3$ ; I, 23.45; II, 26.58.

Calc. for  $\text{C}_{24}\text{H}_{12}\text{Cl}_4\text{O}_{10}\text{N}_2$ : Cl, 22.52%. Found: I, 22.43; II, 22.41.

Some of the air-dried material which dissolved readily in benzene giving a colorless solution, was then dissolved in acetone and the solution was bright yellow in color. A fraction crystallized from acetone remained constant in weight when kept for several days in a vacuum over phosphorus pentoxide. Moreover, on heating in the electric oven at  $105^{\circ}$  for two hours, there was no loss in weight. When, however, the temperature was raised to  $140^{\circ}$ , the product melted and after heating five hours

it became constant in weight, one molecule of water being lost. Acetone could not be detected in the vapors given off from the material. The substance then gave, on analysis, results for the anhydrous diacetate. Dinitrophenoltetrachlorophthalein diacetate, therefore, crystallizes from benzene with two molecules of water, one molecule being held more firmly than the other. It crystallizes from acetone with only one molecule of water.

Dinitrophenoltetrachlorophthalein diacetate is readily soluble in benzene, acetone and ethyl acetate, but almost insoluble in methyl and ethyl alcohols. It does not dissolve in cold 10% sodium hydroxide solution, but on warming partial saponification takes place, the solution becoming deep orange in color.

**Monobromodinitrophenoltetrachlorophthalein.**—Ten grams of dinitrophenoltetrachlorophthalein were suspended in 200 cc. of glacial acetic acid, and 6 g. of bromine in 25 cc. of glacial acetic acid added dropwise. The dinitro product did not dissolve on boiling the solution. Six grams more of bromine were then added, and the solution heated till the dinitro product was completely dissolved. The clear solution was poured into a large excess of water and the yellow precipitate crystallized from a mixture of acetone and ethyl alcohol. After recrystallizing a few times all fractions showed a sharp melting point of 220–221°. A fraction crystallized from glacial acetic acid showed no variation in the melting point.

The chlorine and bromine determinations on this compound were made by the method already described.<sup>1</sup> After heating, the contents of the tube were dissolved in *dilute* nitric acid, care being taken to keep the solution cold and to avoid large excess of nitric acid. (When these precautions were not taken, a yellow filtrate was always obtained on filtering off the carbon. This was due to free bromine which would be lost and cause low results in the halogen content.)

The following results were obtained on the material dried at 120°:

	Substance. Gram.	Silver halides. Gram.	Tenth-normal silver nitrate.	Chlorine. Per cent.	Bromine. Per cent.
I.....	0.2243	0.2740	18.00 cc.	22.77	12.81
II.....	0.2441	0.2969	19.56 cc.	23.01	12.17
Calculated for $C_{20}H_7BrCl_4N_2O_8$ .....				22.70	12.79

Subst., I, 0.3414; II, 0.3778; cc. 0.1 N HCl; I, 11.00; II, 11.89.

Calc. for  $C_{20}H_7BrCl_4N_2O_8$ : N, 4.48%. Found: I, 4.51; II, 4.41.

The monobromodinitrophenoltetrachlorophthalein was obtained as a bright yellow, crystalline compound, showing slightly more color than the dinitrophenoltetrachlorophthalein, and differing from the latter in its greater solubility in the ordinary solvents. The compound is readily soluble in caustic alkalies and alkali carbonates with a deep orange color. It is insoluble in alkali bicarbonates.

<sup>1</sup> *Am. Chem. J.*, 41, 380 (1909).

**Action of Dry Ammonia on Monobromodinitrophenoltetrachlorophthalein.**—When placed in dry ammonia gas, this compound gradually absorbed five molecules of ammonia and came to constant weight in two days, changing in color from a bright yellow to a dark brown.

Subst., 0.5652; gain in wt., 0.0741.

Calc. for  $C_{20}H_7BrCl_4N_2O_8 \cdot 5NH_3$ :  $NH_3$ , 11.99. Found: 11.59.

When this salt was placed in a tube and a current of dry air passed over it, three molecules of ammonia were lost within an hour. The diammonium salt is not stable and gradually loses ammonia on standing in a desiccator over calcium chloride, at the end of seven days less than one molecule of ammonia remaining. A small amount of ammonia is held indefinitely at room temperature. When, however, this product is heated to  $100^\circ$  for an hour, all ammonia is driven off, and the compound returns to its original color and weight.

**Dibromodinitrophenoltetrachlorophthalein** was obtained as follows: Ten grams of dinitrophenoltetrachlorophthalein were suspended in 200 cc. of glacial acetic acid, and 15 g. of bromine in 25 cc. of glacial acetic acid added. The solution was heated to boiling when the dinitro compound dissolved completely, and at the end of two hours a bright yellow precipitate began to separate from the boiling solution. It was then filtered and the product crystallized from acetone. After recrystallizing a few times, a small amount of a compound with a lower melting point, undoubtedly the monobromo compound, was separated. All fractions then melted sharply at  $271$ – $272^\circ$ , with decomposition. A fraction from glacial acetic acid also had the same melting point. The following results were obtained on analysis:

Subst. Gram.	Silver halides. Gram.	Tenth-normal silver nitrate.	Chlorine. Per cent.	Bromine. Per cent.
0.2787	0.3684	23.31 cc.	19.85	22.11

In the above determination the mixture of silver halides was treated with chlorine and the following results obtained:<sup>1</sup>

Subst. Gram.	Silver halides. Gram.	Decrease. Gram.	Chlorine. Per cent.	Bromine. Per cent.
0.2787	0.3684	0.0340	19.95	21.93
Calculated for $C_{20}H_6Br_2Cl_4N_2O_8$ .....			20.15	22.71

Analysis of the compound for nitrogen gave the following results:

Subst., I, 0.4161; II, 0.3800; cc. 0.1 *N* HCl; I, 11.62; II, 10.33.

Calc. for  $C_{20}H_6Br_2Cl_4N_2O_8$ : N, 3.98. Found: I, 3.91; II, 3.81.

The dibromo compound differs from the monobromo product in its greater insolubility in acetone, glacial acetic acid, benzene, ethyl and methyl alcohols. It is soluble in acetone; less soluble in glacial acetic acid, and only sparingly soluble in methyl and ethyl alcohols and in

<sup>1</sup> *J. Am. Chem. Soc.*, 36, 702 (1914).

benzene. It dissolves in caustic alkalis and alkali carbonates, with a reddish orange color. It is insoluble in alkali bicarbonates.

**Action of Dry Ammonia on Dibromodinitrophenoltetrachlorophthalein.**—This product absorbed five molecules of ammonia in 20 hours and changed from a bright yellow to a bright orange color.

Subst., I, 0.5286; II, 5294; gain in wt.; I, 0.0611; II, 0.0618.

Calc. for  $C_{20}H_6Br_2Cl_4N_2O_8 \cdot 5NH_3$ :  $NH_3$ , 10.97%. Found: I, 10.36; II, 10.45.

When dry air was passed over this salt at room temperature, three molecules of ammonia were lost very readily, the product changing in color from a bright orange to a dark orange color. An analysis made by heating the salt to  $125^\circ$  and collecting the ammonia in standard tenth-normal hydrochloric acid solution, showed that the product was the diammonium salt.

Subst., 0.5530; cc. 0.1 *N* HCl, 13.85.

Calc. for  $C_{20}H_6Br_2Cl_4N_2O_8 \cdot 2NH_3$ :  $NH_3$ , 4.61%. Found: 4.20.

When all of the ammonia was driven off, the product returned to the original weight and color of the dibromo compound. The diammonium salt is not stable in the air, but slowly loses ammonia and takes up moisture. In a desiccator over fused calcium chloride, the ammonia is slowly lost, less than one molecule remaining after standing ten days.

**Diaminophenoltetrachlorophthalein.**—Ten grams of dinitrophenoltetrachlorophthalein were heated with a solution of 100 cc. of absolute alcohol saturated with dry hydrochloric acid gas and 50 g. of crystallized stannous chloride on the water bath for a half hour. Complete reduction of the dinitro compound took place and a copious white precipitate of the double tin salt of the diamino compound separated. This was filtered off, washed with concentrated hydrochloric acid and dissolved in hot water. The tin was removed by passing hydrogen sulfide into the acidified solution and the colorless filtrate carefully neutralized with ammonia. The free base separated as a coffee-brown crystalline powder. It was recrystallized from ethyl alcohol by the addition of water and after crystallizing a few times, obtained as bright orange-colored crystals. The following results were obtained on analysis:

Subst., I, 0.2240; II, 0.2873; cc. 0.1 *N*  $AgNO_3$ ; I, 18.50; II, 23.68.

Subst., 0.4979; cc. 0.1 *N* HCl, 19.87.

Calc. for  $C_{20}H_{12}Cl_4N_2O_4$ : N, 5.77%; Cl, 29.19%. Found: N, 5.59; Cl, I, 29.28; II, 29.23.

The diaminophenoltetrachlorophthalein does not melt even when heated to  $335^\circ$ . It turns dark, however, showing decomposition. It dissolves in caustic alkalis, alkali carbonates, and in ammonia, with a prussian blue color. These alkaline solutions, however, are unstable, and on long standing the color gradually disappears. The diamino compound does not dissolve in alkali bicarbonates. It dissolves in concentrated sulfuric acid with a pink color. On warming slightly no change

takes place, but on adding a small amount of water, the solution becomes colorless. In concentrated hydrochloric acid, the bright orange crystals of the diamino compound are changed to those of the colorless hydrochloride.

**Diaminophenoltetrachlorophthalein Dihydrochloride.**—Two grams of the pure diamino compound were boiled for an hour with 200 cc. of hydrochloric acid solution (1 : 1). The colorless hydrochloride was then filtered off, washed with water containing hydrochloric acid, and dried in the air for one week. The following result was obtained on analysis of the air-dried product:

Subst., 0.1452; cc. 0.1 *N* AgNO<sub>3</sub>, 15.50.

Calc. for C<sub>20</sub>H<sub>12</sub>Cl<sub>4</sub>N<sub>2</sub>O<sub>4</sub>·2HCl: Cl, 38.07%. Found: 37.86.

The hydrochloric acid was determined by weighing portions of the air-dried material into Erlenmeyer flasks, adding water, and heating until the hydrochloride was decomposed. The insoluble free base was filtered off, and the acid in the filtrate determined by titration with standard alkali, enough of the diaminophenoltetrachlorophthalein remaining in solution to act as indicator.

Subst., I, 0.4956; II, 0.3089; cc. 0.1 *N* HCl, I, 17.40; II, 10.94.

Calc. for C<sub>20</sub>H<sub>12</sub>Cl<sub>4</sub>N<sub>2</sub>O<sub>4</sub>·2HCl: HCl, 13.05%. Found: I, 12.80; II, 12.92.

The diaminophenoltetrachlorophthalein dihydrochloride is soluble in water but insoluble in water containing hydrochloric acid. When its aqueous solution is boiled, the salt is decomposed and the free diaminophenoltetrachlorophthalein crystallizes from the solution.

**Tetranitrophenoltetrachlorophthalein.**—This compound was made as follows: 60 g. of phenoltetrachlorophthalein were heated on the water bath to a temperature of 80–90° about an hour with 720 g. of sulfuric acid (sp. gr. 1.84). Complete solution took place and when a small portion was withdrawn and poured into water there was no precipitation of the phthalein, showing that complete conversion into the sulfonic acid had taken place. The solution was cooled to 0° and a mixture of 70 g. of nitric acid (sp. gr. 1.42) and 70 g. of sulfuric acid (sp. gr. 1.84) slowly added and the solution mechanically stirred for an hour, the temperature being allowed to rise to 35°. At the end of this time, the solution became cloudy and the yellow nitration product began to separate out. The nitration mixture was allowed to stand overnight and added to a large amount of water. The crude product was light yellow in color and the yield was about 80%. It was crystallized several times from acetone and obtained in the form of very fine needles, melting at 289–290°. Fractions crystallized from both nitrobenzene and glacial acetic acid showed no change in the melting point. Some of the product, crystallized from acetone, was dried in the air and a weighed amount placed in an evacuated desiccator over phosphorus pentoxide. It stood several

days, and a small amount of mechanically-held solvent was lost. When this material was heated in a drying tube at  $185^{\circ}$ , two molecules of water were given off.

Subst., I, 0.4180; II, 0.6417; loss (water); I, 0.0211; II, 0.0344.

Calc. for  $C_{20}H_6Cl_4O_{12}N_4 \cdot 2H_2O$ :  $H_2O$ , 5.36%. Found: I, 5.05; II, 5.36.

In order to prove that no acetone was given off, the vapors from the drying tube were passed into an absorption bottle containing water. No acetone could be detected by the iodoform reaction.

The anhydrous material gave the following results on analysis:

Subst., I, 0.2464; II, 0.2600; cc. 0.1 *N*  $AgNO_3$ ; I, 15.57; II, 16.34.

Subst., 0.3333; cc. 0.1 *N*  $HCl$ , 21.27.

Calc. for  $C_{20}H_6Cl_4O_{12}N_4$ : N, 8.81%; Cl, 22.51%. Found: N, 8.94; and Cl, I, 22.41; II, 22.28.

The tetranitrophenoltetrachlorophthalein differs from the dinitrophenoltetrachlorophthalein in its greater insolubility in the ordinary organic solvents. It is comparatively soluble in acetone; soluble in acetic acid to the extent of less than one-half per cent., and practically insoluble in methyl and ethyl alcohols and in benzene. It dissolves in caustic alkalies and alkali carbonates with a clear yellow color, more concentrated solutions having an orange color. Unlike the dinitrophenoltetrachlorophthalein, it dissolves in alkali bicarbonates with a yellow color. This behavior shows the stronger acid properties of the tetranitro compound.

**Action of Dry Ammonia on Tetranitrophenoltetrachlorophthalein.**—The anhydrous compound was treated with dry ammonia gas. More than two molecules of ammonia were absorbed in less than one minute, and the product changed from yellow to a deep orange color. At the end of an hour four molecules of ammonia were absorbed, but the product continued to absorb ammonia very slowly for two days, increased very markedly in volume, and finally absorbed five molecules of ammonia.

Subst., I, 0.3975; II, 0.4540; gain in wt.; I, 0.0518; II, 0.0594.

Calc. for  $C_{20}H_6Cl_4O_{12}N_4 \cdot 5NH_3$ :  $NH_3$ , 11.81%. Found: I, 11.53; II, 11.57.

The salt was placed in a tube and a current of *dry* air passed over it, previous work having shown that the salt was quite hygroscopic, absorbing moisture from the air and at the same time losing ammonia. In the course of a few hours, almost three of the five molecules of ammonia were lost. It was then placed in a vacuum over phosphorus pentoxide for several days. No weight was lost after the first day. This compound, according to the calculations from the amount of ammonia still held, was the diammonium salt. This was further verified by heating it at  $150^{\circ}$  and collecting the ammonia in an absorption bottle, containing standard hydrochloric acid solution. The excess hydrochloric acid was then titrated with standard ammonium hydroxide, using methyl red as indicator.

Subst., 0.3975, wt. of salt, 0.4176; cc. 0.1 *N* HCl, 11.80.

Calc. for  $C_{20}H_{16}Cl_4O_{12}N_4 \cdot 2NH_3$ :  $NH_3$ , 5.09%. Found: 4.81.

After heating, the product returned to the original weight and color of the tetranitro compound.

**Tetranitrophenoltetrachlorophthalein Dibenzoate.**—This compound was prepared in the same way as the corresponding dinitro product (page 2490). The yield of the dibenzoate was practically quantitative, and the product appeared as very fine, almost colorless crystals. It was recrystallized from nitrobenzene by the addition of ethyl alcohol. On heating the air-dried product to  $135^\circ$ , no loss in weight ensued. The following results were obtained on analysis:

Subst., I, 0.2269; II, 0.2805; cc. 0.1 *N*  $AgNO_3$ ; I, 10.69; II, 13.21.

Calc. for  $C_{34}H_{14}Cl_4O_{14}N_4$ : Cl, 16.81%. Found: I, 16.71; II, 16.70.

The tetranitrophenoltetrachlorophthalein dibenzoate melts with decomposition at  $285^\circ$ . It dissolves readily in hot nitrobenzene, but is practically insoluble in methyl and ethyl alcohols, ethyl acetate, acetone, ether, benzene, and xylene. It is insoluble in cold dilute sodium hydroxide. On boiling, partial saponification takes place, the supernatant liquid becoming orange in color.

An attempt was made to prepare a benzoate of tetranitrophenoltetrachlorophthalein by means of the Baumann-Schotten reaction. Instead of the expected benzoyl derivative, a potassium salt of tetranitrophenoltetrachlorophthalein was obtained.

**Tetranitrophenoltetrachlorophthalein Diacetate.**—This compound was prepared in the same way as the corresponding dinitro product (page 2491). It was crystallized from ethyl acetate and obtained in pale yellow crystals, which did not possess a sharp melting point, becoming molten when heated in a melting point tube to  $200^\circ$ . The following results were obtained on analysis:

Subst., I, 0.2568; II, 0.2392; cc. 0.1 *N*  $AgNO_3$ ; I, 14.20; II, 13.20.

Calc. for  $C_{24}H_{10}Cl_4O_{14}N_4$ : Cl, 19.70%. Found: I, 19.61; II, 19.57.

Tetranitrophenoltetrachlorophthalein diacetate is readily soluble in xylene and ethyl acetate. It is practically insoluble in methyl and ethyl alcohols, ether, acetone, and benzene. When boiled with dilute caustic alkali, it saponifies slowly, but only partially.

**Tetraaminophenoltetrachlorophthalein.**—Eight grams of tetranitrophenoltetrachlorophthalein were heated on a boiling water bath with 150 cc. of alcohol saturated with dry hydrochloric acid gas, and containing 80 g. of crystallized stannous chloride. The solution was diluted with a large amount of water and evaporated to about one-third of the original volume, in order to get rid of the alcohol. No separation of the amino compound or the tin chloride double salt took place, even on long standing. Hydrogen sulfide was then passed through the solu-

tion, diluted to 250 cc., until all the tin was removed. The filtered solution was evaporated to small bulk and carefully *neutralized* with ammonium hydroxide. The free base appeared as chocolate brown flocks, which were filtered off and dried. By crystallizing from ethyl alcohol, the tetraamino compound was obtained as a light brown, crystalline powder, which did not melt even when heated to 335°. The yield was very small, less than one gram of the purified product being obtained. The following results were obtained on analysis:

Subst., 0.2660; cc. 0.1 *N* AgNO<sub>3</sub>, 20.48.

Calc. for C<sub>24</sub>H<sub>14</sub>Cl<sub>4</sub>O<sub>4</sub>N<sub>4</sub>: Cl, 27.49%. Found: 27.30.

Tetraaminophenoltetrachlorophthalein differs markedly from the corresponding diamino compound in its greater solubility in the ordinary solvents. It dissolves readily in water while the diamino compound is almost insoluble. It dissolves in caustic alkalis and alkali carbonates with a blue color, which is not nearly as intense as that produced by the diamino compound. The alkaline solutions when exposed to the air are much more unstable than those of the diamino compound, the blue color soon changing to green and finally to a straw color.

#### Theoretical.

By the action of nitric acid on phenoltetrachlorophthalein, a dinitro- and a tetranitro-derivative have been prepared. Although the positions of the nitro groups in these compounds have not been proven in this paper, it is logical to assume that the nitro groups enter each phenol molecule in the ortho positions to the hydroxyl groups and in the meta positions to the tetrachlorophthalic acid residue. Schestakoff and Nocken<sup>1</sup> state that both nitro groups in *dinitrophenolphthalein* are in the same phenol residue, but the evidence which they present to establish this view is by no means conclusive.<sup>2</sup> Although these nitro compounds of phenoltetrachlorophthalein are light yellow in color, it is probable that the color is due to the chromophoric action of the nitro groups and therefore the lactoid formula should be assigned to them. The ortho position of the nitro group in the phenol molecule probably conditions the color to some extent; for instance, orthonitrophenol has a marked yellow color, while paranitrophenol is colorless. From the above considerations the following formulas are assigned to the nitrophenoltetrachlorophthaleins (page 2499).

Dinitrophenoltetrachlorophthalein crystallizes from solvents in the anhydrous condition, while the tetranitro compound holds two molecules of water, which are not lost on remaining several days in a vacuum over phosphorus pentoxide. Since the latter compound dissolves readily in alkali bicarbonates, it can best be represented as a hydrate of the carbinol carboxylic acid.

<sup>1</sup> *Ber.*, 47, 331 (1914).

<sup>2</sup> Oddo, *Gazz. chim. ital.*, 43, II, 175 (1913) and *Ber.*, 47, 967 (1914).

Dinitrophenol-tetrachlorophthalein.

Tetranitrophenol-tetrachlorophthalein.

The fact that the tetranitro compound holds two molecules of water, while the dinitro derivative crystallizes in the anhydrous form, may be explained by the more marked acid properties of the former. This is clearly shown by the fact that tetranitrophenoltetrachlorophthalein dissolves in alkali bicarbonates while the dinitro derivative does not, and also by the fact that tetranitrophenoltetrachlorophthalein absorbs *five* molecules of ammonia while the dinitro compound absorbs but *four*. When these abnormal salts are exposed to the air the dinitro compound loses practically all of its ammonia while the tetranitro derivative forms a stable diammonium salt. This latter compound has a deep orange color and is best represented by the following quinoid formula:

Diammonium salt of tetranitrophenoltetrachlorophthalein.

Monobromo- and dibromodinitrophenoltetrachlorophthaleins have been made by the bromination of dinitrophenoltetrachlorophthalein. These compounds have acid properties intermediate between those of the dinitro- and tetranitrophenoltetrachlorophthaleins. That both of

these bromo compounds have stronger acid properties than dinitrophenoltetrachlorophthalein is shown by the fact that they absorb more ammonia and that they have weaker acid properties than the tetranitrophenoltetrachlorophthalein by the fact that they do not decompose alkali bicarbonates. These compounds are therefore best represented by lactoid formulas.

Monobromodinitro-  
phenoltetrachlorophthalein.

Dibromodinitro-  
phenoltetrachlorophthalein.

Phenoltetrachlorophthalein and dinitrophenoltetrachlorophthalein form colorless dibenzoates. Both crystallize from benzene with a molecule of water which is not lost on remaining several days in a vacuum over phosphorus pentoxide. In each case this form is probably the hydrate and not the carbinol acid since they are both insoluble in cold caustic alkalies.

Hydrate of  
phenoltetrachlorophthalein  
dibenzoate.

Hydrate of  
dinitrophenoltetrachloro-  
phthalein dibenzoate.

On heating to  $120^\circ$ , both compounds lose the molecule of water, as shown in the above formulas.

Dinitrophenoltetrachlorophthalein diacetate crystallizes from benzene in very pale yellow crystals, which hold two molecules of water, neither of which is lost on remaining several days in a vacuum over phosphorus pentoxide. On heating to  $105^\circ$  for an hour, one molecule of water is lost, and after continued heating at  $105^\circ$ , or more readily at  $140^\circ$ , the compound melts and the second molecule of water is lost. From acetone the compound crystallizes with only one molecule of water, which is lost

only at 140°. It seems highly probable, therefore, that the product from acetone is the hydrate

while the product from benzene is this hydrate with a molecule of water of crystallization. The fact that the substance is not soluble in the cold in caustic alkalis shows that it is not the carbinol carboxylic acid.

Oddo<sup>1</sup> made dinitrophenolphthalein diacetate, which he describes as a dimorphous body. It is very probable that the white product obtained by him from benzene is a hydrate, while the yellow form, obtained either by heating the white modification above its melting point, or by crystallizing it from alcohol, is the anhydrous diacetate.

Tetranitrophenoltetrachlorophthalein forms a colorless dibenzoate, and a very pale yellow diacetate. Since these compounds are insoluble in alkalis and possess little color, they probably have the lactoid structure and may be represented by the following formula in which Ac represents an acetyl or a benzoyl group:

Diaminophenoltetrachlorophthalein is obtained by the reduction of dinitrophenoltetrachlorophthalein. It dissolves in alkalis with an intense Prussian blue color, while with hydrochloric acid it forms a colorless dihydrochloride, thus exhibiting the properties of both an acid and a base. That the basic properties are weak is shown by the fact that the hydrochloride is readily hydrolyzed by heating its aqueous solution. The structure of these compounds is best represented by the following formulas:

<sup>1</sup> *Gazz. chim. ital.*, 43, II, 175 (1913).

Dipotassium salt of  
diaminophenoltetrachloro-  
phthalein (colored).

Dihydrochloride of  
diaminophenoltetrachloro-  
phthalein (colorless).

Tetraaminophenoltetrachlorophthalein results from the reduction of tetranitrophenoltetrachlorophthalein. Unlike the diaminophenoltetrachlorophthalein, it is readily soluble in hydrochloric acid solution. It dissolves in alkalis with only a faint blue color, which soon disappears on standing, probably owing to the formation of the salt of the carbinol acid. Diamino- and tetraaminophenoltetrachlorophthalein probably are best represented by the following structural formulas:

Diaminophenol-  
tetrachlorophthalein.

Tetraaminophenol-  
tetrachlorophthalein.

It is interesting to note that these phthaleins are *colored* (possibly due to an orthoquinoid condition) and that they form *colorless* salts with acids.

### Summary.

The results of this investigation may be briefly stated as follows:

1. Phenoltetrachlorophthalein has been made from tetrachlorophthalic acid and shown to be a chemical individual and not a mixture of isomers. In all probability both hydroxyl groups occupy the para positions to the methane carbon atom.
2. Dinitro- and tetranitrophenoltetrachlorophthalein have been prepared and the action of ammonia on these compounds has been studied.
3. The diacetates and the dibenzoates of the nitro compounds have been made, thus showing the presence of two hydroxyl groups.
4. The corresponding amino compounds have been obtained by the reduction of the nitro compounds. These compounds have both acid and

basic properties, dissolving in alkalis with a *blue* color and forming *colorless* hydrochlorides.

5. Monobromo- and dibromodinitrophenoltetrachlorophthalein have been prepared and the action of ammonia on these compounds has been studied.

6. The effect of introducing acid groups into the phenoltetrachlorophthalein molecule has been studied. Tetranitrophenoltetrachlorophthalein has the strongest acid properties; dinitrophenoltetrachlorophthalein the weakest, while the monobromo- and dibromodinitrophenoltetrachlorophthalein stand intermediate.

## THE PYROGENETIC DECOMPOSITION OF AMIDES. I.

By R. S. BOEHNER AND C. E. ANDREWS.

Received September 11, 1916.

It is a well-known fact that, on distillation, the acid amides of both the aliphatic and aromatic series decompose to a very slight degree into the corresponding cyanides and water. Wöhler and Liebig<sup>1</sup> passed the vapor of benzamide through a red hot glass tube obtaining a small quantity of an oily liquid which was later identified as phenyl cyanide. In view of the decomposition of alcohols into ethylene hydrocarbons, or ethers, and water, on being passed through hot tubes filled with various materials,<sup>2</sup> it was thought possible that a more complete decomposition of the amides into cyanides and water might be effected by a similar method. Since the products of decomposition of amides, namely the cyanides and water, have a much lower boiling point than the amides, it was thought that the method referred to above might be modified by heating the amides with the contact material in a flask whose outlet was high enough to permit the cyanides and water to distill off, but would cause the amides to condense in the flask and drop back upon the hot contact material. The contact substances used were aluminium oxide, pumice stone, glass, sand, and graphite. By the above method and using the substances mentioned a much more complete decomposition of the amides into the cyanides and water was effected.

### Experimental.

A round-bottomed flask of 100 cc. capacity, containing the contact substance and amide, and provided with a ground-glass stopper with the outlet tube about 25 cm. above the bottom of the glass, was heated in an asbestos air bath. The heating was in each case regulated so that the

<sup>1</sup> *Ann.*, 3, 249 (1832).

<sup>2</sup> Ipatiew, *Ber.*, 34, 596, 3579 (1901); *Ibid.*, 35, 1047, 1057 (1902); *Ibid.*, 36, 1990 (1903); Sabatier and Mailhe, *Compt. rend.*, 146, 1376 (1908); *Ibid.*, 147, 106 (1908); *Ibid.*, 148, 1734 (1909).

cyanide and water formed would distil off but so that at the same time the amide would condense and return to the flask before the outlet was reached. The temperature, measured by a thermometer placed in the bath and outside the flask, naturally varied with the amide used and was probably not accurately observed. It was generally at  $250^{\circ}$  to  $260^{\circ}$ . The operation required about four hours for completion. The escaping water and cyanide vapors were condensed in an ordinary condenser and caught in a receiver cooled and closed as completely as possible in order to avoid loss by evaporation. The amount of cyanide obtained was determined according to the method of Gatterman,<sup>1</sup> a method which is not quantitative but gives low values.

The relative proportions in which to use the amides and contact substance were determined by repeated trials with acetamide and aluminium oxide. The best results were obtained using 50 g. of the oxide to 10 g. of the amide. In all the experiments thereafter 10 g. of any amide were employed and a volume of the finely ground contact substance equal to the volume of 50 g. of aluminium oxide.

In all the experiments the odor of ammonia was noticeable and there was a slight blackening of the contact material due to some slight carbonization.

In the case of formamide it was found that the amide distilled off practically unchanged. The procedure was therefore modified by heating the contact substance alone to  $250^{\circ}$  to  $300^{\circ}$  and then allowing the amide very slowly to drop upon the hot material in the flask. The hydrocyanic acid formed was passed into a solution of caustic potash and the amount of potassium cyanide formed was then determined by precipitation with standard silver nitrate solution and titration of the excess silver by Volhard's process.

Because of the high boiling point of phenylacetamide and its ready sublimation this method was found unsatisfactory, the greater part subliming over before decomposing into the cyanide and water.

### Summary.

Acid amides may be decomposed very largely into the cyanides and water by heating in a flask with various substances—aluminium oxide, pumice stone, sand—the flask being provided with an outlet sufficiently far above the contact substance to permit the more volatile cyanide and water to escape while causing the amides to condense and drop back upon the hot contact material.

## THE PYROGENETIC DECOMPOSITION OF AMIDES. II.

BY R. S. BOEHNER AND A. L. WARD.

Received September 11, 1916.

In the previous paper<sup>1</sup> it has been shown that the acid amides may be decomposed into the cyanides and water by heating with various contact materials but the method used did not permit of an accurate determination of the temperature at which the most complete decomposition could be effected. In order to determine this the amides were passed through hot tubes filled with these contact substances, the temperature being determined by a Hoskins' pyrometer. Using this method a temperature of about 425° was found to give the best results when passing acetamide through a tube filled with aluminium oxide and this temperature was employed in working with the other contact materials. It has thus been possible to effect practically a complete decomposition of the amides into cyanide and water, allowance being made for the lack of quantitative methods for the determination of the cyanides under the conditions obtaining in this work.

### Experimental.

Combustion tubing wrapped in asbestos paper was wound with "Nichrome" ribbon, this covered with several layers of asbestos paper, and the whole placed in an iron pipe which was also covered with asbestos paper. The current from a 110 volt lighting circuit served to give the required temperature. The pyrometer couple was enclosed in a hard glass tube before being placed in the combustion tubing. A. Mailhe,<sup>2</sup> endeavoring to reduce the amides by passing their vapors mixed with hydrogen over reduced nickel and copper, obtained unsatisfactory results because of the lack of volatility of the amides. In order to overcome this difficulty air was passed through the slightly boiling amide contained in a flask and thence passed by means of a glass tube into the furnace. In this way 20 g. of amide were completely and satisfactorily volatilized and carried over the contact material in the course of about five hours. In the case

<sup>1</sup> THIS JOURNAL, 38, 2503 (1916).

<sup>2</sup> Chem. Ztg., 31, 1146 (1907).

of-benzamide, however, it was found that the tube connecting the flask and furnace became clogged with the solid amide. Benzamide, contained in a porcelain boat, was therefore placed directly in the end of the inner tube of the furnace, and air passing over this when heated serving to carry it forward over the contact material. The pyrometer in this case measured the temperature between the two tubes of the furnace. The products of decomposition in all cases passed into a condenser and were collected and determined by the method mentioned in the previous paper.<sup>1</sup>

To determine what effect, if any, the air would have on the reaction below the point at which oxidation might take place, nitrogen was substituted for air and determinations were also made in which the amide vapors were made to pass over the contact material without the aid of gases. The amounts of methyl cyanide obtained from 20 g. of acetamide using aluminium oxide and pumice stone, respectively, as contact substances at a temperature of 425°, were as follows:

Aluminium oxide and with acetamide.

In presence of air gave	11.4 g. CH <sub>3</sub> CN.	82% of theory
In presence of nitrogen gave	9.3 g. CH <sub>3</sub> CN.	66.2% of theory
Without gases gave	7.2 g. CH <sub>3</sub> CN.	53.2% of theory

Pumice stone and acetamide.

	12.7 g. CH <sub>3</sub> CN.	91.5% of theory
	8.0 g. CH <sub>3</sub> CN.	57.5% of theory
	2.5 g. CH <sub>3</sub> CN.	18.0% of theory

Acetamide and propamide vapors along with air were passed through empty tubes, 10.8% and 10% of the theoretical yield being respectively obtained.

The general results are given in the following table, air being used in each case with 20 g. of amide at a temperature of about 425°:

TABLE I.

Substance.	Aluminium oxide.		Pumice stone.		Sand.		Graphite.	
	Wt. of cyanide.	% of theory.	Wt. of cyanide.	% of theory.	Wt. of cyanide.	% of theory.	Wt. of cyanide.	% of theory.
Acetamide.....	11.4	82.0	12.7	91.5	12.0	86.3	10.5	75.5
Propamide.....	13.0	86.1	13.5	89.4	13.5	89.4	..	..
Normal-butyramide.	13.2	83.0	14.0	88.0	14.0	88.0	..	..
Iso-butyramide.....	..	..	14.5	91.2	..	..	..	..
Iso-valeramide.....	..	..	14.7	89.1	..	..	..	..
Caproamide.....	13.9	80.9	15.0	89.3	..	..	..	..
Benzamide.....	..	..	..	..	13.6	90.6	..	..

The contact materials here used may be arranged in order of efficiency in promoting the decomposition of the amides as follows: Pumice stone, sand, aluminium oxide, and graphite. The variations in extent of decomposition with the different contact materials are but small and we are of the opinion that they may be explained by the differences in the state of division of the particles of the contact substances, the more finely divided providing a larger surface and being the more effective.

<sup>1</sup> THIS JOURNAL, 38, 2503 (1916).

A. Mailhe's<sup>1</sup> reduction of the amides to amines by passing the vapors of the former along with hydrogen over finely divided nickel and copper may be explained by assuming that the amides decompose into the cyanide and water and that the cyanides were then reduced to the amines. On passing acetamide over finely divided nickel at 180° to 200° without hydrogen it was found that a slight decomposition into cyanide and water had taken place.

### Summary.

The acid amides may be completely decomposed into the cyanides and water by passing their vapors along with air over various contact material at a temperature of about 425°.

## RESEARCHES ON AMINES. VI. THE UTILIZATION OF HYPOCHLORITE COLOR REACTIONS IN ESTABLISHING THE MECHANISM OF THE ACTION OF DIMETHYLSULFATE ON ANILINE.

By NORMAN A. SHEPARD.

Received August 19, 1916.

The method of alkylating amines recently proposed by Werner,<sup>2</sup> by means of which monomethylated amines can be obtained by alkylation with dimethylsulfate in benzene solution, gave promise of important practical applications. According to this investigator a primary amine like aniline and this ester interact in molecular proportions, under such conditions, giving practically a quantitative yield of the methylsulfuric acid salt of the monomethylated derivative. The transformation was expressed by him in the following manner:

Having occasion to apply this method for the production of methyl  $\beta$ -phenylethylamine,  $\text{C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{NHCH}_3$ , the writer was surprised to find that the crystalline addition product formed by interaction of dimethylsulfate and  $\beta$ -phenylethylamine did not give the desired alkyl derivative when decomposed with alkali. On the contrary, the greater portion of the original amine was recovered unaltered. In order to determine the cause of the failure to obtain alkylation in this case, attention was naturally turned to a study of Werner's reaction. This work has now been completed and the purpose of this paper is to record new data that have been obtained, which are not in accord with his interpretation.

Previous to the work of Werner, Ullmann<sup>3</sup> had investigated the be-

<sup>1</sup> *Chem. Ztg.*, 31, 1146 (1907).

<sup>2</sup> *J. Chem. Soc.*, 105, 2762 (1914).

<sup>3</sup> *Ann.*, 327, 104 (1903).

havior of dimethylsulfate toward aniline. According to him, *two* molecular proportions of the base react with *one* of the ester in ether solution, forming one molecule of the methylsulfuric acid salt of aniline and leaving one molecule of monomethylaniline in solution as expressed in the following equation:

The writer has now obtained data which indicate clearly that the interpretation of Ullmann is the correct one. Using equimolecular proportions of aniline and ester and following the directions of Werner exactly, not only did the crystalline addition product prove to be the methylsulfuric acid salt of the *unalkylated* base, but the yields produced in no case approached the theoretical value based on his equation. In fact, these yields were only approximately one-half what should have been produced according to Equation 1. While 9.3 g. of aniline should yield theoretically 21.9 g. of addition product, in six separate experiments, taking special precautions to keep the temperature low and exclude moisture, the yields actually obtained were 13.7, 9.9, 11.2, 10.25, 12.5 and 11.1 g., respectively. On the other hand, these yields approach very closely the calculated value according to Ullmann's interpretation, 10.25 g., in fact, being exactly the theoretical quantity based on Equation 2. That the addition product was the methylsulfuric acid salt of aniline and not methylaniline, was shown by decomposing it with strong alkali. The base, which separated as an oil, was identified as unaltered aniline by its color reaction with hypochlorite solution, by conversion into its hydrochloride, and further by transformation into *sym.* diphenylthiourea when treated with phenylisothiocyanate. Thus the yields and chemical nature of the crystalline addition product confirm the conclusions of Ullmann.

The course of the reaction, however, varied somewhat from that described by Ullmann. It will be seen, when using equimolecular proportions of ester and base, that, after the first stage of the reaction is complete, one-half of the dimethylsulfate should still remain unaltered. This complicates the reaction considerably, for the monomethylaniline does not remain free in the benzene solution under such conditions, but separates in the form of an oil as the salt of methylsulfuric acid as expressed in Equation 3, and the tertiary base simultaneously formed, can then also

$$2\text{CH}_3\text{NHC}_6\text{H}_5 + (\text{CH}_3)_2\text{SO}_4 = \text{C}_6\text{H}_5\text{NHCH}_3.\text{CH}_3\text{SO}_4\text{H} + \text{C}_6\text{H}_5\text{N}(\text{CH}_3)_2 \quad (3)$$

further react with the excess of ester, giving a methylsulfuric acid salt, as has been shown by Claesson and Lundvall.<sup>1</sup> These various stages in the reaction can actually be demonstrated by keeping the temperature of the reaction mixture at 0°. The progress of the alkylation can then be readily observed and followed by means of the hypochlorite

<sup>1</sup> *Ber.*, 13, 1703 (1880).

color reactions. If the oily addition product, formed in the second stage of the reaction, begins to separate before the crystalline product is removed, it clings very tenaciously to the latter and it is for this reason that the yields of the latter recorded above lack greater uniformity. This oil was never entirely homogenous. It consisted chiefly of the methylsulfuric acid salt of methylaniline but always contained some aniline and dimethylaniline also in combination as methylsulfuric acid salts. The product of the reaction was thus *not* exclusively a salt of monomethylaniline as claimed by Werner, but a mixture consisting of the salts chiefly of unaltered material with some mono- and di-alkylated base, but with these latter forms not in sufficient quantity to make the application of equimolecular proportions of base and ester in cold benzene solution of any practical value for alkylating purposes.

Further proof for Ullmann's interpretation of this reaction is found in the fact that the yield of crystalline addition product is largely increased on using two molecular proportions of aniline. Werner states, to the contrary, that under these conditions the excess of aniline was recovered unaltered in the mother liquors. The writer finds that the yield is largely increased with these proportions, giving 88% of the theoretical quantity of crystalline addition product based on Equation 2.

Werner based his entire proof, that the crystalline product was a derivative of methylaniline, on a hypochlorite color reaction for this base. In view of the fact that Beilstein's *Handbuch*<sup>1</sup> states that this base gives no coloration with bleaching powder solution, as is also stated of both methyl- and dimethylaniline in the latest edition of Richter's *Organische Chemie* (1913), it seemed of distinct value to make a comparative study of all the hypochlorite color reactions of these three bases. It was found that, under certain conditions, each of these bases gives a well-defined and characteristic color reaction with bleaching powder solution and the results of this work are recorded in Tables I and II, illustrating the behavior in different concentrations. The deep reddish purple coloration produced by aniline in neutral or alkaline solution with bleaching powder solution, discovered by Runge,<sup>2</sup> confirmed by Hofmann,<sup>3</sup> and carefully studied by Nietzki,<sup>4</sup> is a very satisfactory color test for this base. The writer has found, however, that in the presence of large amounts of methylaniline (25% or more), the test is unreliable, giving only an indefinite brown precipitate with no purple coloration. The first observation, as far as the writer is aware, of a hypochlorite color reaction for methyl- and dimethylaniline, is recorded by Willm and Girard.<sup>5</sup> These investigators

state that the former gives a dark blue-violet and the latter a yellow color with bleaching powder solution, but no mention of the conditions, such as concentration or acidity, under which these colors were obtained, was made. Three years previous to this, Hofmann<sup>1</sup> made the observation that methylaniline gives no coloration with hypochlorite solution, which is absolutely correct, *provided the solution is neutral*. In *alkaline* solution Leech<sup>2</sup> has recently shown that this base gives a fine transient navy blue, easily distinguishable from the aniline coloration. The writer has found this test to be very satisfactory indeed and more sensitive to traces of methylaniline than the method of testing in *acid* solution employed by Werner (cf. Table II). This latter method consists in adding bleaching powder solution and then a few drops of dilute sulfuric acid to an aqueous solution of the base, when a deep indigo-blue color develops if methylaniline is present. This test is very brilliant and quite satisfactory, provided the reagents are added in the order given above, *i. e.*, bleaching powder solution *first* and *then* the acid. It has now been found on the other hand that if the order of adding the reagents is reversed and the bleaching powder solution is added to an acid solution of the base, aniline also will give a deep navy blue color, very easily confused with that produced by methylaniline. In fact only on very careful observation can the two colors be distinguished, but when compared side by side it was found that the blue produced by aniline is less brilliant, almost always murky and distinctly more fugitive than that produced by methylaniline. On short standing (about one hour), it changes to a murky brown suspension, while the test with methylaniline will remain clear and retain its intensity without appreciable fading for twenty-four hours. Even after forty-eight hours the color is still quite brilliant. It is advisable in this test to use a moderate excess of bleaching powder solution, but an excess of sulfuric acid should be avoided.

It can now readily be seen how Werner drew wrong conclusions from his color test. A water solution of the crystalline addition product,  $C_6H_5NH_2 \cdot CH_3SO_4H$ , is strongly acid to litmus paper and therefore on adding bleaching powder solution all conditions are favorable for producing the navy blue color from aniline. The writer has found that the water solution of his addition product gives an excellent deep navy blue when tested as Werner directed. If, however, the methylsulfuric acid is first neutralized before testing, this navy blue color is not obtained and the familiar reddish purple of aniline appears. As Werner made no attempt apparently to liberate the free base and identify it other than through this color reaction, he failed to realize that this navy blue was not peculiar

<sup>1</sup> *Ber.*, 7, 526 (1874).

<sup>2</sup> *THIS JOURNAL*, 35, 1042 (1913).

to methylaniline alone and therefore gave an erroneous interpretation to his reaction.

To identify dimethylaniline, Werner employed the deep orange-yellow color reaction, first mentioned by Willm and Girard,<sup>1</sup> but he does not state the conditions necessary for the successful production of this coloration. The writer finds that this test is very satisfactory and reliable, provided it is carried out in a slightly *acid* medium, for this base gives no coloration in neutral or alkaline solution. Strong acid solutions, however, should be avoided, for the test may be entirely negative under such conditions; the yellow color is quickly destroyed by alkalies or a large excess of calcium hypochlorite solution.

### Experimental Part.

The Action of Dimethylsulfate on Aniline at Room Temperature.—To 9.3 g. of aniline (freshly distilled) in 75 cc. of benzene (distilled over

<sup>1</sup> *Loc. cit.*

sodium), 12.6 g. of dimethylsulfate (1 mol) in 25 cc. of benzene were added cooling at first to prevent any rise in temperature. Every precaution was taken to have all the reagents absolutely dry and the ester was washed with sodium bicarbonate to remove any methylhydrogen sulfate, carefully dried and then twice distilled *in vacuo* before use. The crystalline addition product began to separate almost immediately and, after standing for 24 hours at room temperature, was filtered by suction. A thick, yellow oil adhered to the crystals, which was partially removed by thorough pressing out and washing with benzene. After drying over concentrated sulfuric acid, the last traces of this oily material were pressed out on a porous plate. The weight was then 9.9 g. The yield of this crystalline addition product will vary considerably; in three duplicate experiments 9.3 g. of aniline yielded 13.7, 11.2, and 10.25 g., respectively. In every case, even after long drying, the products were oily and did not melt sharply. The water solution was acid but did not give a precipitate with barium chloride. When this addition product was decomposed in aqueous solution with strong potassium hydroxide, a yellowish brown oil separated, which was extracted with ether and dried over caustic potash. Dry hydrochloric acid was then passed into this ether solution, when aniline hydrochloride separated as crystals melting at  $198^{\circ}$ .

The benzene mother liquor from the crystalline product contained a yellow oil, insoluble in benzene, which became dark green on standing. The benzene was decanted from this oil and allowed to stand, when more oil gradually deposited. An aqueous solution of this oil was acid to litmus, gave no test for sulfates with barium chloride, but gave a strong color reaction for methylaniline. When decomposed with sodium hydroxide, 1.4 g. of mixed bases were liberated. Treatment of this mixture with phenylisothiocyanate gave 0.5 g. of *sym.* diphenylthiourea (corresponding to 0.2 g. of aniline) and 0.7 g. of methyldiphenylthiourea (corresponding to 0.3 g. of methylaniline). These urea derivatives were separated by crystallization from alcohol, when the former separated in plates, melting at  $150-1^{\circ}$ . The alcohol mother liquor did not deposit crystals and it was only after removing the alcohol, triturating with petroleum ether and cooling to  $-16^{\circ}$ , that the methyldiphenylthiourea would deposit in a crystalline state. This was then recrystallized from alcohol when it separated in stout prisms, melting at  $85-7^{\circ}$ . No lowering of the melting point was observed, when both these urea derivatives were mixed with the corresponding pure substance. Extraction of the residues from the mother liquors of the thiourea derivatives, with dilute hydrochloric acid and neutralization of the resulting solution with potassium hydroxide, gave 0.6 g. of a light brown oil. The solution of this oil in 3.0 g. of 20% hydrochloric acid, cooled to  $-5^{\circ}$  and then treated with 0.35 g. of sodium nitrite dissolved in the least possible quantity of water, deposited 0.5 g.

of a deep orange-yellow powder, which decomposed with explosive violence at  $165-7^{\circ}$ . Though decomposing somewhat low, it agreed in all its properties with *p*-nitroso-dimethylaniline hydrochloride (m. p.  $177^{\circ}$ ), which was prepared for comparison.

The original benzene solution was now allowed to evaporate spontaneously. About 2.0 g. of oil remained, which was soluble in water. Bleaching powder solution showed this to be a mixture of dimethylaniline with some methylaniline, both in the form of salts. An aqueous solution is acid, but gives no precipitate with barium chloride.

**The Action of Dimethylsulfate on Aniline at  $0^{\circ}$ .**—The above reaction was repeated, using the same proportions, but allowing the reaction to proceed at continued low temperature in a refrigerator. After standing for 15 hours, the crystalline addition product was pure white but, at the end of 18 hours, a very light yellow color was beginning to appear. Upon filtering at once, 12.5 g. of addition product (after drying over sulfuric acid) were obtained. It was only very slightly oily and no oil had as yet separated in the benzene mother liquor. In a duplicate experiment, also carried out at  $0^{\circ}$ , the salt was filtered after 3.5 hours. The deposition of addition product was not yet complete, under these conditions, but there was no oil and the product was pure white. On standing 16 hours longer, still at  $0^{\circ}$ , the remainder of the product, separating in crystalline leaves and free from any oil, deposited, bringing the total yield up to 11.1 g. It melted sharply at  $158-60^{\circ}$ , gave no test for sulfate and on prolonged exposure to the air did not appear particularly hygroscopic. The aqueous solution was strongly acid and gave a strong color reaction for aniline with calcium hypochlorite after neutralization with alkali. Liberation of the free base with alkali and treatment with phenylisothiocyanate gave *sym.* diphenylthiourea in 66% yield (after complete purification).

Calc. for  $C_7H_{11}O_4NS(C_6H_5NH_2 \cdot CH_3SO_3H)$ : N, 6.83. Found: N, 6.67, 6.68.

Titration with 0.1061 *N* KOH, using phenolphthalein as the indicator:

I. 0.1803 g. required 8.35 cc. II. 0.4039 g. required 18.75 cc. KOH.

Calc. for  $C_7H_{11}O_4NS$ :  $CH_3SO_3H$ , 54.63. Found:  $CH_3SO_3H$ , 55.06, 55.19.

The benzene mother liquor, containing *no* oil, was allowed to stand at  $0^{\circ}$ . The yellow oil soon began to separate. The benzene was decanted after 29 hours' standing at  $0^{\circ}$  and then let stand at room temperature for 2 days. A second crop of oil had then separated. The benzene solution, which, previous to the second deposition of oil, had given color tests for both mono- and di-methylaniline, now gave *no* test for the former, but a strong test for the latter. The combined oily layers weighed about 6.0 g., but contained a considerable quantity of benzene. This yellow oil turned green on standing as before and an aqueous solution was acid to litmus but gave no test for sulfuric acid. It gave a strong test for

methylaniline, but was not homogeneous, for, on conversion into thio-urea with phenylisothiocyanate as in the previous experiment, 1.6 g. of free bases gave about 0.3 g. of *sym.*-diphenylthiourea (corresponding to 0.12 g. of aniline), 1.5 g. of methyl-diphenylthiourea (corresponding to 0.7 g. of methylaniline), and 0.2 g. of dimethylaniline was extracted from the residues by hydrochloric acid. The last product was identified by the deep yellow coloration produced by bleaching powder in acid solution.

The benzene mother liquor from the yellow oil left a residue of 2.7 g. on spontaneous evaporation, which consisted of a light yellow syrup containing a few drops of a non-miscible brownish oil, which did not dissolve when treated with water. This was extracted with ether (weight = 0.10 g.); it was not dimethylaniline as shown by color tests, but, on boiling with caustic soda, the white precipitate with barium chloride in acid solution indicated that it was unaltered dimethylsulfate. The water soluble portion of the above residue gave no precipitate with barium chloride until saponified with boiling alkali; the test for sulfate was then strong. Sodium hydroxide liberated 0.15 g. of oil which was identified, by its color reactions and also by conversion into *p*-nitrosodimethylaniline hydrochloride, as dimethylaniline.

**The Action of One Molecular Proportion of Dimethylsulfate on Two Molecular Proportions of Aniline at 0°.**—Three and five-tenths grams of dimethylsulfate in 7 cc. of benzene were added to 5.2 g. of aniline (2 molecular proportions), in 21 cc. of benzene and the mixture allowed to stand for 16 hours in a refrigerator. The product, which was not oily, weighed 5.0 g. after standing for one week over concentrated sulfuric acid. This yield corresponds to 88% of the theoretical quantity, calculated from Ullmann's equation. The benzene mother liquor was a light brown color and contained no oil. This was allowed to stand for 8 hours at 0°; no oil deposited. A water extract of a portion of the now deep brown benzene solution gave a strong color test for methylaniline. After standing for several days at room temperature, only a trace of oil separated.

NEW HAVEN, CONN.

## ACTION OF OXALYL CHLORIDE ON PRIMARY, SECONDARY AND TERTIARY ALCOHOLS.

BY ROGER ADAMS AND L. F. WEEKS.

Received August 5, 1916.

Staudinger,<sup>1</sup> who was the first to find a convenient method for the preparation of pure oxalyl chloride, studied several of its reactions. He found that it reacted normally with ethyl alcohol to give ethyl oxalate,

<sup>1</sup> *Ber.*, 41, 3558 (1908); 46, 1426 (1913); *Chem. Zentr.*, 1910, I, 307.

with ammonia and amines to give oxamides. He used it in certain Friedel and Craft's<sup>1</sup> syntheses in the hope of preparing 1,2-diketones, but obtained such compounds in only a few cases. In general, the reaction products were the same as he would have obtained if he had used phosgene. Thus, oxalyl chloride had broken down to phosgene and carbon monoxide before reacting. Staudinger<sup>2</sup> studied the action of oxalyl chloride in Friedel and Craft's reactions more carefully a few years later, and found that the speed of the reaction had much to do with the products which resulted; if a fairly active hydrogen was present in the benzene molecule, as the para hydrogen in anisol, then the reaction took place quickly, and anisil was produced; if unsubstituted benzene were used where there is no active hydrogen, then the oxalyl chloride decomposed first and benzophenone was produced. Liebermann<sup>3</sup> studied the action of oxalyl chloride with and without anhydrous aluminum chloride, on anthracene, ditolyl, indene, etc., and obtained similar results. If he used high temperatures and no aluminum chloride, products the same as those which would form from phosgene were produced, at low temperatures and in the presence of aluminum chloride diketones. In every case, however, the yields of the diketones were small.

The action of oxalyl chloride on mercaptans<sup>4</sup> gave thioesters and on aminoacids,<sup>5</sup> hydrazines,<sup>6</sup> ureas,<sup>7</sup> the normal oxalic acid derivatives in practically all cases, a few exceptions<sup>8</sup> being noted when oxalyl chloride acted like phosgene.

One other interesting and general reaction of oxalyl chloride was discovered by Staudinger<sup>9</sup> who noted the similarity of oxalyl chloride to certain inorganic acid chlorides. Various aldehydes and ketones reacted very readily with it, and gave good yields of products the same as those obtained with phosphorus pentachloride.

Sometime ago it was found in this laboratory,<sup>10</sup> that oxalyl chloride and pyridine reacted at low temperatures with phenols to give quantitative yields of the phenyl or substituted phenyl esters. It was observed, however, during this work, that if the reactions between certain of the phenols and oxalyl chloride were carried out at room or at higher temperatures,

dehydration products and not simple esters resulted. It seemed possible, therefore, that if oxalyl chloride were made to react with alcohols under the right conditions, it might act as a dehydrator and ethylene derivatives would result. Oxalyl chloride would be an especially good reagent for such a purpose, since all of the products of the reaction, except the unsaturated compound, would be gaseous. To test this we have taken different types of primary, secondary and tertiary alcohols and tried the action of oxalyl chloride on them. Different alcohols yielded different products, and although we have not yet studied a sufficient number so that a complete generalization may be made as to the exact reaction which will take place, we give below the results already in hand.

As characteristic primary alcohols, we chose *n*-propyl, isobutyl, isoamyl and benzyl alcohols, and allowed oxalyl chloride to act directly on them at room temperatures in the proportion of two molecules of alcohol to one of acid chloride. In each case, immediate reaction took place, and simple esters formed, just as Staudinger found with ethyl alcohol. The esters resulting were very pure and the yields were practically quantitative. For a rapid and convenient method of obtaining small amounts of pure oxalic acid esters of primary alcohols, the above is certainly to be recommended. We tried glycol also, and used the proportion one molecule of diatomic alcohol to one molecule of oxalyl chloride; the cyclic ester, ethylene oxalate, resulted.

For secondary alcohols, we studied benzhydrol, phenyl methyl carbinol and menthol. Benzhydrol in benzene solution gave a small yield of a white solid which proved to be benzhydryl ether. Phenyl methyl carbinol and menthol we treated without a solvent, and obtained in both cases as principal products the corresponding unsaturated compounds styrene and menthene. Small amounts of impure higher boiling products which formed in these last two reactions, we have not worked up, but the boiling points indicated that they were not the corresponding chlorides or oxalates. It was very possible, therefore, that in these instances some carbonates had formed. In general, the purity and yields of the products from the secondary alcohols were not very satisfactory. Possibly a change in conditions, however, might improve them.

For tertiary alcohols, we chose trimethyl carbinol, dimethylethyl carbinol, triphenyl carbinol and pinakone, and treated in each case (except with pinakone) two molecules of alcohol with one of chloride; with pinakone we used one molecule of alcohol to one of chloride. The triphenyl carbinol was dissolved in benzene, but no solvent was used with the others. Instantaneous reaction took place, and the first three yielded chlorides, oxalic acid separating out at the same time. Although the yields and the purity of the chlorides were not so extremely good as the yields and purity of the esters formed by the action of primary alcohols,

still they were very satisfactory. Pinakone reacted differently, as might be expected, since there is a great tendency here for water to split out and for a subsequent rearrangement into pinakoline. We were able to isolate two products, pinakoline and a solid which proved to be the corresponding carbonic acid ester. Here oxalyl chloride reacted like phosgene, and each chlorine atom then combined with a hydrogen atom of a hydroxyl group, yielding a cyclic carbonate.

In conclusion, our work has shown that oxalyl chloride reacts in several ways with alcohols. Primary alcohols go very smoothly to esters, most tertiary alcohols give good yields of chlorides, secondary alcohols and certain tertiary alcohols yield different types of products, dehydration products, such as ethers, or more generally, where such a reaction is possible, unsaturated compounds with small amounts of carbonic acid derivatives as secondary products.

We are now studying the action of oxalyl chloride and pyridine at low temperatures on different kinds of alcohols, and have already obtained oxalates with certain secondary alcohols. We hope this will be general with all alcohols, in which case, on account of the ease of formation at such a low temperature, the quantitative yields produced, and the ease with which the compounds produced, crystallize, we will show oxalyl chloride to be a convenient and valuable reagent for hydroxyl groups.

#### EXPERIMENTAL PART.

##### Primary Alcohols.

1. *N*-Propyl Alcohol, Isoamyl Alcohol, Isobutyl Alcohol.—In these experiments, a small boiling flask with the side arm attached to a condenser was used. The neck of the flask was fitted with a cork stopper holding a separatory funnel. The pure alcohols (2 mols), *n*-propyl, isobutyl or isoamyl, were placed in the flask and oxalyl chloride (1 mol) was allowed to drop very slowly from the funnel into the alcohol. The contents of the flask immediately heated up and fumes of hydrochloric acid gas were given off. When all the oxalyl chloride had been added, the contents of the flask were simply distilled. The weight of the crude distillate in each case corresponded to practically a quantitative yield of ester. On careful redistillation very pure esters resulted.

*n*-Propyl oxalate,  $(C_3H_7)_2C_2O_4$ , b. p. 211–212°.

Isobutyl oxalate,  $(C_4H_9)_2C_2O_4$ , b. p. 228–229°.

Isoamyl oxalate,  $(C_5H_{11})_2C_2O_4$ , b. p. 267–268°.

2. Benzyl Alcohol.—Benzyl alcohol (2 mols) was heated with oxalyl chloride (1 mol) in the same manner as the above alcohols. After the addition of the chloride, however, the reaction product was allowed to cool and a white crystalline mass formed in the flask. This was crystallized from alcohol, thus yielding practically a quantitative yield of pure benzyl oxalate.

Benzyl oxalate,<sup>1</sup>  $(C_6H_5CH_2)_2C_2O_4$ , m. p. 80.5–81.5°

3. **Glycol.**—Oxalyl chloride (1 mol) and glycol (1 mol) were allowed to react and then cooled as in the case of the benzyl oxalate. A pasty mass formed which, crystallized from ethyl oxalate, gave a m. p. 153°, and was undoubtedly the same compound as that which Bischoff<sup>2</sup> obtained from ethyl oxalate and glycol.

Ethylene oxalate,  $C_2H_4C_2O_4$ , m. p. 153°.

### Secondary Alcohols.

1. **Benzhydrol.**—A small flask with the benzhydrol (2 mols) dissolved in warm benzene was fitted with a stopper holding a reflux condenser and a small dropping funnel containing the oxalyl chloride (1 mol). The oxalyl chloride was allowed to run in slowly and the mixture then refluxed for half an hour. On spontaneous evaporation, an oil resulted which, on standing, gradually solidified to a pasty crystalline mass. This was clay-plated, then crystallized from alcohol, and was proved by analysis to be benzhydrol ether. The yield was about 30% of the theory. M. p. 107.5–108°.

Calc. for  $[(C_6H_5)_2CH]_2O$ : C, 89.14%; H, 6.28%. Found: C, 88.72; H, 6.45.

2. **Phenyl Methyl Carbinol.**—Phenyl methyl carbinol (2 mols) in an apparatus similar to that used for the primary alcohols was treated with oxalyl chloride (1 mol). The reaction mixture was distilled under diminished pressure (about 40 mm.) and yielded a main fraction boiling under 100° and a small fraction boiling at a much higher temperature. Oxalic acid remained behind in the distilling flask. The chief product was treated with bromine until no more was readily absorbed at a low temperature. A white crystalline mass resulted which after one recrystallization proved to be pure styrene bromide, thus showing styrene to be the main compound formed in the reaction. The small portion of higher boiling material was not studied further.

3. **Menthol.**—The reaction was carried out in the same way as for phenyl methyl carbinol, except that here a simple instead of a vacuum distillation was undertaken. Most of the distillate came over below 215° and rapidly absorbed bromine to form menthene bromide, thus proving menthene to be the chief product of the reaction. The material boiling above 215°, as it was so small in amount and so impure, was not studied further, but since it was higher boiling than menthyl chloride and lower boiling than menthyl oxalate, we concluded it was probably impure menthyl carbonate.

### Tertiary Alcohols.

1. **Trimethyl Carbinol, Dimethylethyl Carbinol.**—The same apparatus was used as for the primary alcohols. During the addition of the oxalyl

<sup>1</sup> *Ber.*, 35, 3441 (1902).

<sup>2</sup> *Ibid.*, 40, 2806 (1907).

chloride, oxalic acid gradually separated out of the reaction mixture. On distillation trimethyl chloromethane, in one case, and dimethyl ethyl chloromethane in the other, were produced in good yields. On redistillation, the chlorides were readily purified.

Trimethyl chloromethane,  $(\text{CH}_3)_3\text{CCl}$ , b. p.  $51-52^\circ$ . Dimethyl ethyl chloromethane,  $(\text{CH}_3)_2\text{C}_2\text{H}_5\text{CCl}$ , b. p.  $84-86^\circ$ .

2. **Triphenyl Carbinol.**—Triphenyl carbinol (2 mols) was dissolved in benzene in an ordinary flask, the stopper of which was fitted with a reflux condenser and a dropping funnel holding the oxalyl chloride (1 mol). On addition of the chloride, instantaneous reaction took place. After warming gently a short time, the mixture was allowed to evaporate and the resulting solid crystallized from benzene. It proved to be triphenyl chloromethane.

Triphenylchloromethane,  $(\text{C}_6\text{H}_5)_3\text{CCl}$ , m. p.  $100-101^\circ$ .

3. **Pinakone.**—Pinakone (1 mol) was treated directly with oxalyl chloride (1 mol) in an apparatus similar to that used with the primary alcohols. On distillation of the reaction mixture, a liquid boiling between  $100-128^\circ$  resulted, which proved to be impure pinakolin. A reddish residue left in the flask solidified on cooling and crystallized from alcohol in long, white needles, which on analysis were found to be the carbonate of pinakone. M. p.  $176-177^\circ$ .

Calc. for  $[(\text{CH}_3)_2\text{C}]_2\text{CO}_3$ : C, 58.33%; H, 8.33%. Found: C, 58.34; H, 8.28.

## THE CRYSTALLIZATION OF CALCIUM TARTRATE.

By F. D. CHATTAWAY.

Received September 13, 1916.

Few salts have been more frequently prepared than calcium tartrate on account of its employment for the recognition of the acid and it is therefore surprising to find that little is known of its behavior when crystallizing from aqueous solution. When a soluble calcium salt is added to a neutral solution of a soluble tartrate the compound which first separates is not the ordinary orthorhombic tetrahydrated salt,  $\text{C}_4\text{H}_4\text{O}_6\text{Ca} \cdot 4\text{H}_2\text{O}$ , but a hexahydrated form,  $\text{C}_4\text{H}_4\text{O}_6\text{Ca} \cdot 6\text{H}_2\text{O}$ , which crystallizes in long, slender needles. This is unstable at the ordinary temperature and transforms with loss of two molecules of water into the well known tetrahydrated salt, small crystals of which quickly make their appearance among the needle-shaped crystals and grow at the expense of the latter, which dissolve and ultimately disappear.

### Experimental Part.

When equal volumes of 0.2 *N* solutions of calcium chloride and potassium sodium tartrate are mixed the liquid remains clear for a short time,

Fig. 1.

Fig. 2

then small tufts of needle-shaped crystals make their appearance and rapidly grow until in a few minutes the whole is filled with such tufts which finally interlace, a felted mass of crystals resulting which can be inverted without any of the mother liquor escaping. If kept at the ordinary temperature small crystals of the orthorhombic tetrahydrated form of calcium tartrate soon make their appearance and grow rapidly while the unstable needle-shaped crystals dissolve and finally disappear. The orthorhombic crystals thus produced, which are very finely shaped and often of considerable size, sink down in the beaker and form a comparatively thin layer. If the crystalline pulp of needle-shaped crystals be stirred or shaken vigorously, transformation is more rapid and after a few minutes the needle-shaped form is converted into the compact form, the crystals of which having been quickly formed are small and subside on being left at rest as a fine crystalline precipitate.

On gradually warming the felted mass much more rapid transformation takes place, the needle-shaped crystals crumble away, while a shower of small well-shaped rhombic crystals falls to the bottom of the beaker. In the appended plate, Fig. 1 shows a beaker, about half its natural size, filled with a felted mass of needles of the

hexahydrated modification immediately after crystallization had taken place. Fig. 2 shows the same beaker 24 hours later after complete transformation of the hexahydrated into the tetrahydrated modification had occurred.

If solutions of lower concentration than  $0.2\ N$  are mixed, the deposition of the needle-shaped crystals is slower and they are consequently larger in size. Fig. 3 shows a cluster of such crystals about the natural size which separated on mixing one-fifteenth normal solutions and Fig. 4 shows the same cluster after 24 hours when partial transformation had occurred.

When normal solutions of potassium sodium tartrate and calcium chloride are mixed, a slightly flocculent precipitate is at once formed which becomes denser and definitely crystalline as the small needles increase in size. Half normal solutions show the same appearance, the original precipitate being, however, less in amount. When one-third normal solutions are mixed the initial precipitate is very slight while with  $0.02\ N$  solutions, as above described, the mixed liquid remains clear for a short time until the tufts of needles appear.

The needle-shaped modification which first separates contains 6 molecules of water of crystallization, two of which are

Fig. 3.

Fig. 4.

lost during transformation. For purposes of analysis the hexahydrated crystals prepared as above described by mixing equal amounts of 0.2 *N* solutions of calcium chloride and potassium sodium tartrate were separated by filtration, using a water pump, and thoroughly washed on the filter with distilled water. They were then quickly washed twice with alcohol and once with ether and rapidly pressed between filter paper. The last traces of adhering moisture were removed by exposing them for five minutes over calcium chloride in a vacuum desiccator.

The new form was thus obtained as very fine, colorless needles. When exposed to the air, water was slowly given off, and a crystalline powder of the tetrahydrated form was obtained. When left in a stoppered bottle transformation slowly took place, the crystals became moist, and water was given off which bedewed the sides of the bottle, a crystalline powder of the tetrahydrated form again being produced.

Transformation and loss of water is more rapid at a slightly raised temperature. At the ordinary temperature three or four days' exposure to the air is required before transformation is complete and the weight constant, while at 40° only a few hours' exposure are needed. The crystals of the tetrahydrated form can be heated to 60° in a current of air without any appreciable loss of weight. The loss of water during transformation was estimated by exposing a weighed quantity of the needle-shaped modification to the air until its weight remained constant.

1.5522 lost 0.1884 of water. Loss of water = 12.13%.

The calcium in the needle-shaped modification was estimated by igniting a weighed amount in the air and weighing the calcium oxide obtained.

1.1717 g. gave 0.2227 of calcium oxide.  $\text{Ca} = 13.58\%$

$\text{C}_4\text{H}_4\text{O}_6\text{Ca}_2\cdot 6\text{H}_2\text{O}$  requires loss of  $2\text{H}_2\text{O} = 12.16\%$ .  $\text{Ca} = 13.52\%$

Mr. T. V. Barker, to whom the thanks of the author are due, has measured some crystals of the orthorhombic tetrahydrated modification obtained by the slow transformation of the hexahydrated form. He found them to be crystallographically identical with those successively examined by Pasteur,<sup>1</sup> by Rammelsberg,<sup>2</sup> and by Hintze.<sup>3</sup>

In confirmation of the work of these observers no hemihedral facets were observed but, as Pasteur notes, absence of geometrical enantio-morphism does not necessarily preclude asymmetry of structure.

The new hexahydrated modification crystallizes in long, very slender, doubly refracting needles with straight extinction and is not suitable for goniometrical examination.

THE 5,5-DIMETHYL-3-R-2-THIOHYDANTOINS.<sup>1</sup>

By J. R. BAILEY AND A. T. McPHERSON.

Received May 19, 1916.

In the year 1908, Bailey and Randolph published in the *Berichte* of the German Chemical Society an article entitled "Kritische Bemerkungen zu einer Abhandlung von W. Marckwald, M. Neumark and R. Stelzner: Ueber Thiohydantoine und von diesen derivierende Basen."<sup>2</sup> In working out methods for the desulfurization of thiohydantoins,<sup>3</sup> Bailey and Randolph had occasion to prepare certain 5,5-dimethyl-3-R-2-thiohydantoins of the general formula

where R represents an alkyl or an aryl.

In the table below is given a list of the substances described in the article of Marckwald, Neumark and Stelzner, "Ueber Thiohydantoine und von diesen derivierende Basen,"<sup>4</sup> which were later prepared by Bailey and Randolph. The compounds in the article of the German investigators, which were under criticism by Bailey and Randolph, as well as the additional substances which are discussed in the present paper, were contributed to the article of Marckwald, Neumark and Stelzner by Dr. Stelzner, at the time a co-worker of Prof. Marckwald. A comparison of the melting points of the substances, obtained by Stelzner on the one hand and by Bailey and Randolph on the other hand, indicates beyond any doubt that the compounds, obtained in these two investigations and to which are ascribed the same constitution, are not identical.

	Melting points.	
	By Stelzner.	By Bailey and Randolph.
(a) 3,5,5-Trimethyl-2-thiohydantoin.....	53°	145°
(b) 5,5-Dimethyl-3-phenyl-2-thiohydantoin....	67°	174°
(c) Methyl ether of "b".....	Zähflüssiges helles Liquidum	96°
(d) Platinum salt of "c".....	132°	240°
(e) Picrate of "c".....	174°	194°
(f) 5,5-Dimethyl-3- <i>p</i> -tolyl-2-thiohydantoin....	85°	223°

In regard to the results tabulated above, Bailey and Randolph made the following statement:

<sup>1</sup> This paper was sent to Dr. Stelzner in May for his criticism but no reply has been received. Because of the uncertainty of mails to Germany at the present time it does not seem best to wait longer before publication.—EDITOR.

<sup>2</sup> *Ber.*, 41, 2505 (1908).

<sup>3</sup> *Ibid.*, 41, 2494 (1908).

<sup>4</sup> *Ber.*, 24, 3278 (1891).

"Da nun aus den Ergebnissen unserer Mitteilung über die Entschwefelung von Thiohydantoinen mit grösster Wahrscheinlichkeit zu folgern ist, dass wir die wirklichen Thiohydantoine erhalten haben, so kann die von Stelzner den betreffenden Verbindungen zugesprochene Konstitutionsformel nicht zutreffend sein. Welche Formel die in Rede stehenden Substanzen in Wirklichkeit besitzen, haben wir nicht ermitteln können. Da bei den betreffenden Versuchen stets eine alkoholische Lösung der Senföle benutzt wurde, so drängte sich uns der Gedanke auf, dass die von Stelzner beschriebenen

Derivate vielleicht Thiourethane,  $\text{C}_2\text{H}_5\text{OCNH} - \text{R}$ , waren, die irrtümlicherweise für Thiohydantoine gehalten worden sind. Dieser Annahme steht jedoch die Thatsache entgegen, dass die Analysenresultate Stelznerns die in den meisten Fällen die Bestimmung von Kohlenstoff, Wasserstoff, Stickstoff und Schwefel umfassen, gut auf die Thiohydantoin-Formel stimmen. Da die in unseren beiderseitigen Beobachtungen zutage getretenen Differenzen kaum auf Tautomerie zurückgeführt werden können, so muss es sich um eine Isomerie handeln, deren Aufklärung noch aussteht."

The substances obtained by Stelzner are now given in Richter's "Lexikon der Kohlenstoffverbindungen" as *isomers* of the Bailey and Randolph compounds. However, Dr. Stelzner has, since the publication of the Bailey and Randolph article, worked over the ground and writes:

"Wie Sie bereits richtig vermuteten, beziehen sich die von mir herrührenden Schmelzpunktsangaben auf die bei der Kondensation von Aminosäuren mit Senfölen bei Gegenwart von alkoholischen Kali gleichzeitig oder vielleicht richtiger zunächst entstehenden Thiourethane.....meine Analysenzahlen aber sich auf die Thiohydantoine." In justice to Dr. Stelzner his explanation should be quoted of "der ganz merkwürdige Zufall dass die in der Bruttoformel so gänzlich verschiedenen Thiourethane und Thiohydantoine in der prozentualen Zusammensetzung sich einander recht nahe stehen, und dementsprechend auch die teils von mir, teils von anderer Seite ausgeführten Analysen keinen Hinweis auf die in meinen Thiohydantoinen zweifellos noch vorhandenen Verunreinigungen gaben."

In whatever way the errors in Stelzner's work may be accounted for, it is simply our aim in the present article to direct attention to the fact that none of the supposed 5,5-dimethyl-3-R-2-thiohydantoins or their derivatives, described in the article referred to above, were obtained by Stelzner—at least in a form approximating purity.

As *o*-tolyl-dimethylthiohydantoin and some derivatives of this are also described by Stelzner in the article referred to above, it seemed desirable that this work also be investigated. Here again products have been obtained that do not correspond in their melting points with the results obtained by Stelzner, as is evident from the following tabulated comparison:

	Melting points.	
	By Stelzner.	By Bailey and McPherson.
(a) 5,5-Dimethyl-3- <i>o</i> -tolyl-2-thiohydantoin.	175°	195.5°
(b) Methyl ether of "a".....	Schmilzt bei Zimmertemperatur	75°
(c) Platinum salt of "b".....	No data	220°
(d) Sulfate of "b".....	208°	196°
(e) Picrate of "b".....	212°	152°

There is no possibility that Stelzner was confused in the work on the *o*-tolyl derivatives by the presence of *o*-tolylthiourethane, because the latter substance is described in the literature as a liquid. It is true that, as shown in the experimental part of this article, this thiourethane, when pure, is a crystalline solid at room temperature, but in its preparation a liquid is always obtained and considerable care must be exercised in its preparation to effect crystallization.

In justice to Dr. Stelzner, attention should be directed to the fact that at the time he carried out his work  $\alpha$ -aminoisobutyric acid was a substance difficult to prepare and the sulfate with which he worked might have been contaminated with ammonium sulfate. There is some probability of this, in view of the fact that he assigned to this salt the formula  $(\text{CH}_3)_2\text{C}(\text{NH}_2)\text{COOH} \cdot \text{H}_2\text{SO}_4$ . Bailey and Randolph showed the formula of the normal salt to be  $[(\text{CH}_3)_2\text{C}(\text{NH}_2)\text{COOH}]_2 \cdot \text{H}_2\text{SO}_4$ . Experiments have convinced us that Stelzner's acid salt can be prepared, but it will not stand recrystallization from water as stated by Stelzner.

#### Experimental Part.

The  $\alpha$ -aminoisobutyric acid used in this work was prepared according to the method of Gulewitsch.<sup>1</sup> The *o*-tolyl mustard oil, made from *o*-toluidine, boiled at  $238^\circ$  at 744 mm. The boiling point given by Mainzer<sup>2</sup> is  $237^\circ$ . As a further confirmation of the purity of the mustard oil, the following derivatives were made:  $o\text{-CH}_3\text{C}_6\text{H}_4\text{NHCSNH}_2$ ,  $o\text{-CH}_3\text{C}_6\text{H}_4\text{-NHCSNHC}_6\text{H}_5$ , and  $(o\text{-CH}_3\text{C}_6\text{H}_4\text{NH})_2\text{CS}$ . These preparations melted at  $159^\circ$ ,  $139.5^\circ$ , and  $158.5^\circ$ , respectively, which data stand in accord with the melting points given in Beilstein for these substances.

hydantoin is readily prepared according to the method of Marckwald, Neumark and Stelzner,<sup>3</sup> as follows: An alcoholic solution of equimolecular amounts of *o*-tolyl mustard oil and potassium aminoisobutyrate is boiled one hour, the alcohol distilled off, the residue taken up with water, and then the thiohydantoin precipitated by the addition of hydrochloric acid. Our preparation, purified by recrystallization from dilute alcohol and then from benzene, melted at  $195.5^\circ$  without decomposition. From benzene the thiohydantoin crystallizes in short, thick, microscopic prisms without end faces.

Calc. for  $\text{C}_{12}\text{H}_{14}\text{ON}_2\text{S}$ : C, 61.54%; H, 5.98%; N, 11.97%; S, 13.67%.

Found: C, 61.69; H, 6.19; N, 12.03; S, 13.92.

<sup>1</sup> *Ber.*, **39**, 1184 (1906).

<sup>2</sup> *Ibid.*, **15**, 1413 (1882).

<sup>3</sup> *Ibid.*, **24**, 3280 (1891).

**5,5-Dimethyl-3-*o*-tolylhydantoin.**—As a proof of the constitution of the above thiohydantoin, it was desulfurized with bromine by the method of Bailey and Randolph.<sup>1</sup> The new substance thus obtained crystallizes from a benzene-petrolie ether mixture in the form of characteristic, thin, prismatic plates, melting at 172° undecomposed.

Calc. for  $C_{12}H_{14}O_2N_2$ : C, 66.06%; H, 6.42%; N, 12.84%.

Found: C, 66.16; H, 6.61; N, 12.62.

**Methyl Ether of 5,5-Dimethyl-3-*o*-tolyl-2-thiohydantoin.**—The methyl ether was prepared according to the method of Marckwald, Neumark and Stelzner by boiling an alcoholic solution of the thiohydantoin with a slight excess of methyl iodide in the presence of one mol of potassium hydroxide until the solution was neutral to litmus. On recrystallization from petrolie ether, it is obtained in the form of short prisms, which melt undecomposed at 75°.

Calc. for  $C_{12}H_{16}ON_2S$ : C, 62.90%; H, 6.45%; N, 11.29%; S, 12.91%.

Found: C, 63.05; H, 6.56; N, 11.47; S, 12.87.

**Picrate of the Methyl Ether.**—The picrate separates in thin, yellow plates on the addition of picric acid to an alcoholic solution of the methyl ether. After recrystallization from alcohol, it melts with decomposition at 152°.

Calc. for  $C_{19}H_{19}O_8N_3S$ : N, 14.68%. Found: N, 14.75.

**Platinum Salt of the Methyl Ether.**—On the addition of platinic chloride to a solution of the methyl ether in dilute hydrochloric acid, an oil separates which, on standing a short time, changes to an orange-red, crystalline solid. Purification is effected by washing with water and with petrolie ether. On rapid heating this substance melts with complete decomposition at 220°.

Calc. for  $C_{26}H_{34}O_4N_4S_2PtCl_6$ : Pt, 21.57%. Found: Pt, 21.50.

**Sulfate of the Methyl Ether.**—The methyl ether is dissolved in the calculated amount of sulfuric acid in alcohol and the sulfate then precipitated with dry ether. The substance purified by several precipitations from alcoholic solution with ether, is obtained in the form of slender, microscopic prisms and melts at 196°.

## ACTION OF AROMATIC ALCOHOLS ON AROMATIC COMPOUNDS IN THE PRESENCE OF ALUMINUM CHLORIDE. I.

BY RALPH C. HUSTON AND THEODORE E. FRIEDMANN.

Received September 16, 1916.

The condensation of aromatic alcohols with aromatic compounds to form derivatives of di- or triphenylmethane is commonly brought about by the following dehydrating agents: sulfuric acid,<sup>1</sup> phosphorus pentoxide,<sup>2</sup> zinc chloride,<sup>3</sup> dilute or concentrated hydrochloric acid,<sup>4</sup> sulfuric and acetic acids,<sup>5</sup> absolute alcohol,<sup>6</sup> stannic chloride,<sup>7</sup> and acetic acid.<sup>8</sup>

Aluminum chloride has been used as a dehydrating agent in organic chemistry by Merz and Weith,<sup>9</sup> Sholl and Seer,<sup>10</sup> Wass,<sup>11</sup> Graebe,<sup>12</sup> Jaubert,<sup>13</sup> Frankforter and Kritchevsky,<sup>14</sup> Frankforter and Kokatnur,<sup>15</sup> and others.<sup>16</sup>

We do not find, however, a record of the dehydrating action of aluminum chloride on aromatic alcohols and aromatic compounds. This preliminary

paper is the first of a series of articles which we hope to publish on this field.

When benzyl alcohol was mixed with a little more than the molecular equivalent of benzene, and the mixture treated with anhydrous aluminum chloride, a rather vigorous reaction took place. Heat and hydrochloric acid were evolved, and the mass became dark colored and pasty. After decomposing with ice water, and extracting with ether five compounds were isolated by fractional distillation.

The product formed in the largest amount (30% theory) boiled, after redistillation at 262–264°. It was identified further by analysis and oxidation to benzophenone, as diphenylmethane.

The residue was distilled under 30 mm. pressure until the temperature rose to 350°. This distillate was then separated by fractionation at 20 mm. into two portions, which came over between 250° and 265° and between 308° and 316°, respectively. The first of these consisted chiefly of *p*-dibenzylbenzene (8% theory) together with a little *o*-dibenzylbenzene, and an oily impurity. The *p*-dibenzylbenzene was identified by melting point, analysis, bromination and oxidation to *p*-dibenzoylbenzene; the *o*-dibenzylbenzene by its melting point.

The fraction which came over at 308–316° at 20 mm. has the formula, as indicated by analysis and molecular weight determination,  $\text{C}_{27}\text{H}_{24}$ . It is probably either tribenzylbenzene,  $\text{C}_6\text{H}_3(\text{CH}_2\text{C}_6\text{H}_5)_3$ , or methylene-*bis*-diphenylmethane,  $\text{C}_6\text{H}_5\text{CH}_2\text{C}_6\text{H}_4\text{CH}_2\text{C}_6\text{H}_4\text{CH}_2\text{C}_6\text{H}_5$ . A subsequent paper will contain a more complete description of this compound.

The residue from the vacuum distillation was distilled at ordinary pressure and yielded about 20% of the theoretically possible amount of crude anthracene. This was purified by sublimation and oxidized to anthraquinone.

The yields of the products are greatly influenced by the amounts of the reagents used, and the temperature at which the reaction is carried out. In one experiment where the temperature was kept below 35° and a large excess (5.2 mols) of benzene was used, the diphenylmethane almost equaled in weight the benzyl alcohol taken. Conditions which gave large yields of diphenylmethane gave small yields of anthracene.

Schramm<sup>1</sup> and Radziewanowski<sup>2</sup> found that this same rule held when benzylchloride and benzene react in the presence of  $\text{AlCl}_3$ .

Verley<sup>3</sup> (working under reduced pressure) prepared diphenylmethane from chloromethylethyl ether, benzene, and aluminum chloride. Since he obtained evidence of a small amount of benzylethyl ether in the reac-

<sup>1</sup> *Ber.*, 26, 1706 (1893).

<sup>2</sup> *Ibid.*, 27, 3237 (1894).

<sup>3</sup> *Bull.*, [3] 17, 914 (1897).

tion mixture, he assumed that the reaction takes place in three steps: First, the chloromethylethyl ether reacts with benzene to give benzylethyl ether,  $\text{C}_6\text{H}_6 + \text{ClCH}_2\text{OC}_2\text{H}_5 \xrightarrow{\text{AlCl}_3} \text{C}_6\text{H}_5\text{CH}_2\text{OC}_2\text{H}_5 + \text{HCl}$ . Second, the ether thus formed reacts with hydrochloric acid to form benzyl chloride and alcohol,  $\text{C}_6\text{H}_5\text{CH}_2\text{OC}_2\text{H}_5 + \text{HCl} \longrightarrow \text{C}_6\text{H}_5\text{CH}_2\text{Cl} + \text{C}_2\text{H}_5\text{OH}$ . Third, the benzyl chloride then reacts with a second molecule of benzene to give diphenylmethane,  $\text{C}_6\text{H}_5\text{CH}_2\text{Cl} + \text{C}_6\text{H}_6 \xrightarrow{\text{AlCl}_3} \text{C}_6\text{H}_5\text{CH}_2\text{C}_6\text{H}_5 + \text{HCl}$ .

In the light of this explanation we thought it of interest to determine the effect of aluminum chloride on a mixture of benzylethyl ether and benzene. The ethyl ether of benzyl alcohol when mixed with  $1\frac{2}{3}$  mols benzene and treated with  $\text{AlCl}_3$  reacted much less readily than did benzyl alcohol under the same conditions. The products of the reaction were the same<sup>1</sup> but the yields were much smaller. The reaction mixture yielded, after standing more than a week, about 15% of unchanged benzylethyl ether.

If the hypothesis of Verley is correct and if benzylethyl ether is fairly stable in the presence of benzene and aluminum chloride, one would expect to obtain a considerable amount of benzylethyl ether from the reaction mixture when chloromethylethyl ether is treated with benzene and aluminum chloride. An experiment was made with the conditions comparable to those of the preceding experiment. The reaction was much more vigorous and seemed to be complete at the end of two days. A great deal more anthracene was formed as compared to the diphenylmethane than was the case when either benzyl alcohol or benzylethyl ether was used. We were unable to obtain *any* benzylethyl ether from the reaction mixture.

These results led us to try the effect of an excess of aluminum chloride on chloromethylethyl ether alone. A vigorous reaction set in and hydrochloric acid was given off. After standing overnight (protected from moisture by  $\text{CaCl}_2$ ) the mixture was decomposed with ice water. A volatile oil separated out and the odor of formaldehyde was quite distinct.

While these experiments are not conclusive, they lead us to suggest an alternate explanation for the action of aluminum chloride on a mixture of chloromethylethyl ether and benzene. We suggest that the ether is first decomposed by the aluminum chloride to form formaldehyde,<sup>2</sup> which then reacts with benzene to form diphenylmethane and anthracene. It is quite possible that both reactions occur simultaneously, but the large amount of anthracene formed,<sup>3</sup> and the absence of an appreciable amount of benzylethyl ether both point to the second hypothesis.

<sup>1</sup> Meyer (*J. prakt. Chem.*, [ii] 82, 538 (1910)) has shown that  $\text{P}_2\text{O}_5$  acts on benzylethyl ether and benzene to give diphenylmethane.

<sup>2</sup> Compare with the findings of Waas, *Ber.*, 15, 1128 (1882).

<sup>3</sup> Frankforter and Kokatnur (*loc. cit.*) have shown that formaldehyde benzene and aluminum chloride yield a large amount of anthracene.

We are unable at the present time to throw much light on the mechanism of the reaction between aromatic alcohols, aromatic compounds and aluminum chloride. We hope to be able to explain it more fully in future papers. Our work, thus far, has shown the formation of an intermediate product which resembles the intermediate product formed in Friedel and Kraft's reaction. A rather large proportion of  $\text{AlCl}_3$  is necessary for the production of a good yield of diphenylmethane.

It may be that a further study of this reaction will help to give an insight into the mechanism of the reaction between aldehydes, aromatic compounds and aluminum chloride.<sup>1</sup>

### Experimental.

**Benzyl Alcohol, Benzene and Aluminum Chloride, I.**—Fifty-five grams of benzyl alcohol (freshly prepared from benzaldehyde and free from chlorine) were added to 50 g. of benzene. The mixture was cooled and stirred constantly with a motor. Aluminum chloride was added in small portions until a total of 40 g. had been added. The temperature was kept at 30–35° except for a brief period when it rose to 55°. Much hydrochloric acid was evolved and the mixture became dark colored, pasty and fluorescent. It was allowed to stand at room temperature for ten days, and was then decomposed with ice water and extracted with ether. The ether extract was dried over  $\text{CaCl}_2$ . Most of the ether was driven off and the residue was fractionated.

#### Second Fractionation.

60–130°, 12.5 g. (mostly benzene); 130–240°, 0.7 g.; 240–280°, 25.5 g.

The pressure was reduced to 30 mm. and the distillation continued until nothing more would come over under 350°. The distillate weighed 20 g. This was subjected to fractionation at 20 mm.

#### Second Fractionation.

245–265°, 10.5 g.; 265–305°, 1.5 g.; 308–316°, 5.27 g.

The residue (15 g.) was distilled at ordinary pressure, until the flask melted and nothing more would come over. 8.5 g. of a yellow oil came over and solidified in the receiver.

The fraction which came over at 240–280° at ordinary pressure had after repeated distillation, a constant boiling point of 262–264°. 20 g. of it yielded 14 g. of benzophenone when oxidized with potassium dichromate, and sulfuric acid.<sup>2</sup> An analysis gave the following:

0.1708 g. subst. gave 0.5802 g.  $\text{CO}_2$  and 0.1127 g.  $\text{H}_2\text{O}$ .

Calc. for  $\text{C}_{18}\text{H}_{12}$ : C, 92.8%; H, 7.2%. Found: C, 92.58%; H, 7.39%.

The substance is, therefore, diphenylmethane.

The fraction which came over at 245–265° at 20 mm. was redistilled.

<sup>1</sup> See Dinesmann, *Compt. rend.*, **141**, 201 (1905); and Frankforter and Kritchevsky, *THIS JOURNAL*, **36**, 1511 (1914); **37**, 385 (1915).

<sup>2</sup> Zincke, *Ann.*, **159**, 377 (1871).

Most of it came over between 252–255°. On standing overnight the larger part of it crystallized. It was cooled and filtered at the pump. The crystals were dried between filter papers and recrystallized alternately from alcohol and ether. 5.3 g. of colorless plates melting at 85–86° were obtained. 1 g. of these when oxidized with 2 g. of  $\text{CrO}_3$  in acetic acid gave 0.8 g. of *p*-dibenzoyl benzene, melting at 159–160°. Another 1 g. portion was brominated in chloroform solution.<sup>2</sup> A dibromide was obtained which melted, after repeated recrystallization, from petroleum, ether and benzene, at 112.5°. An analysis of the hydrocarbon gave:

0.1826 g. subst. gave 0.6247 g.  $\text{CO}_2$  and 0.1142 g.  $\text{H}_2\text{O}$ .

Calc. for  $\text{C}_{20}\text{H}_{18}$ : C, 92.97%; H, 7.03%. Found: C, 93.29%; H, 7.01%.

It is, therefore, *p*-dibenzylbenzene,  $\text{C}_6\text{H}_5\text{CH}_2\text{C}_6\text{H}_4\text{CH}_2\text{C}_6\text{H}_5$ .

From the combined filtrates of the *p*-dibenzylbenzene, a small amount (0.7 g.) of *o*-dibenzylbenzene melting at 78° was obtained.

The fraction which came over at 308–316° at 20 mm. was redistilled. Most of it came over between 312° and 314°. An analysis and molecular weight determination indicated the formula  $\text{C}_{27}\text{H}_{24}$ .

0.2067 g. and 0.1998 g. of subst. gave 0.702 g. and 0.6807 g.  $\text{CO}_2$ , and 0.1275 g. and 0.1284 g.  $\text{H}_2\text{O}$ .

Calc. for  $\text{C}_{27}\text{H}_{24}$ : C, 93.05%; H, 6.95%. Found: C, 92.64%, 92.91%; H, 6.91%, 7.19%.

Calculated molecular weight, 348.2. Found: 342.4 and 354.

The yellow solid which was obtained by heating the residue after the vacuum distillation was freed from oil by means of a porous plate, crystallized from benzene and alcohol and sublimed. The sublimate had the characteristic appearance of anthracene. It melted sharply at 212–213°. 2 g. were oxidized with chromium trioxide and acetic acid. After recrystallization from glacial acetic acid the resulting fine needles melted at the correct temperature for anthraquinone, 276–277°.

**Benzyl Alcohol, Benzene and Aluminum Chloride, II.**—Fifty grams of benzyl alcohol were added to 200 g. benzene and treated with 35 g. aluminum chloride in small portions. The temperature was easily kept between 30° and 35°. The mixture turned reddish brown and gave off hydrochloric acid. After five days it was poured into ice water. The aqueous portion was separated from the benzene portion and extracted with ether. Most of the ether was driven from the extract and the residue was added to the benzene portion. This was dried over  $\text{CaCl}_2$  and subjected to fractionation.

#### Second Fractionation

60–110°, 142 g. (benzene); 110–235°, 4 g.; 235–280°, 46.5 g.

The pressure was reduced to 30 mm. and the distillation continued to 350°. 11.5 g. came over. This was refractionated at 20 mm.

<sup>1</sup> Zincke, *Ber.*, **9**, 31 (1876).

<sup>2</sup> Thiele and Balhorn, *Ibid.*, **37**, 1467 (1904).

## Second Fractionation.

245–265°, 7.5 g.; 265–305°, 1 g.; 308–316°, 2.5 g.

The small amount of residue (2.5 g.) was heated under atmospheric pressure. About 1 g. of crude anthracene was obtained.

These fractions yielded, on purification:

Diphenylmethane.....	44.5 g.
<i>p</i> -Dibenzyl benzene.....	4.2 g.
<i>o</i> -Dibenzyl benzene.....	0.5 g.
Hydrocarbon, C <sub>27</sub> H <sub>24</sub> .....	2.0 g.
Anthracene.....	0.6 g.

**Benzylethyl Ether,<sup>1</sup> Benzene and Aluminum Chloride.**—Fifty grams of the ether were mixed with an equal weight of benzene and stirred while 40 g. of aluminum chloride were added in small portions. Cooling was omitted. The temperature rose to about 45°. Hydrochloric acid was given off and the mixture became dark colored. The reaction was quite slow, hydrochloric acid being evolved in considerable amount for about a week. After ten days the mass was decomposed with ice water, extracted with ether, dried and distilled.

## Second Fractionation.

60–110°, 18 g. (benzene); 110–220°, 7.5 g.; 220–280°, 9 g.; 240–350° (30 mm.), 6 g.

The residue distilled at atmospheric pressure yielded 4 g. of crude anthracene.

Most of the fraction from 110° to 220° boiled at 178–182°. It was identified as unchanged benzylethyl ether. The fraction from 220° to 280° was crude diphenylmethane. The fraction from 240° to 350° (30 mm.) yielded 2 g. of *p*-dibenzyl benzene, 0.3 g. *o*-dibenzyl benzene, and about 1 g. of the hydrocarbon C<sub>27</sub>H<sub>24</sub>.

**Chloromethylethyl Ether, Benzene and Aluminum Chloride.**—Thirty-five grams of freshly prepared chloromethylethyl ether were dissolved in 75 g. of benzene, and treated with 35 g. of aluminum chloride. The reaction was quite violent. Although the aluminum chloride was added very slowly and the mixture well cooled, the temperature rose to 43°. Hydrochloric acid was evolved rapidly. The mixture turned red, then reddish brown and became rather pasty. After three days it was decomposed with ice water and extracted with ether. A small amount (2 g.) of a yellow precipitate remained undissolved and was filtered off. This was not investigated. The ether extract was dried over CaCl<sub>2</sub> and distilled.

## Second Fractionation.

60–120°, 12 g. (benzene); 120–220°, 0.5 g.; 220–280°, 9.8 g.; 235–350° (30 mm.), 2.5 g.

Twelve grams crude anthracene were obtained from the residue.

<sup>1</sup> This ether was freshly prepared from benzyl chloride and sodium ethylate. It gave a faint cloudiness when tested for chlorine.

The thermometer rose rapidly from  $120^{\circ}$  to  $220^{\circ}$ . No evidence of benzyl-ethyl ether was found. The fraction from  $220^{\circ}$  to  $280^{\circ}$  was identified as diphenylmethane. No investigation was made for the oil which came over between  $235^{\circ}$  and  $350^{\circ}$  at 30 mm.

**Chloromethylethyl Ether and Aluminum Chloride.**—Fourteen grams of chloromethylethyl ether were placed in a flask fitted with a calcium chloride tube and treated with an excess (22 g.) of aluminum chloride in small amounts. A vigorous reaction set in, heat was evolved, and hydrochloric acid was given off rapidly. After standing overnight, all reaction seemed to have ceased. The flask contained a reddish brown syrup and some unchanged aluminum chloride. The whole was poured into ice water. A small amount of volatile oil came to the surface. The aqueous solution smelled strongly of formaldehyde. A portion was just neutralized with NaOH and filtered. A piece of filter paper, moistened with ammoniacal silver nitrate solution, was turned black when held over the warmed filtrate.

## THE MOLECULAR WEIGHT OF SOME ALCOHOLATES OF CHLORAL AND BUTYLCHLORAL IN BENZENE SOLUTION.

BY MARGUERITE WILLCOX AND ROGER F. BRUNEL.

Received September 16, 1916.

The partial dissociation of chloralethylalcoholate into its constituents when dissolved in organic solvents, first investigated by Beckman,<sup>1</sup> was more extensively examined by Willcox and Brunel in a recent article,<sup>2</sup> in connection with an investigation of the replacement of one alcohol by another in such alcoholates. It has now been found that other alcoholates of chloral and butylchloral are likewise, as would be expected, somewhat dissociated in solution.

An examination of Table II, p. 1827, in the above paper by the authors, and of the reactions on which it is based, make evident certain conclusions as to the relative tendency to dissociation which these alcoholates of various alcohols should exhibit. It is there concluded that as we pass downward in the table, in the list of alcohols there studied, the affinity of the alkyl groups for the hydroxyl becomes relatively greater than their affinity for the chloral and butylchloral radicals. The tendency of the alcohols to form alcoholates with the aldehydes, involving separation of the alkyl group from the hydroxyl, should, therefore, decrease in this order, so that the degree of dissociation of the alcoholates should increase as we pass downward in the list of alcohols in this table. The following experiments show

<sup>1</sup> *Z. physik. Chem.*, 2, 724 (1888).

<sup>2</sup> *THIS JOURNAL*, 38, 1821 (1916).

this to be the case, the alcoholates of primary alcohols being least highly, those of tertiary alcohols most highly dissociated, with those of secondary alcohols falling between them. The concentrations are not the same for all of them, but are sufficiently close to make the relationship clear.

The purest benzene obtainable was frozen out four times, dried with calcium chloride and phosphorus pentoxide, and distilled. B. p. 79.4. The value 4.9 was used for the constant. The concentrations are given in per cent. by weight.<sup>1</sup>

Solute.	$\Delta$ .	Per cent. conc.	Mol. wt.		Per cent. dissociation.

If some of these more highly dissociated alcoholates underwent some dissociation in the equilibrium experiments of the earlier paper by the authors, above referred to, it would have to be taken into account in order to determine the true equilibrium between the molecular forms of the alcoholates. A little consideration will show that it could not affect the order in which the alcohols would fall in the series there studied, but would merely accentuate the differences in the end points which would be found if the dissociation were negligible in amount.

It cannot be stated with certainty whether or not such dissociation occurred. The concentration of the tertiary alcoholates fell, in the chloral series, as low as 2 g., that of butylchloral-*d*-sec.butylalcoholate in some cases as low as 9 g. per hundred cc. of solution. Expressed as per cent. by weight both of these values would be somewhat higher. These are concentrations at which the alcoholates concerned should be somewhat dissociated. But it must be kept in mind that there were always two such alcoholates present when equilibrium was reached giving a common dissociation product, and it is reasonable to assume that some suppression of the dissociation of each would occur. If we assume that we may apply the principle frequently employed in the case of electrolytic dissociation, according to which each substance dissociates as if it were present occupying

<sup>1</sup> In the former paper the words under the curve, *loc. cit.*, p. 1835, "percentage concentration," should read "Grams solute per 100 g. solvent," that being the manner of designating the concentrations in all of the molecular weight determinations in that paper.

a part of the total volume of the solution corresponding to its own mol. fraction of the dissociating substance present; and if we keep in mind the fact that the total amount of dissociating substance in the solutions in the equilibrium experiments was always 30% or more, it appears improbable that any considerable degree of dissociation could have occurred there.

## STUDIES IN THE CYCLOPENTADIENE SERIES. IV. THE FORMATION OF CYCLOPENTADIENODIHYDROPYRIDAZINES.

By WILLIAM J. HALE.

Received September 19, 1916.

In an earlier publication<sup>1</sup> upon 5-nitro-2,3-diacetylcyclopentadiene, attention was called to the fact that only one of the acetyl groups could be involved in the formation of oximes, anils or hydrazones. In a second publication<sup>2</sup> upon 5-nitro-2,3-dibenzoylcyclopentadiene the same general results were experienced. The possibility of steric hindrance interfering with the reaction of hydroxylamine or the hydrazines upon carbonyl groups attached to adjacent carbon atoms presented its usual doubtful significance; its elimination from consideration however followed immediately the study of these monohydrazones.

When, for example, one of the carbonyl groups of diacetylcyclopentadiene (I) enters into reaction there occurs a rearrangement of affinity; a rearrangement from that condition of equilibrium, where either one or the other of these carbonyl groups may exist transitorily in enolic form, to a condition stabilized with reference to one carbonyl group now involved with the basic nitrogen as oxime or hydrazone. The double linking thus established between the nitrogen and the carbon, with the consequent alternate double and single linkings around the ring, leads directly to the enolic form (III) of the second carbonyl group, a form naturally

<sup>1</sup> THIS JOURNAL, 34, 1583 (1912).

<sup>2</sup> *Ibid.*, 35, 70 (1913).

in equilibrium with the ketonic form (II) but one now highly favored through this oxime or hydrazone structure. An illustration is afforded by the diagrams on page 2535.

The instability of the monohydrazone and monophenylhydrazones of these cyclopentadiene derivatives has been noted in the earlier publications.<sup>1</sup> In all cases they were found to undergo readily an intramolecular condensation with the production of colored compounds of double ring structure. The study of these compounds has shown that the double ring formation can have proceeded only from the enolic structure shown in (III). When the monophenylhydrazone of 5-nitro-2,3-diacetylcyclopentadiene (IV) is considered, the inner condensation is found to proceed readily from its enolic form (V), even in solutions in anhydrous solvents, to a structure (VI) of the pyridazine type:

This insoluble product, a beautiful orange-yellow in color, is slowly precipitated also from the alkaline solutions of the monophenylhydrazone, the acid hydroxyl and basic hydrogen thus being lost in the production of a neutral pyridazine. This new type of compound must, however, be classed as a cyclopentadienodihydropyridazine.

This development of a pyridazine ring from the 1,2-diacetyl class of compounds at once recalls the history and discussion of the reactions of hydrazine and phenylhydrazine upon diacetosuccinic ester and especially upon acetonylacetone and diphenacyl—the two compounds which were involved in the syntheses of the cyclopentadienes now under consideration. The work of Alexander Smith<sup>2</sup> and of Gabriel and co-workers<sup>3</sup> has established the mode of formation of pyridazines from 1,4-diketones and their derivatives, but in the study of one member of this latter class—

<sup>1</sup> *Loc. cit.*

<sup>2</sup> *Ann.*, **289**, 310 (1896).

<sup>3</sup> *Ber.*, **32**, 395 (1899); **34**, 3257 (1901); **42**, 654 (1909).

diacetosuccinic ester—Curtius<sup>1</sup> procured also a bismethylpyrazolone and later Bülow<sup>2</sup> isolated from this same reaction an N-aminodimethylpyrrole dicarboxylic ester—a compound formed by the simultaneous condensation of one of the amino groups of hydrazine with both of the 1,4-carbonyl groups. This manner of condensation requires the presence of both carbonyl groups in enolic form; it proceeds best in acetic acid solution and to no large yield. According to the structure of diacetylcyclopentadiene, when one of the carbonyl groups reacts in enolic form the second is forced to assume the ketonic structure. It is therefore impossible for a simple pyrrole type of condensation to proceed directly from the cyclopentadiene derivative. Furthermore, all of the products of the condensations for our consideration have failed to show the presence of the pyrrole ring. It is generally accepted also that 5-membered rings when entering into poly-ring nuclei condense more readily with 6-membered rings; hence the possibility of developing a second 5-membered ring—that of a pyrrole—is here disfavored.

Paal and his co-workers<sup>3</sup> observed that diphenacyl, acetylacetone and certain  $\gamma$ -keto esters condensed with hydrazines to form dihydropyridazines; these products were sometimes isolated, but more often were oxidized in the air to the corresponding pyridazines. A similar class of compounds therefore may be expected from the action of hydrazines upon diacetylcyclopentadiene, a compound in which the original stem of these  $\gamma$ -diketones, though now without labile hydrogen, is still present. A few examples of condensed nuclei involving a pyridazine ring as one component have been known. The oxidation of such compounds has unfailingly proved their complete structures. Thus Täuber<sup>4</sup> was the first to prove the structure of phenazone by discovering a pyridazine tetracarboxylic acid in the oxidation product which resulted when phenazone was treated with a very large amount (ten times its weight) of potassium permanganate in neutral solution. Through the loss of two molecules of carbon dioxide from the two carboxyl groups on the two carbon atoms adjacent to the nitrogen atoms there remained finally a 4,5-dicarboxylic acid. Gabriel<sup>5</sup> studied the oxidation of phthalazine by use of potassium permanganate and obtained this same pyridazine dicarboxylic acid as is required by theory. In both of these examples the heterocyclic ring appears the more stable. The oxidation of anisyl cinnoline by Stoermer and Gaus<sup>6</sup> yielded a 4-anisylpyridazine-5,6-dicarboxylic acid, a further indication of the stability of the pyridazine ring. In this latter case,

<sup>1</sup> *J. prakt. Chem.*, [2] 50, 508 (1894).

<sup>2</sup> *Ber.*, 35, 4311 (1902).

<sup>3</sup> *Ibid.*, 36, 491, 497, 2538 (1903); 37, 4382 (1904); 40, 4598 (1907).

<sup>4</sup> *Ibid.*, 28, 451 (1895).

<sup>5</sup> *Ibid.*, 36, 3373 (1903).

<sup>6</sup> *Ibid.*, 45, 3104 (1911).

as well as in the others, the action of a neutral solution of potassium permanganate at the temperature of the water bath seems most effective for the oxidation of these condensed nuclei to their simple pyridazine derivatives.

Just as with the monophenylhydrazone of nitrodiacetylcyclopentadiene so also with the monohydrazone (VII) this inner condensation proceeding from its enolic form (VIII) led directly to a cyclopentadienodihydropyridazine (IX) as indicated below:

The monohydrazone is very unstable and scarcely can be isolated owing to the great ease with which it undergoes this intramolecular condensation. The absence of any labile hydrogen on a carbon atom adjacent to the second carbonyl group would argue indeed against the appearance of an enolic form in readiness for the further condensation with the hydrazine or phenylhydrazine stem. We may assume, therefore, that the shift in linkings within the cyclopentadiene ring itself, transforming the possible isonitro group to a simple nitro group, is the direct source of this available hydrogen for the second carbonyl group. The replacement of the ketonic oxygen of the first carbonyl group by the basic hydrazine stem acts, of course, as the cause of this directed shift.

A study of the oxidation products of these cyclopentadienodihydropyridazines has led to the following considerations: The orange-red product (IX) obtained from the hydrazone we may term 1,4-dimethyl-6-nitro-2,3-cyclopentadienodihydropyridazine. The diagram on page 2539 will indicate the course of its oxidation by potassium permanganate in neutral aqueous solution. The first break occurs between carbon atoms 6 and 7; the intermediate product—a simple dihydropyridazine derivative—is at once oxidized to the corresponding pyridazine and the second break then occurs between carbon atoms 5 and 6, thus making possible the produc-

tion of two carboxyl groups attached to adjacent carbon atoms in the pyridazine ring. The final product is 3,6-dimethylpyridazine-4,5-dicarboxylic acid (X) a colorless dibasic acid closely resembling the pyridazine dicarboxylic acid already known.

The orange-yellow compound (VI) produced in the intramolecular condensation of the phenylhydrazone of diacetylcyclopentadiene is to be classed as a 2-phenyl-1,4-dimethyl-6-nitro-2,3-cyclopentadienodihydropyridazine. Its oxidation to a dihydropyridazine was best accomplished by the use of potassium permanganate in acetone solution. Its slight solubility in water and alkalies, together with the tendency for an aqueous potassium permanganate solution to carry the oxidation as far as possible toward a pyridazine, required the presence of some solvent which would permit the oxidation to proceed at lower temperatures. In this way the phenyl group upon the nitrogen atom remained in position and the yield of product was not below the ordinary. According to the diagram below the course of the oxidation may be described as a break first occurring between carbon atoms 6 and 7 with the carbon atom 7 passing into carboxyl; the maintenance of the dihydropyridazine structure then forcing the second break between carbon atom 5 and the pyridazine ring. The keto derivative thus formed is a 1-phenyl-3,6-dimethyl-4-ketodihydropyridazine-5-carboxylic acid (XI). This latter is a colorless insoluble monobasic acid. In the mother liquors the presence of nitric and oxalic acids was detected; the latter naturally arises from the elimination of the pair of carbon atoms 5 and 6 in the cyclopentadiene ring. As a check, trial oxidations, where the permanganate had been employed in aqueous

and not in acetone solution, were found to give confirmatory tests for the presence of oxalic acid.

In applying this study to the nitrodibenzoylcyclopentadienes it is found that the monohydrazone (XII) passes most readily into the corresponding 1,4-diphenyl-6-nitro-2,3-cyclopentadienodihydropyridazine (XIII), and that the monophenylhydrazone (XIV) passes almost as quickly into the 1,2,4-triphenyl-6-nitro-2,3-cyclopentadienodihydropyridazine (XV).

The oxidation of these latter products was not attempted. The compounds were beautifully colored and showed all of the reactions characteristic of the former or dimethylpyridazine class.

All of these compounds showed marked stability; their fusion or decomposition points are high and acids or alkalis are practically without action upon them. Their color from a deep yellow to a red is highly characteristic. This stability of the dihydropyridazine ring is of course to be referred directly to the double ring structure; the formation of the stable pyridazine naturally followed wherever possible in the oxidation products. The inner condensation among members of the monoxime class (III) has not yet been studied. It does not, however, proceed with the ease which we should anticipate were there hydrogen directly tied to the nitrogen atom. The condensation therefore must proceed in the manner of anhydrides and require outside agencies which will be considered at another time.

#### Experimental Part.

**1,4-Dimethyl-6-nitro-2,3-cyclopentadieno-1,4-dihydropyridazine**  $\text{C}_7\text{H}_5\text{N}_2(\text{CH}_3)_2(\text{NO}_2)$  (IX).—This compound is best prepared by dissolving 1 g. of 5-nitro-2,3-diacetylcyclopentadiene in 20 cc. of water containing 1 g. of sodium carbonate. To the clear yellow solution is then

slowly added 1 g. of powdered hydrazine sulfate. The yellow monohydrazone which separates in part again redissolves by the heat of the reaction and the orange-red precipitate of the pyridazine shortly makes its appearance. The mixture (which must still be alkaline) is then heated for a few moments over a free flame to insure the solution of any hydrazone or cyclopentadiene unacted upon. Upon filtering the hot mixture the pyridazine is collected upon the filter fairly pure and in excellent yield. This cyclopentadienopyridazine is readily soluble in acetone or acetic ester; fairly soluble in alcohol, acetic acid or benzene; slightly soluble in chloroform, ether or water and insoluble in ligroin. It crystallizes best from alcohol in small beautiful red prisms decomposing at  $240-5^{\circ}$ . As noted in the preparation above this pyridazine is not affected by sodium carbonate. It does, however, dissolve in sodium hydroxide solution to give the sodium salt from which the free substance may again be liberated by acids.

0.1288 g. subst. gave 0.2666 g.  $\text{CO}_2$ , and 0.0570 g.  $\text{H}_2\text{O}$ .

0.1486 g. subst. gave 30.1 cc.  $\text{N}_2$  ( $22.5^{\circ}$  and 738.4 mm. over  $\text{H}_2\text{O}$ ).

Calc. for  $\text{C}_9\text{H}_9\text{O}_2\text{N}_3$ : C, 56.52; H, 4.75; N, 22.00. Found: C, 56.45; H, 4.95; N, 22.12.

**3,6-Dimethyl-4,5-pyridazine Dicarboxylic Acid,  $\text{C}_4\text{N}_2(\text{CH}_3)_2(\text{COOH})_2 \cdot \text{H}_2\text{O}$  (X).**—One gram of the dimethylcyclopentadienodihydropyridazine just described was brought into solution in 100 cc. of water containing just sufficient potassium hydroxide to convert it into the potassium salt. To this clear red solution 5.6 g. of potassium permanganate dissolved in 140 cc. of water (4%) were slowly added and the reaction mixture heated overnight under a reflux condenser at the temperature of the water bath. In the morning a few cc. of the permanganate solution may still be found necessary to complete the oxidation and after a little further heating the excess of permanganate may be decomposed by alcohol and the mixture filtered. The manganese dioxide remaining upon the filter is boiled up once with water and again filtered. The combined filtrates are then acidified with  $\text{HCl}$  and evaporated to dryness upon the water bath. The dry residue is now extracted several times with alcohol and the combined alcoholic extracts evaporated to dryness. This final residue is treated with only a few drops of water (to dissolve salt) and the undissolved portion filtered off. This insoluble portion is then dissolved in hot water, boiled with bone black and filtered; the filtrate, upon evaporation to small volume, yields about 0.2 g. of the colorless dimethylpyridazine dicarboxylic acid. This compound is fairly soluble in alcohol or water; slightly soluble in acetic acid and insoluble in ether, ligroin, chloroform, acetone, acetic ester or benzene. It crystallizes best from water in small colorless prisms decomposing at  $226-8^{\circ}$  and containing one molecule of water of crystallization. In the mother liquors as first obtained in the oxidation described the presence of nitric acid

could just be identified, but besides carbonic acid no other acid was found present. The neutral permanganate solution therefore just sufficed for the splitting off of the one carbon atom out of the cyclopentadiene ring and the conversion of the carbon atoms adjacent to the pyridazine ring into corresponding carboxyl groups as explained previously. The dihydropyridazine, formed in the first step, is of course oxidized immediately to the pyridazine but the methyl groups remain in position unattacked. Had the oxidation not progressed to this stage, tests for the presence of imino hydrogen would have shown other than negative.

0.1676 g. subst. gave 0.2750 g.  $\text{CO}_2$ , and 0.0755 g.  $\text{H}_2\text{O}$ .

0.1436 g. subst. gave 17.6 cc.  $\text{N}_2$  ( $25^\circ$  and 738.9 mm. over  $\text{H}_2\text{O}$ ).

0.1620 g. subst. lost nothing over  $\text{H}_2\text{SO}_4$  but lost 0.0138 g.  $\text{H}_2\text{O}$  at  $112^\circ$ .

Calc. for  $\text{C}_8\text{H}_8\text{O}_4\text{N}_2\cdot\text{H}_2\text{O}$ : C, 44.84; H, 4.71; N, 13.09; 8.42  $\text{H}_2\text{O}$ . Found: C, 44.75; H, 5.04; N, 13.22;  $\text{H}_2\text{O}$ , 8.52.

From this acid a white insoluble silver salt was prepared in the usual manner. Upon analysis

0.1872 g. silver salt gave 0.1304 g.  $\text{AgCl}$ .

Calc. for  $\text{C}_8\text{H}_8\text{O}_4\text{N}_2\text{Ag}_2$ : Ag, 52.64. Found: Ag, 52.43.

A further check on the presence of two carboxyl groups was made by boiling a solution of this acid with Iceland spar contained in a small flask attached to a regular  $\text{CO}_2$  absorption train such as used for combustions. The weight of carbon dioxide liberated is a direct measure of the acid hydrogen.

0.1012 g. subst. liberated 0.0206 g.  $\text{CO}_2$  from  $\text{CaCO}_3$ .

Calc. for  $2\text{H}^+$  in  $\text{C}_8\text{H}_8\text{O}_4\text{N}_2\cdot\text{H}_2\text{O}$ : H, 0.96. Found: H, 0.93.

**2-Phenyl-1,4-dimethyl-6-nitro-2,3-cyclopentadienodihydropyridazine**,  $\text{C}_7\text{H}_2\text{N}_2(\text{C}_6\text{H}_5)(\text{CH}_3)_2(\text{NO}_2)$  (VI).—This product is readily prepared by adding an excess of phenylhydrazine to an alcoholic solution of nitrodiacetylcyclopentadiene (I) and warming the mixture for an hour or more. Upon cooling the precipitation of the pyridazine is practically completed. The isolation of the intermediate monophenylhydrazone is in no wise necessary and rather to be avoided. The yield is almost quantitative. This phenylcyclopentadienopyridazine is readily soluble in chloroform, acetic ester or acetone; it is fairly soluble in alcohol or benzene; slightly soluble in ether or water and insoluble in ligroin. It crystallizes best from alcohol in the form of small yellow needle clusters melting at  $193^\circ$ . It is unaffected by warming with alkali or with acid. In fact the red alkaline solution of the monophenylhydrazone, just mentioned, slowly precipitates this pyridazine in crystalline form.

0.1202 g. subst. gave 0.2962 g.  $\text{CO}_2$  and 0.0552 g.  $\text{H}_2\text{O}$ .

0.1457 g. subst. gave 21.2 cc.  $\text{N}_2$  ( $23.4^\circ$  and 741.4 mm. over  $\text{H}_2\text{O}$ ).

Calc. for  $\text{C}_{15}\text{H}_{15}\text{O}_2\text{N}_3$ : C, 67.39; H, 4.90; N, 15.73. Found: C, 67.22; H, 5.14; N, 15.87.

**1-Phenyl-3,6-dimethyl-4-keto-1,4-dihydro-5-pyridazine Carboxylic Acid**,  $\text{C}_{14}\text{N}_2\text{O}(\text{C}_6\text{H}_5)(\text{CH}_3)_2\text{COOH}$  (XI).—A neutral solution of potassium

permanganate acts very slowly upon the insoluble phenyldimethylcyclopentadienopyridazine. A higher temperature however suffices for a somewhat more rapid oxidation, but is likely also to carry the reaction too far. In order that the phenyl group may remain upon its original nitrogen atom, this oxidation must lead to a dihydropyridazine derivative and hence one may look for a ketodihydropyridazine if the oxidation is successful. This desired result was accomplished through the use of potassium permanganate in acetone solution. One gram of the phenyldimethylcyclopentadienodihydropyridazine in 20 cc. of acetone was slowly added to a solution of 30 g. of potassium permanganate in 600 cc. of acetone, to which previously about 50 cc. of water had been added. The contents of the flask, fitted with reflux condenser, were kept at boiling temperature by means of the water bath. After decolorization of the permanganate still more of this powdered reagent was added little by little until almost another 30 g. were consumed. At this point (after 4 hours' boiling) the decolorization proceeded very slowly and the reaction was considered at an end. The clear filtrate from the reaction mixture was next evaporated to dryness, taken up in a little water, acidified with hydrochloric acid and extracted with ethyl acetate. It is well also to digest the large amount of manganese dioxide with water, filter, evaporate to small volume, acidify and extract with ethyl acetate. From these ethyl acetate extracts the colorless oxidation product is obtained by evaporation. This phenyldimethylketodihydropyridazine carboxylic acid is readily soluble in acetone, chloroform, acetic ester, benzene or acetic acid; it is fairly soluble in alcohol or carbon tetrachloride; slightly soluble in ether or water and insoluble in ligroin. It crystallizes best from alcohol in fine, colorless needles melting at  $220^{\circ}$ .

0.1454 g. subst. gave 0.3414 g.  $\text{CO}_2$  and 0.0674 g.  $\text{H}_2\text{O}$ .

0.1359 g. subst. gave 14.6 cc.  $\text{N}_2$  ( $22^{\circ}$  and 735.4 mm. over  $\text{H}_2\text{O}$ ).

Calc. for  $\text{C}_{18}\text{H}_{12}\text{O}_3\text{N}_2$ : C, 63.90; H, 4.96; N, 11.43. Found: C, 64.04; H, 5.18; N, 11.71.

As this acid does not form an insoluble silver salt or similar product adapted to a simple analysis the presence of the single carboxyl group was determined from the weight of carbon dioxide liberated when the acid, a little water and some alcohol, to aid its solution, were brought in contact with barium carbonate in a small flask as described in a previous experiment.

0.1346 g. subst. liberated 0.0118 g.  $\text{CO}_2$  from  $\text{BaCO}_3$ .

Calc. for  $1\text{H}^+$  in  $\text{C}_{18}\text{H}_{12}\text{O}_3\text{N}_2$ : H, 0.41. Found: H, 0.40.

The barium carbonate worked to a better advantage in this case than the iceland spar.

The production of this ketodihydropyridazine carboxylic acid leaves no room for doubt concerning the original structure of the double ring molecule. The oxidation must have proceeded as indicated, (VI) into

(XI), and oxalic acid should be found as a by-product. Both the liquors, from the oxidation at lower temperatures in acetone solution and the trial oxidation carried out in neutral aqueous solution at the temperature of the water bath, gave distinct and positive tests for the presence of oxalic acid. Nitric acid also was present in traces.

**1,4-Diphenyl-6-nitro-2,3-cyclopentadienodihydropyridazine**,  $C_7H_3N_2 \cdot (C_6H_5)_2(NO_2)$  (XIII).—This product is prepared by dissolving nitrodibenzoylcyclopentadiene<sup>1</sup> in a mixture of benzene and alcohol and adding an excess of hydrazine hydrate in alcoholic solution. The clear red solution is then warmed on a water bath for a few hours when the precipitation of the diphenylcyclopentadienopyridazine will be found complete. This substance is only fairly soluble in acetone, acetic ester, chloroform, benzene, alcohol or acetic acid; it is slightly soluble in ether and insoluble in ligroin or water. It crystallizes best from acetone in small orange-red prisms decomposing at  $275-80^\circ$ . This diphenyl derivative is not affected by acids or dilute alkalies; it is, however, soluble in alcoholic sodium hydroxide and may again be precipitated from this solution by acid. No successful means presented itself for the isolation of the intermediate monohydrazone (XII) owing to its great instability.

0.1376 g. subst. gave 0.3658 g.  $CO_2$  and 0.0562 g.  $H_2O$ .

0.1470 g. subst. gave 18.3 cc.  $N_2$  ( $24.2^\circ$  and 738.6 mm. over  $H_2O$ ).

Calc. for  $C_{18}H_{13}O_2N_3$ : C, 72.36; H, 4.16; N, 13.34. Found: C, 72.52; H, 4.57; N, 13.48.

**1,2,4-Triphenyl-6-nitro-2,3-cyclopentadienodihydropyridazine**,  $C_7H_2N_2 \cdot (C_6H_5)_3(NO_2)$  (XV).—This is prepared by digesting a hot benzene solution of nitrodibenzoylcyclopentadiene with an excess of phenylhydrazine for 8 or 9 hours at the temperature of the water bath. The red crystals of the triphenyl derivative are slowly precipitated. The monophenyl hydrazone as described by Thorp and the writer<sup>2</sup> might first have been prepared and its conversion to the pyridazine accomplished simply by boiling its solution in alcohol or benzene; this step, however, is unnecessary and not to be recommended. Triphenylcyclopentadienopyridazine is only fairly soluble in chloroform or benzene; slightly soluble in acetone, acetic ester or acetic acid and insoluble in ether, alcohol, ligroin or water. It crystallizes best from chloroform in small orange-red prisms melting sharply at  $287^\circ$ . It is unaffected by acids and alkalies.

0.1710 g. subst. gave 0.4823 g.  $CO_2$  and 0.0734 g.  $H_2O$ .

0.1850 g. subst. gave 19.1 cc.  $N_2$  ( $25^\circ$  and 718 mm. over  $H_2O$ ).

Calc. for  $C_{28}H_{17}O_2N_3$ : C, 76.70; H, 4.38; N, 10.74. Found: C, 76.93; H, 4.81; N, 10.81.

The formation of this new class of compounds, the condensed 5-carbon ring and pyridazine, is made possible through the presence of a basic hydrogen atom in the hydrazine substituent of the carbocyclic ring in

<sup>1</sup> *Loc. cit.*

<sup>2</sup> THIS JOURNAL, 35, 73 (1913).

proper position to an hydroxyl in an adjacent substituent. For the aid granted by the trustees of the Wolcott Gibbs Fund in the prosecution of this research and for the assistance rendered on this account by Messrs. G. O. Gutekunst and Edgar C. Britton the writer wishes to express his appreciation and indebtedness.

## HALOGENATION. XIV. BROMINATION OF HYDROCARBONS BY MEANS OF BROMINE AND NITRIC ACID.

BY RASIK LAL DATTA AND NIHAR RANJAN CHATTERJEE.

Received September 19, 1916.

In continuation of the researches of the action of *aqua regia* on organic bodies in general, the study of the action of a mixture of nitric and hydrobromic acids was taken in hand. In analogy with the action of *aqua regia*, it was thought that a mixture of nitric and hydrobromic acids, which is capable of giving bromine in the nascent state, would effect brominations more satisfactorily than bromine, and this has been found to be the case. The bromination of benzene has been effected by this reagent with the formation of monobromobenzene in good yield. As a considerable amount of nitric acid is used up, in the first instance, to liberate bromine from hydrobromic acid, it was found satisfactory to employ bromine and nitric acid only. In fact, the mixture of the acids is less active than bromine and nitric acid on account of the water added as the medium of hydrobromic acid.

As bromination could as well be carried out directly with or without the help of a carrier, the advantages of the method may be pointed out. In the case of ordinary bromination with or without carrier, the reaction is one of substitution, liberating an amount of hydrobromic acid equal to that of bromine which enters the molecule. But in the case of bromination in the presence of nitric acid, all the bromine enters the molecule, the nitric acid helping the oxidation of hydrobromic acid to bromine, as soon as it is formed. This bromine is available for further bromination. Hence it is evident that only half the usual amount of bromine will be required for brominations by this method. Here the nitric acid acts as the oxidizing agent facilitating the introduction of bromine, itself being reduced to nitrous gases. Furthermore, the reagent is very active, effecting brominations very rapidly and energetically, so much so that frequent rupture of substances subjected to its action is the result. Those brominations which require a considerable time for their course even with the help of a carrier, could be effected most speedily and satisfactorily. The method is specially suitable for tolerably light hydrocarbons but with the higher ones the process is not quite satisfactory as the chances of

nitration are also great on account of the strong nitric acid, as has been pointed out before in the course of chlorination by means of *aqua regia*.<sup>1</sup> In fact, the chances of bromination are greater in the lower hydrocarbons whereas, in the cases of higher hydrocarbons the chances of nitration are greater. These also depend upon the specific nature of the compounds.

As has already been pointed out, a mixture of bromine and nitric acid has been found to be quite a satisfactory brominating agent, giving bromo-derivatives with the aromatic hydrocarbons, the proportion of any particular bromo-derivative depending upon the duration of the reaction. It will be shown later that the reagent is very active and has a simultaneous brominating and oxidizing action with the formation of tetrabromoquinone as end product of such actions. With other organic compounds, aliphatic or aromatic, which break up under the influence of this reagent, bromopicrin seems to have been generally produced.

The results obtained in the bromination of hydrocarbons by this reagent are interesting. Benzene gives a good yield of bromobenzene by carrying on the process for a short time. If, however, the process be prolonged for some time, *p*-dibromobenzene is the chief product. Toluene gives *o*-bromotoluene and 3,4-dibromotoluene on short action while pentabromotoluene is formed by the prolonged action of the reagent. *o*-Xylene yields monobromo-*o*-xylene readily, while tetrabromo-xylene is the main product of a prolonged action. In the latter case, the product is accompanied by small quantities of *p*-toluic and *o*-toluic acids due to the prolonged oxidizing influence of nitric acid. From *m*-xylene, monobromo-*m*-xylene as also dibromo-*m*-xylene have been obtained on acting with the reagent for a short time, while tetrabromo-*m*-xylene is the product of a somewhat prolonged action. *p*-Xylene gives monobromo-*p*-xylene and dibromo-*p*-xylene, while the prolonged action produces tetrabromo-*p*-xylene. Mesitylene forms monobromo-mesitylene in the cold, while tribromo-mesitylene is the chief product upon heating. With ethyl benzene, monobromo-ethyl benzene is the chief product, but on prolonged action a complicated product is formed which could not be separated and purified.

#### Mixture of Hydrobromic and Nitric Acid as a Brominating Reagent.

**Bromination of Benzene.**—Benzene could be brominated readily by a mixture of hydrobromic and nitric acids with the formation of bromobenzene.

Equal volumes of hydrobromic acid (47%) and nitric acid (sp. gr. 1.35) were gradually mixed in a flask fitted with a reflux condenser and to this benzene is added equal to a fourth part of the acid mixture. The heavy layer of nitrosyl tribromide<sup>2</sup> settles at the bottom while the benzene

<sup>1</sup> THIS JOURNAL, 36, 1007 (1914).

<sup>2</sup> The detailed description of this substance will be communicated shortly.

floats at the top. The reaction is then started by placing the flask on the water bath, removing it from time to time when the vigor of the reaction becomes uncontrollable, which is evident from the escape of considerable amounts of bromine. All the time during the course of the reaction a steady evolution of nitrous fumes takes place. When the evolution of nitrous fumes has ceased the reaction becomes complete. A heavy brown oil is seen deposited at the bottom of the aqueous layer. This is washed with dilute alkali, dried and then distilled. Unchanged benzene comes over at  $80^{\circ}$ , then the temperature rises gradually and most of the product comes over between  $153\text{--}154^{\circ}$  which is the boiling point of bromobenzene. The fraction was again redistilled and the identity was established by a bromine estimation.

Calc., Br = 50.95. Found, Br = 50.35.

The yield obtained by this method is quite satisfactory amounting to 80% of the theory.

#### Bromination by Means of Bromine and Nitric Acid.

**Benzene.**—When the bromination is carried out with the calculated quantities of bromine and nitric acid for a comparatively short time, bromobenzene is the chief product, whereas, if the bromination be carried on with an excess of bromine and nitric acid for a good length of time, *p*-dibromobenzene is the chief product. Other higher bromo-derivatives of benzene could not be obtained, however long the action is carried out. For the preparation of monobromobenzene 36 cc. of benzene are taken in a flask fitted with a reflux condenser and to this 10 cc. of conc. nitric acid and 10.7 cc. (32 g.) of bromine are gradually added. The reaction does not seem to take place at the ordinary temperature. The flask is then placed on the water bath when the reaction begins to take place, as is evident from a steady evolution of brown fumes of oxides of nitrogen. The operation is continued for five hours with the further addition of a little more nitric acid. The mixture refluxes only slightly at the end due to the conservation of benzene into bromobenzene. The heavy oily layer underneath the aqueous layer is taken out, washed with dilute alkali and then dried by means of calcium chloride. It is next distilled over wire gauze in a flask provided with a two-bulbed still-head. Unchanged benzene comes over at about  $80^{\circ}$ , then the temperature rises to about  $140^{\circ}$  when the receiver is changed and bromobenzene is collected until the temperature rises to  $170^{\circ}$ . A dark, viscous residue is left behind within the flask weighing about 2–3 g., which is a mixture of the higher bromo-derivatives. The fraction  $140\text{--}170^{\circ}$  is redistilled and is found to boil at  $153\text{--}154^{\circ}$ . The yield obtained is 60% of the theory. To establish the complete identity of the substance, bromine in the sample was estimated.

Calc., Br = 50.95. Found, Br = 50.47.

It was thought that by using fuming nitric acid, the course of the reaction could be shortened a good deal, but in practice it was not possible. On the other hand, fuming nitric acid diminished the yield on account of its great hydrolyzing action.

For the preparation of *p*-dibromobenzene, 8 g. of benzene are taken in a flask with 12 g. of bromine and 3 cc. of nitric acid. The mixture is at the first instance warmed on the water bath for six hours, when it is found that the mixture refluxes no more, due to the formation of bromobenzene. Then 12 g. more of bromine are added with 3 cc. of nitric acid and the mixture is heated on a sand bath for six hours more when the operation is found to be complete. The semisolid product is separated from the layer of water and heated in a basin to drive off unchanged benzene and bromine, when, on cooling, it begins to solidify and the solidification is hastened by stirring with a glass rod. The crystals were next pressed between the folds of a blotting paper and then recrystallized from alcohol, when *p*-dibromobenzene is obtained in beautiful plates melting at 87°. The yield obtained is nearly quantitative.

Calc., Br = 67.80. Found, Br = 67.45.

**Toluene.**—Toluene gives a mixture of *o*-bromotoluene and 3,4-dibromotoluene by carrying the reaction for a very short time, while by carrying on the reaction for a rather long time with an excess of bromine and nitric acid, penta-bromotoluene is the chief product.

For the preparation of *o*-bromo- and dibromotoluene, 10 cc. of toluene are taken in a flask fitted with a reflux condenser and to this 4 cc. of nitric acid (sp. gr. 1.35) are added and to the mixture 6 cc. of bromine are gradually added in small portions at a time. The reaction takes place almost immediately the substances are mixed, and fumes of oxides of nitrogen are evolved. After a short time, the reaction subsides and nitrous fumes cease to evolve. The mixture is further warmed on the sand bath for half an hour more, when the reaction seems to proceed again with the evolution of nitrous fumes and at the end no more of it comes out, proving that the reaction is complete. The deep brown oil formed is next treated with dilute alkali, washed and dried by means of fused calcium chloride. The dried oil is next distilled. No unchanged toluene comes over; the first fraction was collected between 180–190° and the second fraction, between 200–250°. In the distilling flask there remained behind a charred liquid which consists of higher bromo-derivatives of toluene. On redistilling the first fraction 4 cc. (5.3 g.) of *o*-bromotoluene is obtained, boiling at 180°, while from the second fraction 1 cc. of 3,4-dibromotoluene, boiling at 240–241° has been isolated. Yield of *o*-bromotoluene is 40% of the theory.

For the production of pentabromotoluene the following details are carried out: 5 cc. of toluene are taken in a flask fitted with a condenser

and to this 2 cc. of nitric acid are added from a pipet and then bromine is added gradually in the course of the reaction in 2 cc. at a time. The mixture is warmed on the sand bath, slowly at first, but gradually increasing the temperature of the bath, when it is found that the heavy liquid formed does not reflux so easily. Bromine and a little nitric acid are added from time to time as they are used up. The operation takes about three hours to complete. A dark brown, pasty product is obtained which is chiefly pentabromotoluene mixed with small quantities of the lower bromo-derivatives. For their separation, steam distillation has been found to be very effective. The lower bromo-derivatives come over with the steam, leaving behind a light yellow crystalline product, which is practically pure pentabromotoluene. The crystals were next washed with ether to free them from adhering impurities in which they are insoluble, giving pure pentabromotoluene. This is sublimed and the sublimed product is found to melt at  $280^{\circ}$ . The yield obtained is nearly quantitative.

Calc., Br = 82.13. Found, Br = 81.66.

In the case of toluene, a sweet smell is noticed during the progress of the reaction, which is especially noticeable when purifying the products. This sweet smelling vapor attacks the eyes most powerfully, causing an abundance of tears and considerable amount of pain. This is due to the formation of a small quantity of benzyl bromide.

***o*-Xylene.**—This yields monobromo-*o*-xylene by the short action of bromine and nitric acid, while by the prolonged action, tetrabromo-*o*-xylene is obtained accompanied by *o*- and *p*-toluic acids. For the preparation of monobromo-*o*-xylene, 10 cc. of *o*-xylene are taken in a flask provided with a reflux condenser and to this about 5 cc. of strong nitric acid and 8 g. of bromine are added. The reaction at once starts in with the evolution of brown fumes. After the reaction has subsided the material is warmed on the sand bath for about half an hour, when the operation is found to be complete. The oil is washed, dried and distilled. At first a little unchanged *o*-xylene comes out, then the temperature rises rapidly to  $210^{\circ}$  and the liquid distilling between  $210$ – $220^{\circ}$  is collected separately. After a second distillation it is found to consist of pure monobromo-*o*-xylene boiling at  $214$ – $215^{\circ}$ , the yield obtained being 6 cc. (8.22 g.) or 60% of the theory.

Calc., Br = 43.24. Found, Br = 42.95.

The prolonged bromination of *o*-xylene is carried out as follows: 4 cc. of *o*-xylene are taken in a flask provided with a ground reflux condenser and to this about 2 cc. of strong nitric acid are added and bromine in considerable excess in small quantities from time to time. The whole mixture is heated on the sand bath for about ten hours, when a semisolid product is obtained. The semisolid mass is warmed on the water bath

to free it from unchanged bromine. A brown oily substance is left behind, which is boiled with distilled water. The aqueous extract is decanted off and is allowed to evaporate on the water bath, when a white crystalline substance is obtained, which is found on examination to be *p*-toluic acid melting at  $180^{\circ}$ . The yellow oil obtained in the above operation is found to crystallize when kept aside for a day or two. It is next extracted by means of alcohol, when a part dissolves and gives crystals on evaporation which has been found to melt at  $101^{\circ}$  and on examination is found to be *o*-toluic acid.

The white crystalline substance remaining after alcoholic extraction is found to consist of impure tetrabromo-*o*-xylene, which could, however, be purified with difficulty. It melts between  $250^{\circ}$  and  $256^{\circ}$ .

Calc., Br = 75.82. Found, Br = 75.22.

*m*-Xylene forms a mixture of monobromoxylene and dibromoxylene by the action of bromine and nitric acid, but the product is tetrabromoxylene if the reaction be prolonged for a considerable time. For the preparation of monobromoxylene and dibromoxylene, 10 cc. of *m*-xylene are mixed with 5 cc. of strong nitric acid and 15 g. of bromine, when the reaction starts itself in the cold. After the first action has subsided the reaction mixture is warmed on the water bath for about two hours. The heavy oil that is found to have formed in the reaction is next washed, dried and distilled. Practically no unchanged xylene comes over. The distillate is collected in two fractions, one between  $200-210^{\circ}$  and the other between  $245-260^{\circ}$ . The first portion consists mainly of monobromo-*m*-xylene and the second portion contains dibromo-*m*-xylene. The first fraction is redistilled and found to boil at  $205^{\circ}$ . The yield of the monobromo-derivative obtained is 4 g.

Calc., Br = 43.24. Found, Br = 42.67.

The second fraction solidifies completely after allowing it to stand for some time. The crystals are pressed to free it from adhering liquor and then recrystallized and it is found to melt at  $68^{\circ}$ , the yield obtained being 4.5 g.

Calc., Br = 66.60. Found, Br = 60.27.

For the preparation of tetrabromoxylene 12 cc. of *m*-xylene are heated in the above manner with 4 cc. of nitric acid and an excess of bromine. The mixture is heated on the sand bath for ten hours, bromine being added in small quantities at a time. Occasional replenishing of nitric acid is also necessary. At the end of the operation a semisolid brown mass is obtained. It is first warmed on the water bath to drive off any free bromine present in it. The mass is boiled with water and on cooling the aqueous extract yields beautiful, white silky crystals. The crystals thus obtained are found to be pure tetrabromo-*m*-xylene, melting at  $241^{\circ}$ . The yield obtained is 6 g.

Calc., Br = 75.82. Found, Br = 75.34.

It is necessary to point out that the crystals obtained as the result of first solution in hot water consists of pure tetrabromo-xylene, while the product from subsequent washings contain impurities in the shape of lower bromo-derivatives. The yellow, viscous liquid consists of lower bromoxylenes amounting to 2.4 g. This can be separated, by the method given before, into monobromo- and dibromoxylenes.

***p*-Xylene.**—Eight cc. of *p*-xylene are taken in a flask with 2 cc. of conc. nitric acid and 2 cc. of bromine. Within a short time the reaction begins and nitrous fumes are seen to evolve. After warming on sand bath for fifteen or twenty minutes, the reaction is found to be complete. The oil is next washed, dried and distilled. At first only a small quantity of unchanged xylene comes over between 130–140°. Then the thermometer rises rapidly and monobromo-*p*-xylene distills over between 195–205°, the next fraction distilling between 255–265°, which consists of dibromo-derivative. The first fraction is redistilled and is found to boil at 199–200°. The yield obtained is 5 cc. (6.96 g.), *i. e.*, 55% of the theory.

Calc., Br = 43.24. Found, Br = 42.83.

The second fraction is purified by freezing, on placing it in a mixture of ice and salt. The crystals are pressed out from the adhering impurities. It melts at 75° and is found to be pure 2,5(s)dibromo-*p*-xylene. The yield obtained being 2 cc.

Calc., Br = 60.60. Found, Br = 60.12.

For the preparation of the higher bromo-derivatives of *p*-xylene, 4 cc. of *p*-xylene are heated on a sand bath for about twelve hours with nitric acid and bromine; the latter is added in small quantities from time to time. At the end a semisolid product is obtained which is freed from unchanged bromine by heating on water bath. The solid mass consists of a mixture of *p*-toluic acid and tetrabromo-*p*-xylene. A partial separation can be effected by treatment with alcohol but a complete separation to obtain pure products was not found successful.

**Mesitylene.**—Seven and five-tenths cc. of mesitylene are taken in a flask with a ground condenser and to it 2 cc. of nitric acid and 2 cc. of bromine are added. Reaction at once sets in and it is completed by warming for a few minutes on the sand bath. The heavy oil which is formed as a product of the reaction is washed, dried and distilled. It contains practically no unchanged mesitylene, the greater part is monobromo-mesitylene and comes over between 230–233°. The yield obtained is 4 g., or 46% of the theory.

Calc., Br = 40.21. Found, Br = 39.98.

A tarry residue is left behind in the flask which is a mixture of the higher bromo-derivatives.

By the prolonged action of bromine and nitric acid on mesitylene, tribromo-mesitylene is the chief product.

7.5 cc. of mesitylene are treated with 3 cc. of nitric acid and 6 cc. of bromine. The reaction starts at once and it is continued on a sand bath for three hours; bromine and nitric acid are added gradually in small portions at a time. A semisolid mass is obtained which is warmed on a basin with water to drive off the volatile matter. The product solidifies on cooling and consists of practically pure tribromo-mesitylene. The product on washing with benzene leaves behind white, silky crystals which are found to be pure tribromo-mesitylene, melting at  $222-223^{\circ}$ . The yield obtained is 5.5 g. of tribromo-mesitylene, or 33% of the theory.

Calc., Br = 67.22. Found, Br = 66.83.

**Ethyl Benzene.**—Ethyl benzene gives on short bromination with bromine and nitric acid, a mixture of *o*- and *p*-bromoethyl-benzene. For its preparation, 7 cc. of ethyl benzene are treated with 3 cc. of nitric acid and 4 cc. of bromine. The reaction begins at once with the evolution of nitrous fumes and generally the reaction becomes complete even without warming. The resulting product is washed, dried and distilled. After the passing out of unchanged ethyl benzene, the greater part boiled between  $202-204^{\circ}$ , which is a mixture of *o*-bromoethyl-benzene and *p*-bromoethyl-benzene. The yield obtained is 6 g., or 55% of theory.

Calc., Br = 43.24. Found, Br = 42.11.

After the distillation, a charred residue is left behind in the flask which is a mixture of higher bromo-derivatives of ethyl benzene.

Investigations on similar lines are being continued.

## APPLICATION OF THE NITROMETER FOR THE DETERMINATION OF CONSTITUTION AND ESTIMATION OF NITROGEN IN A CLASS OF NITROCOMPOUNDS. (NITROAMINES.)<sup>1</sup>

BY W. C. COPE AND J. BARAB.

Received September 21, 1916.

The nitrometer reaction was first noted by Crum<sup>2</sup> in 1847; but it was not until 1878 when Lunge<sup>3</sup> succeeded in developing a practical instrument which he called the "nitrometer" that this reaction came into general use. Undoubtedly the most common application of the nitrometer is for

the estimation of nitrogen as nitric oxide (NO) in nitric and nitrous acids their salts and esters. However, the nitrometer is by no means limited to these reactions.

In the literature may be found applications of the nitrometer for analyses of a great variety of compounds. According to Lunge<sup>1</sup> it may be employed in general for all analytical operations in which a definite quantity of gas is evolved, not soluble to a very considerable extent in the liquid from which it is evolved, and not acting upon mercury. He employs the nitrometer for determining the strength of standard acids, by introducing into the nitrometer a measured volume of the acid with an excess of sodium or calcium carbonate and measuring the volume of CO<sub>2</sub> liberated. From this the strength of the acid may be calculated. By using a weighed quantity of carbonate and an excess of acid the carbonate may be determined. The strength of hydrogen peroxide may be determined by measuring the volume of oxygen evolved by the action of bleaching powder and *vice versa*. Potassium ferricyanide in alkaline solution liberates oxygen from hydrogen peroxide and may be analyzed in like manner. Lunge also employed the nitrometer for estimating indigotin in reducing solutions of indigo, by means of absorption of oxygen. For a further list of methods and of the varied application of the nitrometer, Warrington,<sup>2</sup> Allen<sup>3</sup> and Baumann<sup>4</sup> should be consulted.

The fact that in the nitrometer it is possible to obtain the nitrogen as NO from nitric and nitrous esters and not from most characteristic nitrocompounds has long been used as a means of distinguishing the respective esters from nitrocompounds. A statement to this effect was made by Lunge<sup>5</sup> as follows:

"I have also made experiments to determine whether characteristic nitrocompounds will liberate nitric oxide as do the nitric esters by shaking with sulfuric acid and mercury. Although not apparent it would not seem impossible, that under these conditions sulfonic acids form and the feed nitric acid would react upon mercury, *e. g.*,  $C_6H_5NO_2 + SO_3H_2 = C_6H_5SO_3H + NO_2H$ . But nitrobenzol with sulfuric acid on the most vigorous shaking in the nitrometer gave no trace of gas, and furthermore remained unchanged. One may, therefore, safely conclude that the characteristic nitrocompounds have this distinction from the nitric esters of glycerin, cellulose, and other analogous compounds."

As further evidence of the stability of characteristic compounds toward the nitrometer reaction the following nitrocompounds were investigated in this laboratory: Nitromethane, CH<sub>3</sub>.NO<sub>2</sub>; dinitrobenzene, *o*-, *m*- and *p*-C<sub>6</sub>H<sub>4</sub> : (NO<sub>2</sub>)<sub>2</sub>; dinitrophenol, 1 : 2 : 4, C<sub>6</sub>H<sub>3</sub>(OH) : (NO<sub>2</sub>)<sub>2</sub>; dinitronaphthalene, 1 : 8, C<sub>10</sub>H<sub>6</sub> : (NO<sub>2</sub>)<sub>2</sub>; trinitrotoluene, 1 : 2 : 4 : 6,

<sup>2</sup> *J. Chem. Soc.*, 35, 375 (1879).

<sup>3</sup> *J. Soc. Chem. Ind.*, 4, 178 (1885).

<sup>4</sup> *Z. angew. Chem.*, 4, 135, 203, 328, 339, 392, 450 (1891).

<sup>5</sup> *Dingler's Polytechnic. J.*, 245, 171 (1882).

$C_6H_2(CH_3) : (NO_2)_3$ ; and tetranitroaniline, 1 : 2 : 3 : 4 : 6,  $C_6H_4(NH_2) : (NO_2)_4$ .

In no case with any of the above nitrocompounds could any gas be detected in the nitrometer on the most vigorous shaking with sulfuric acid and mercury. In all the above compounds it should be noted that the nitrogen of the nitro group is attached directly to the carbon atom.

In summarizing other reactions which identify characteristic nitrocompounds and nitrous and nitric esters we find the lines rather sharply drawn. The esters are more or less readily saponified by caustic potash into alcohols and the respective salts. Nitrocompounds are not saponifiable. When caustic potash reacts upon these, the products of reaction are not alcohols and nitrites or nitrates. By reduction the esters are converted into alcohol and ammonia, while the nitrocompounds under similar conditions yield as final products aminocompounds. The acid character of the aliphatic nitrocompounds is shown by the fact that one hydrogen atom attached to the same carbon atom as the nitro group is readily replaced by a metal. This cannot apply to the aromatic compounds, since the nitro group is attached to a tertiary carbon atom.

We will now turn to a class of nitrocompounds, the nitroamines, in which the nitro group is attached to carbon through nitrogen. As examples of this class of compounds we will cite nitrourea,

nitramine, usually called tetranitromethylaniline and known commercially as "tetryl."

In spite of the strongly basic character of guanidine, nitroguanidine<sup>1</sup> is a feebly acid substance. When boiled with caustic potash,  $CO_2$ ,  $N_2O$  and ammonia are formed. With zinc dust and acetic acid nitrosoguanidine and then aminoguanidine are formed. By treating with a hydrochloric acid solution of stannous chloride, ammonia and guanidine are formed.

Nitro urea is a strong acid;<sup>2</sup> its alkali salts are neutral in reaction and it expels acetic acid from acetates. From this reaction it should be con-

 \end{array}$$
 sidered an iso-nitrocompound, . On reduction it gives first nitroso and then aminourea.

Trinitromethylnitramine undoubtedly also gives all the characteristic reactions of true nitrocompounds. This compound is of particular interest because it has three nitro groups attached directly to the carbons in the ring and one nitro group linked to carbon through a secondary nitrogen.

The nitroamines described were selected at random as types of nitrocompounds in which the nitro group is attached to carbon through nitrogen. The reactions indicated show them to respond to most reactions for true nitrocompounds. When subjected to the nitrometer reaction they yielded only the nitrogen of the nitro group attached to carbon through nitrogen. In this reaction they behave like the nitric and nitrous esters.

The du Pont<sup>1</sup> modification of the Lunge nitrometer and the decomposition flask method of Berl and Jurrissen<sup>2</sup> were used in the determination of nitrogen. The decomposition flask method of Berl and Jurrissen is not known generally in this country and, therefore, a short description of the apparatus and method of operation will be appropriate. The apparatus consists of a heavy-walled round-bottom flask of 300 cc. capacity, with a ground-in bulb-shaped glass fitting. The fitting is composed of two parts: a 50 cc. tap funnel through the side of the bulb, with its stem extending below the neck of the flask; and an exit tube, containing a two-way stop-cock, in the top of the bulb. The fittings and cocks are all greased with a mixture of vaseline and caoutchouc.

The substance to be analyzed is placed in the flask, which is then closed with the fitting. The flask is evacuated through the exit tube and CO<sub>2</sub> introduced. This operation is repeated three times and the flask is finally again exhausted. About 20 cc. conc. H<sub>2</sub>SO<sub>4</sub> are added through the tap funnel, and the flask is shaken until the substance dissolves. Ten to fifteen grams of mercury are then added through the funnel and the flask shaken until NO is completely evolved.

The success of this method depends principally upon good fittings and pure CO<sub>2</sub>. By using a CO<sub>2</sub> generator similar to the one described by Young and Caudwell<sup>3</sup> and developed by one of us<sup>4</sup> in this laboratory, no difficulty was experienced in obtaining a supply of pure CO<sub>2</sub>. The gas generated in the flask is displaced by the rapid introduction of a saturated solution

<sup>4</sup> "Determination of Nitrogen in Substances Used in Explosives," Bur. Mines, *Tech. Paper* 160.

of sodium sulfate through the funnel and is collected in a buret over mercury. The volume is observed, the gas run into a caustic potash solution, returned to the buret and the reading taken. The quantity of  $\text{CO}_2$  absorbed varies from two to three cubic centimeters. The gas is then passed into a pipet containing a saturated solution of ferrous sulfate and well shaken. The residual gas is then returned to the buret and the reading observed. The residual gas varies from 1.5 to 2.0 cc. In treating a sample of gas obtained in the nitrometer from  $\text{KNO}_3$  in above manner it was found that a 100 cc. sample left a residue of 1.7 cc. It was consequently considered permissible to add this residual gas to the  $\text{NO}$  absorbed by ferrous sulfate. From this volume, after reducing to standard conditions, the percentage of nitrogen was calculated.

Representative samples of gas from each of the compounds analyzed in the du Pont nitrometer were passed into  $\text{FeSO}_4$  solution and in all cases gave results that left no doubt that the gas consisted entirely of nitric oxide.

### Observations on Results.

The nitrometer results are consistently somewhat low. This is due to a slight action of the sulfuric acid on these nitrocompounds and consequent loss of a small amount of gas, before forcing the substance into the nitrometer bulb. The results with the decomposition flask are all well within experimental error.

The nitrometer and especially the decomposition flask method of Berl and Jurrissen are well adapted for the determination of nitrogen in nitrocompounds where the nitro group is attached to the carbon through a nitrogen atom.<sup>1</sup>

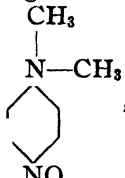

<sup>1</sup> It is, perhaps, of interest to note that these compounds may be considered as esters of nitric acid,  $\text{NO}_2\text{—O—R}$  in which the oxygen atom connecting R with  $\text{NO}_2$  is replaced by NH. It recalls the work of E. C. Franklin who has shown that  $\text{K—NH—H}$  is base and acetamide,  $\text{C}_2\text{H}_5\text{O—NH—H}$  is an acid in anhydrous ammonia.—EDITOR

In the nitric esters we have  $\equiv \text{C}-\text{O}-\text{NO}_2$ , or the  $\text{NO}_2$  group linked to carbon through an oxygen atom. In the nitrocompounds under discussion,  $\equiv \text{C}-\text{N} \begin{cases} \text{H or CH}_3 \\ \text{NO}_2 \end{cases}$ , the nitro group is linked to carbon through a nitrogen atom. If we now turn to the nitrous esters  $\equiv \text{C}-\text{O}-\text{NO}$  we find an  $\text{NO}$  group linked to carbon through oxygen. By analogy we should expect nitroso compounds in which the nitroso group is linked to carbon through nitrogen likewise to yield its nitroso nitrogen in the nitrometer reaction.

Nitroso diphenylamine, , was selected as a compound of

this type. As sulfuric acid causes a rather violent reaction upon this substance the decomposition flask was used for this reaction. The results obtained were 6.97, 6.94, and 7.05% N, theoretical 7.07% N. Again allowing for impurities in the sample, these results are well within experimental error. The gas formed was examined in the same manner as in previous experiments, and was identified as nitric oxide.

To allay any apprehension that this might be a general reaction for all

nitroso compounds, *p*-nitrosodimethylaniline, , was selected

as one which had the nitroso group attached directly to carbon. Sulfuric acid likewise acts rather violently on this substance, but on completing the reaction with mercury, about one-sixth the theoretical quantity of gas was formed, and only a trace of this was absorbed by ferrous sulfate solution. This also shows that the nitroso group must be attached to the carbon atom through nitrogen, in order that the nitroso nitrogen may be determined by the nitrometer reaction.

A curious anomaly occurs when it is attempted to determine nitrogen in urea and guanidine nitrates in the nitrometer in the usual manner, *i. e.*, by dissolving in a small quantity of water, introducing into bulb, then adding the sulfuric acid, etc. Results were obtained varying from 13.3 to 15.6% N if all the gas formed is considered as  $\text{NO}$ . This was not the case, as on a few qualitative tests the gas showed considerable  $\text{CO}_2$  and  $\text{N}_2$  besides the  $\text{NO}$ . Theoretical nitrate nitrogen for urea nitrate is 11.38% and for guanidine nitrate 11.48%. Both these compounds must first be converted into their respective nitrocompounds before they can

be determined in the nitrometer. This is easily accomplished by slowly adding a weighed sample (e. g., 1 g.) of the nitrate to 20 cc. conc. sulfuric acid cooled to  $0^{\circ}$  and kept at this temperature until all the nitrate is dissolved. This converts the nitrate into the nitrocompound, which may then be introduced into the nitrometer, the cup washed with 10 cc. additional sulfuric acid, and the reaction completed in the usual manner. This method will yield practically theoretical results for the nitrates.

### Summary.

1. The nitrometer has been used for a great variety of analytical operations, in which a definite quantity of a gas is evolved, not soluble to a very considerable extent in the liquid from which it is evolved, and not acting upon mercury.

2. The characteristic nitrometer reaction has been used only for nitrous and nitric acid, their salts and esters.

3. Further evidence is given that the nitrometer reaction does not liberate NO from true nitrocompounds in which the nitro group is linked directly to the carbon atom.

4. Characteristic reactions for nitrocompounds are given and evidence is produced that nitrocompounds in which the nitro group is attached to carbon through nitrogen give most of these reactions.

5. The application of the true nitrometer reaction is extended for the determination of nitrogen of the  $\text{NO}_2$  and NO groups in nitroamines and nitrosoamines in which the respective groups are attached to carbon through nitrogen.

6. The nitrometer reaction may be used as a means of ascertaining whether the  $\text{NO}_2$  and NO group is attached directly to the carbon or through a nitrogen atom.

7. An anomaly is noted in which the nitrates of urea and guanidine cannot be determined in the nitrometer in the usual manner. They must be converted into their respective nitrocompounds first, after which they may be readily determined.

## THE COMPOSITION OF NEUROKERATIN.

By BURT E. NELSON.

Received September 9, 1916.

Neurokeratin, which was first isolated by Kühne, is supposed to be the chief characteristic constituent of the neuroglia cells of the brain, and of the axilemma and outer sheath of the medullary substance of the nerve trunks. It is classed chemically with the general group of keratins;

which form the characteristic constituents of the hair, hoofs, horn, nails, shells, scales and other tissues of epiblastic origin, and whose chief characteristics among the other classes of proteins are their insolubility in water, salt solutions, acid and weak alkali solutions, their indigestibility in pepsin-hydrochloric acid, and their relatively high content of sulfur in the molecule.

Widely varying analytical figures have been reported by other observers<sup>1</sup> for the elementary composition of this substance, the discrepancies doubtless arising from different methods used in isolating it, and the analysis of impure products. It was with a view of obtaining more trustworthy results that the following analysis was undertaken:

The material used was the total protein residue from several lots of brains of patients diagnosed as having general paresis, senile dementia (with plaques), and dementia praecox, which had been previously extracted with alcohol, ether, and warm water, for the lipid and extractive matters.

Previous to these extractions the minced brain tissues had been allowed to remain in 85% alcohol for two months, to insure thorough coagulation and hardening of the proteins. This final dried protein residue was finely ground and digested in an incubator at blood heat, six times with one hundred times its amount of pepsin-salt-hydrochloric acid mixture, for twenty-four hours each, or three times after the cessation of the biuret reaction. It was then similarly digested five times with 0.1% solution of sodium hydroxide to dissolve nucleins and finally extracted again with alcohol and ether and dried at a gentle heat.

It formed a pale yellowish, light powder, showing no further changes on treatment with solvents (which removed at most only traces of soluble matters) and had a mineral ash content of 0.22 to 0.25%.

Elementary analysis for carbon and hydrogen, by combustion of one-half gram lots gave:

C, 54.86%, 54.73%, 54.95%, and 54.95%; H, 7.33%, 7.30%, 7.18%, and 7.33%.

Nitrogen determinations by the Kjeldahl method, on half-gram lots, using no catalyzing agent, and continuing the digestions for three hours after the solutions were colorless, gave

N, 13.12%, 13.24%, 13.16%, and 13.16%.

Similarly, sulfur determinations on one-gram lots, by combustion in oxygen gas in a closed calorimeter bomb, gave

Sulfur, 1.37%, and 1.40%.

Phosphorus was entirely absent.

The average elementary analysis of our material is therefore

C, 54.87%; H, 7.28%; N, 13.17%; S, 1.38%; O, 23.07%; and ash, 0.23%.

<sup>1</sup> Hammersten, *Physiol. Chemie*, 6; Argiris, *Z. physiol. Chem.*, 54, 86-94 and ourselves, *Psychiatric Bull. New York State Hospitals*, 9, No. 3.

This is an unusually low nitrogen, and especially sulfur, content for a keratin, although closely similar to the figures obtained in our previous analyses. The other elementary analyses of this substance have varied as follows:

C, 56 to 58.5%; H, 7.25 to 9.00%; N, 11.5 to 14.0%; and S, 1.63 to 2.31%.

In an attempt to further learn the structural make-up of this protein molecule, a single partition of the nitrogen content among the several amino acids, etc., was made, using a slight modification of Van Slyke's method.

2.715 g. of the neurokeratin were hydrolyzed by heating for sixty hours with diluted hydrochloric acid, or until the total amino nitrogen was constant. The resulting solution was then analyzed and gave:

Total hydrolyzed nitrogen 0.3570 g. (100%), ammonia nitrogen 0.01875 g., uncorrected arginine nitrogen 0.01344 g., melanin nitrogen 0.0518 g., total nitrogen precipitated by phosphotungstic acid 0.0896 g., total nitrogen not precipitated by phosphotungstic acid 0.18984 g., amino nitrogen precipitated by phosphotungstic acid 0.0800 g., total amino nitrogen not precipitated by phosphotungstic acid 0.0900 g., and total sulfur precipitated by phosphotungstic acid 0.0378 gram.

By calculation we arrive at figures for the various products of hydrolysis as follows:

Ammonia nitrogen.....	5.24%
Melanin nitrogen.....	14.51%
Arginine nitrogen.....	2.692%
Cystine nitrogen.....	4.40%
Histidine nitrogen.....	6.279%
Lysine nitrogen.....	11.729%
Nitrogen from one or all of pyroline, oxyproline, or tryptophane..	27.95%
Nitrogen from one or all of glutamic acid, aspartic acid, tyrosine, leucine, isoleucine, alanine, or glycocoll.....	25.21%
Total.....	98.01%
Error and loss.....	1.99%

The results of this single fractionation cannot, however, be accepted as final. They do indicate, however, that most of the sulfur exists in the form of cystine, which is characteristic of keratins as a class.

All of the above figures representing the ultimate elementary analysis of this material are in fairly close accord with some previously obtained by us in a similar manner, so the reasons for the discrepancies in published results must, as previously surmised, lie in variations in the purity of the neurokeratins analyzed. The indigestibility of our protein, its insolubility in dilute alkali, and its freedom from phosphorus, would seem to surely eliminate the chance for an admixture with brain globulins, other proteins, or nucleins. Some elastic tissue from the finer cerebral vessels might possibly, however, be present.

The low nitrogen content, as before stated, is peculiar for any protein

of this class, being indeed more nearly like that in the case of some mucin substances, while the sulfur found more nearly coincides with the amount found in most globulins, rather than in keratins.

A. Argiris<sup>1</sup> obtained on analysis of his neurokeratin:

C, 56.60%; H, 7.15 and 7.40%; N, 14.16%; and S, 2.24 to 2.31%, calculated to the ash-free material.

His analysis of the hydrolytic products also gave different results, but was performed after the older methods. On the other hand, one of the analyses quoted by Hammersten gives nitrogen as low as 11.5%.

Whether or not the long standing of the tissues in 85% alcohol and the subsequent extraction with boiling alcohol, might have permanently rendered other of the proteins indigestible and insoluble, or what portion, if any, of similar indigestible proteins might possibly have been left from the cerebral vessels, we are unable to say definitely; but these last then must probably also have been present in preparations of neurokeratin obtained by Kühne and Chittenden's method.

### Conclusions.

Neurokeratin, as obtained by us, is a protein of unusually low nitrogen and sulfur content, as compared with more commonly known keratins, and appears to differ from these latter also in the structural make up of its molecule.

## AN ACCURATE AERATION METHOD FOR THE DETERMINATION OF ALCOHOL IN FERMENTATION MIXTURES.

By ARTHUR W. DOX AND A. R. LAMB.

Received August 28, 1916.

### Introduction.

A great deal of work has been done upon methods for the determination of ethyl alcohol by physical means, principally the specific gravity, the index of refraction, or the boiling point of alcoholic solutions. Physical methods, however, are all open to the same objection, *viz.*, that the presence of any other substance than ethyl alcohol in the solution tested will always cause incorrect—usually high—results. The production of alcohol in fermentation processes, in whose products it is generally desired to estimate the alcohol, is invariably accompanied by the formation of by-products in greater or less amount, even in pure yeast cultures. Many of these other products are volatile, and cannot be separated from the alcohol by distillation, especially in dilute solutions. The estimation

<sup>1</sup> *Loc. cit.*

of the alcohol in such a mixture by physical methods must therefore be very difficult to free from error.

Chemical methods have not received nearly so much attention, perhaps because the physical methods generally consume less time. However, the list of interfering substances should not be nearly so long in the case of the determination of ethyl alcohol by oxidation to acetic acid, since it would include only volatile substances which yield a volatile acid on oxidation. The latter method should therefore be more reliable, and may perhaps be susceptible of development to as great a degree of accuracy.

It is not the purpose of this paper, however, to enter into a discussion of the relative merits of physical and chemical methods, but merely to present the results of a considerable experience with chemical methods for the determination of alcohol, which may be of value to others engaged with fermentation problems.

### The Oxidation of Alcohol.

In the oxidation method there are two possible sources of error, which may be considered separately. The first, which is common to all methods, lies in the difficulty in quantitatively removing the alcohol from the original fermented solution, and in getting it into a convenient volume for oxidation. Direct distillation of a fermented solution is likely to be troublesome, especially when nearly all of the solution must be distilled over in order to get all of the alcohol into the distillate. Distillation with steam in the usual manner will volatilize all of the alcohol only after a very long time, and it is difficult to concentrate the large distillate without losing a considerable amount of the alcohol. The second possible source of error is in the oxidation itself, where the oxidation may be incomplete, yielding aldehyde, or may go too far, with the production of carbon dioxide and water. Other substances than alcohol, which might yield a volatile acid as an oxidation product, might also be present.

The most commonly used oxidizing agent is a sulfuric acid solution of potassium dichromate. Potassium permanganate solution has not often been suggested. A recent paper by Evans and Day<sup>1</sup> has shown that varying amounts of oxalic acid and carbon dioxide are formed in the oxidation, in addition to the acetic acid. The sulfuric acid-dichromate method was used by Hehner,<sup>2</sup> and by Benedict and Norris,<sup>3</sup> who determined the amount of dichromate reduced, and by Dupre,<sup>4</sup> who distilled and titrated the acetic acid formed. Various modifications of Dupre's method have been used by Suzuki, Hastings, and Hart,<sup>5</sup> and by Hart,

<sup>2</sup> *Analyst*, 12, 25 (1887).

<sup>3</sup> THIS JOURNAL, 20, 293 (1898).

<sup>4</sup> *J. Chem. Soc.*, 20, 495 (1867).

<sup>5</sup> *J. Biol. Chem.*, 7, 431-438 (1910).

Hastings, Flint, and Evans,<sup>1</sup> in work on cheese, and by Hart and Willaman,<sup>2</sup> and by Dox and Neidig,<sup>3</sup> in work on corn silage.

### Experimental Part.

**Oxidation Trials.**—Dupre's method, as originally published,<sup>4</sup> is unsupported by data checking it against known alcohol solutions, and has apparently not been standardized by other workers who have used the method. Since a reliable and accurate method was necessary for use in the silage investigations in progress in this laboratory, a careful study of Dupre's method was begun. It seemed that the distillation and titration of the acetic acid formed would be much more trustworthy than the determination of the reduced dichromate, as done by Benedict and Norris,<sup>4</sup> since various organic substances might reduce the dichromate, while the formation of a volatile acid in the oxidation would be much less likely to occur. Therefore the oxidation of standard alcohol solutions by Dupre's method was first studied.

The standard alcoholic solutions were made by weighing out about 10 g. of redistilled, nearly absolute, alcohol, and making up to exactly 1000 cc. with CO<sub>2</sub>-free distilled water. The densities of the original alcohol and of the dilute solutions were determined with a Sprengel pycnometer, and the strength of the dilute alcohol solutions calculated. Samples were taken with a carefully calibrated pipet.

Various mixtures of sulfuric acid and dichromate have been used by other workers, but the exact proportions seem to be of minor importance. The oxidizing solution decided upon and used in most of this work was made up in the following proportions: 10 g. K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>, 20 g. H<sub>2</sub>SO<sub>4</sub>, 70 g. CO<sub>2</sub>-free distilled water. Oxidation in a pressure flask in a boiling water bath was first tried. It was soon found that 30 minutes' oxidation would give as good results as 3 hours. Later it was found that if the solution was merely allowed to stand in the distilling flask a few minutes at room temperature, before distillation, the results obtained were fully as accurate. The reaction seems to be complete in a very few minutes on heating, during the time necessary to bring the solution in the distilling flask to the boiling point. In the case of oxidation at room temperature, the first few cubic centimeters of the distillate sometimes have a slight odor of acetaldehyde, but this small loss is apparently no greater than the loss attendant upon transferring the liquid from the pressure flask to the distilling flask in the case of oxidation with heat.

Dupre and later workers with his method have reduced the excess dichromate in the oxidizing solution with zinc, before distillation. This

<sup>1</sup> *J. Agr. Res.*, 2, 193 (1914).

<sup>2</sup> *THIS JOURNAL*, 34, 1619 (1912).

<sup>3</sup> *Iowa Agr. Exp. Sta., Research Bull.* 7 (1912) and 16 (1914).

<sup>4</sup> *Loc. cit.*

extra step is not only entirely unnecessary, but it is often a source of trouble in the distillation. Therefore it has not been done in this work.

The distillation of the volatile acid from the oxidizing solution is carried on carefully over a free flame, using an asbestos board with a small circular opening for the bottom of the distilling flask. The combination of a glass bead with two small pieces of pumice stone in the distilling flask has been found the most satisfactory preventive of both bumping and foaming during the distillation. If care is taken not to permit the volume of liquid in the distilling flask to become low enough to allow sulfuric acid to be carried over, the distillation gives no trouble whatever. If barium hydroxide solution is used for the titration, the presence of any sulfuric acid in the distillate will at once be detected. The oxidizing solution is repeatedly distilled with additions of  $\text{CO}_2$ -free distilled water, until the last titration is 0.5 cc. of a decinormal solution, or less. This is generally after four or five distillations. If care is taken, the error due to carbon dioxide is negligible. Some representative data secured on this part of the process are shown in Table I.

TABLE I.—OXIDATION OF KNOWN ALCOHOL SOLUTIONS.

Conditions.	Calc. g. alcohol.	Found g. alcohol.	Recovery. %.
Oxidation at 100°, 30-40 min.....	0.238	0.236	99.2
	0.238	0.235	98.7
	0.257	0.257	100
	0.257	0.256	99.6
Oxidation at room temperature.....	0.238	0.237	99.6
	0.257	0.256	99.6
	0.257	0.257	100

Only when the method of oxidation had been perfected, and reliable results in that part of the process assured, were the more uncertain preliminary steps studied.

**Distillation of Alcohol Solutions.**—Previous investigators have concentrated the alcohol solution obtained from steam distillation by successive redistillations, distilling off each time about one-half to three-fourths of the volume in the flask. This method is very tedious and far from quantitative. Bacon,<sup>1</sup> of the Bureau of Chemistry, has shown that it is possible, by nearly saturating the alcohol solution with common salt, to distill off all the alcohol in the first one-fifth of the volume distilled, Bacon's suggestion was carried further in this work, by adding the salt to the original solution to be distilled with steam, thus liberating both the alcohols and the volatile acids much more readily, and getting them over practically completely in the first 500 cc. of distillate. It is noteworthy that although lactic acid was present in the solution, no hydrochloric acid was liberated. Solid phenolphthalein was added to the distillate, the volatile acids titrated and fixed; and the alcoholic solution easily

<sup>1</sup> U. S. Dept. Agr., Bur. Chem., *Circ.* 74 (1911).

concentrated in one or two distillations with salt to a convenient volume for oxidation. A few typical results obtained with known solutions by this method are shown in Table II. This table also shows the result obtained by the concentration of a known solution from 500 cc. to 50 cc. with the use of salt, to compare with steam distillation with salt followed by concentration. In one distillation shown the salt used was ammonium sulfate.

TABLE II.—DISTILLATION AND OXIDATION OF KNOWN ALCOHOL SOLUTIONS.

Conditions.	Calc. g. alcohol.	Found g. alcohol	Recovery. %.
Distilled and concentrated with NaCl.....	0.238	0.210	88.2
	0.238	0.225	94.6
	0.238	0.216	90.8
Concentrated only, with NaCl.....	0.238	0.228	96.6
Distilled and concentrated with $(\text{NH}_4)_2\text{SO}_4$	0.238	0.218	91.6

Steam distillation of alcohol solutions generally gives just such variable results as are shown in this table. It is evident that the greatest loss of alcohol in this method occurs during the distillation with steam.

#### Aeration Method.

Since the saturation of an alcoholic solution with a soluble salt brings about the liberation of the alcohol by distillation so readily, it seemed probable that alcohol could be volatilized by aeration at room temperature from a similarly saturated solution. Ammonium sulfate was chosen as a suitable salt for the purpose, and was found more efficient than sodium chloride. A known amount of alcohol in 100 cc. of water was placed in a Drexel gas-washing bottle with 80 g. of ammonium sulfate. This was connected to a series of two bottles, each containing 50 cc. of oxidizing solution, which were followed by a flask containing a definite amount of 0.1 *N* barium hydroxide solution. A soda-lime tube and a guard bottle containing oxidizing solution were placed at the beginning of the train, and a stream of air was drawn through at a moderate rate with a water pump. This method gave at first more or less variable results. It was necessary to determine the amount of volatile acid, exclusive of carbon dioxide, which had been caught by the barium hydroxide solution, and to distill off the rest of the acetic acid from the oxidizing solution. However, the volatilization of the alcohol was found to be complete in about 8 hours' aeration, and the amount of alcohol recovered averaged from 90% to 96%.

Benedict and Norris<sup>1</sup> make the statement that concentrated sulfuric acid takes up alcohol as readily as it does water. Therefore a bottle containing 20 cc. of the acid was substituted for the oxidizing solution, and the barium hydroxide and soda-lime were eliminated. After aeration the sulfuric acid was carefully added to 100 cc. of saturated solution of

<sup>1</sup> *Loc. cit.*

potassium dichromate, oxidized, and distilled as before. More accurate and more uniform results were obtained than before, and other advantages were secured. As the alcohol is not oxidized until after the aeration is completed, there is no danger of loss of volatile acid. The sulfuric acid takes up the alcohol more completely than does the oxidizing solution. The alcohol is brought into a small volume, and may be left in that condition indefinitely, if not convenient to make the oxidation at once. A smaller number of bottles is necessary in the train, and less attention is required.

Instead of a regular gas-washing bottle as a container for the sulfuric acid, it is preferable to use an ordinary 100 cc. graduated cylinder, fitted with a rubber stopper carrying an inlet and an outlet tube. The inlet tube may be slightly constricted at the lower end, or a bulb with small perforations, similar to a Folin bulb, may be blown at the end, to secure still more efficient absorption. However, it is necessary in any case to use two cylinders of sulfuric acid, in order to secure the most complete recovery of the alcohol. It seems that this is not because the stream of air is too large or too fast, but because the reaction between the alcohol and the sulfuric acid is reversible, and therefore a small amount of the alcohol passes over into the second cylinder. The recovery of alcohol was increased by 1%-2% when the second cylinder was first used.

A few representative results showing the average accuracy of the method are given in Table III. In nearly all cases, the oxidation was at room temperature.

TABLE III.—THE DETERMINATION OF ALCOHOL IN KNOWN SOLUTIONS BY THE AERATION METHOD.

Conditions.	Calc. g. alcohol.	Found g. alcohol.	Recovery. %.
Oxidizing solution used to fix alcohol. . .	0.238	0.227	95.4
	0.238	0.226	95.0
	0.238	0.229	96.2
Concentrated H <sub>2</sub> SO <sub>4</sub> used to fix alcohol.	0.257	0.248	96.5
	0.257	0.250	97.3
	0.257	0.252	98.1
	0.257	0.254	98.8
	0.103	0.101	98.0
	1.620	1.594	98.4
	0.0202	0.0201	99.5

The aeration train, as now made up, consists of a guard bottle of oxidizing solution, followed by the saturated ammonium sulfate solution containing the alcohol, and by two cylinders of concentrated sulfuric acid, the first containing about 18 cc. and the second 8-10 cc. of acid. The rate at which the air is drawn through is about 25 liters per hour. The aeration is generally complete in 8-10 hours, but slightly higher results are obtained by aeration at a slower rate for 24 hours, minimizing the spattering of the sulfuric acid. After the aeration is complete, the

sulfuric acid is mixed with 10–15 g. of dichromate in water in the distilling flask, and the cylinders well rinsed with CO<sub>2</sub>-free water. The mixture is allowed to stand about 15 minutes, and then distilled as described above.

The ammonium sulfate used should be as nearly neutral as possible. The commercial C. P. salt sometimes contains a considerable amount of bisulfate.

It is interesting to know that volatile fatty acids cannot be determined by aeration, either with ammonium sulfate or sodium chloride, although they distill over from a saturated salt solution at 100° faster than the alcohol.

Quite large amounts of alcohol, up to two grams, can be determined accurately by this method. Larger amounts can be determined by using a smaller sample. In the presence of half a gram of alcohol or more, the sulfuric acid and dichromate solutions must be mixed carefully and cooled.

The entire determination requires from 12 to 30 hours, but requires personal attention amounting in time to less than one hour. The results obtained are as accurate and more trustworthy than those obtained by any other method applicable to fermentation mixtures which is known to the authors. This method has been used for the determination of alcohol in various kinds of silage with very satisfactory results.

**Interfering Substances.**—Acetone is oxidized but slightly under the conditions of this method. It is carried over by aeration, but most of it distills unchanged from the oxidizing solution. About 0.6 g. of acetone yielded only 0.003 g. of acetic acid. If oxidized for 2 or 3 hours in a pressure flask at 100°, however, it is nearly all oxidized to acetic acid.

Certain esters, especially ethyl acetate, interfere with the determination of alcohol by this method, but these may be determined separately.

Acetaldehyde is readily volatilized and oxidized to acetic acid, but aldehydes generally occur in fermentation mixtures only in small quantities as intermediate products.

Methyl alcohol is almost completely oxidized under these conditions to carbon dioxide and water. Some recent investigators have apparently overlooked this fact in dealing with mixtures of alcohols, which were oxidized and determined as the corresponding acids by the Duclaux method. Only 0.012 g. of methyl alcohol was recovered as formic acid from 0.185 g. by aeration and oxidation.

According to Thorpe and Holmes,<sup>1</sup> pyridine is not changed by the sulfuric acid-dichromate mixture, allyl alcohol is completely oxidized to carbon dioxide and water, and methyl acetate yields both carbon dioxide and acetic acid. They also state that ethyl alcohol yields constantly

<sup>1</sup> *J. Chem. Soc.*, 85, 1 (1904).

0.5% of its weight as carbon dioxide. The correction may be applied, if desired. The presence of toluol does not effect the accuracy of the method, as the toluol is not oxidized.

### Summary.

The determination of ethyl alcohol by oxidation with sulfuric acid-dichromate solution has been carefully studied. It is considered that the best results are obtained when the alcohol is finally determined by distillation and titration of the acetic acid formed.

The preparation of the solution by distillation, even from a saturated salt solution, is tedious and troublesome and far from quantitative.

The alcohol solution may be saturated with ammonium sulfate and the alcohol carried over into concentrated sulfuric acid by a current of air at room temperature. The alcohol-sulfuric acid solution may then be mixed with a solution of potassium dichromate and the acetic acid distilled off at once. Results accurate within 1.5% of the amount used have been obtained by this method.

Necessary precautions and interfering substances are discussed.

## THE EFFICIENCY OF THE AERATION METHOD FOR DISTILLING AMMONIA; IN ANSWER TO CERTAIN CRITICISMS.

By PHILIP ADOLPH KOBER.

Received September 3, 1916.

From his "Comparative Study of Aeration and Heat Distillation in the Kjeldahl Method for the Determination of Nitrogen" Falk<sup>1</sup> concludes that "the aeration procedure in the ordinary Kjeldahl method for nitrogen very often gives inaccurate and therefore unreliable results, and should not be used."

This conclusion is based on his failure to remove all of the ammonia by aeration. Dillingham<sup>2</sup> has also recorded failure to obtain satisfactory results for the same reasons, while Bock and Benedict<sup>3</sup> and Greenwald<sup>4</sup> report great variations in the results of their determinations without accounting for them.

Accordingly, I have studied carefully the records of these observers in their published articles in the hope of discovering the sources of error, whether in the method or in the manner in which it was used.

Falk attempts to employ the results of Davis, as confirmatory data, in saying that:

<sup>1</sup> THIS JOURNAL, 38, 916 (1916).

<sup>2</sup> *Ibid.*, 36, 1310 (1914).

<sup>3</sup> *J. Biol. Chem.*, 20, 47 (1915).

<sup>4</sup> *Ibid.*, 21, 61 (1915).

"Davis found aeration to give unsatisfactory results in the determination in cottonseed meal and proposed to heat the solution during aeration."

But Davis<sup>1</sup> said that: "If the flask \* \* \* were placed in an asbestos box \* \* \* the solutions kept warm an hour and a half," and "the results checked with results obtained by ordinary Kjeldahl." Heat was only proposed if larger amounts of substance were used and then only for "fifteen minutes," and in conclusion, "the method described by Kober if modified as described will give good results with other nitrogen containing bodies."

The reason for this modification is apparent, as Davis states on page 56, that "the stream of air drawn by the ordinary glass pump was not strong enough to carry over the ammonia by the time the solution cooled," thus showing that he realized the necessity for strong aeration. However, it is quite unnecessary to heat, because a little longer aeration accomplishes the same result.

In the experiments of Gill and Grindley<sup>2</sup> mentioned by Falk, only the analysis of one substance failed to yield satisfactory results. When compared to a large number of accurate results which they obtained this is of little significance. These observers strongly recommended the aeration procedure for the distillation of ammonia in urea and urine estimations.

Finally, in citing the work of others Falk relies for most of his support on Dillingham,<sup>3</sup> but he overlooks the essential fact that to Dillingham's technic can be attributed all his unsatisfactory results. He used a flask of large diameter (800 cc. capacity), and thereby spread out and decreased the height of the liquid through which the ammonia should pass and almost destroyed the efficiency of his aeration. That the higher the column for a given liquid, the more efficient the aeration, is too obvious to need but passing mention. Dillingham's attention was called to this oversight two years ago, but no re-investigation, although promised, has thus far appeared. Whether any other defects in his technic are involved it is impossible to say.

*To sum up, then, the only support in the literature found by Falk, was one instance with a defective pump (Davis), and another instance with an unsuitable flask (Dillingham).*

Considering Falk's results independently, the following points are to be noted:

1. Disagreement in the results obtained by aeration.
2. With one or two exceptions, the amount of ammonia undistilled was nearly proportional to the total amount present originally.

<sup>1</sup> THIS JOURNAL, 31, 56 (1909).

<sup>2</sup> *Ibid.*, 31, 1249 (1909).

<sup>3</sup> *Ibid.*, 36, 1310 (1914).

3. That the amount of aeration varied as much as 39%, and even 30%, in a series of distillations "testing before and after the run."

4. That the speed of aeration during a run was never tested, and is therefore unknown.

It is clear from these four points that the main cause of the discrepancies in the results was poor aeration.

That the aeration was weak at the Harriman laboratory, due to inadequate water supply for the overcrowded rooms, was found by the writer personally and is shown by the fact that Falk's collaborator in this paper, Sugiura, under more favorable conditions in former years, when less water was used for other purposes, did get good checks for the aeration procedure.<sup>1</sup>

It is a very simple matter to test out the efficiency of aeration by adding Nessler's solution to the Kjeldahl residue, as was recommended in a previous paper,<sup>2</sup> but this seems not to have been considered by Falk, even though with steam distillation an increase in titration alone is no test for ammonia. Dissolved alkali from the glass condenser, if used, will alone account for such a phenomenon.

To re-check the cardinal points the following demonstration was made: An ordinary Kjeldahl distillation was run with an extra absorption bottle.

After aeration Nessler's reagent was added to the Kjeldahl flask and Graves' reagent to the extra absorption bottle. The negative result with the residue in the Kjeldahl flask leaves no question that all the ammonia had been aerated over, and since there was no ammonia in the extra absorption bottle it was proved conclusively that all the ammonia was in the first absorption bottle and was completely absorbed.

Where there is an abundance of air supply, as in institutes particularly equipped with air compressors and vacuum systems, and in all laboratories where the "micro" form of apparatus is used, which requires much less air, no such aeration difficulty is found. That in many laboratories water suction pumps are inefficient was brought out by Pennington<sup>3</sup> and accounts for the failure of Boussingault in 1850 to apply successfully the aeration method using only 56 liters an hour, while Folin employing 600-700 liters an hour was the first to demonstrate successfully that ammonia can be distilled by aeration from weakly alkaline solutions and absorbed quantitatively.

The positive results for urea estimations by Henriques<sup>4</sup> and Gammeltoft are not mentioned by Falk. He also fails to cite the work of Potter<sup>5</sup> and Snyder who state that "as to accuracy and ease Kober's statements have

<sup>1</sup> THIS JOURNAL, 35, 1603 (1913).

<sup>2</sup> Kober and Graves, *Ibid.*, 35, 1601 (1913).

<sup>3</sup> THIS JOURNAL, 32, 561 (1909).

<sup>4</sup> *Skand. Archiv. Phys.*, 25, 166 (1911); *Bohr-Gedachnesschrift*.

<sup>5</sup> *J. Ind. Eng. Chem.*, 17, 226 (1915).

been confirmed." Furthermore, a large number of other workers who have used aeration in one form or another for distillation of ammonia have been completely overlooked.

It is of interest to note that while Falk was completing his article, Van Slyke<sup>1</sup> and Cullen, at the Rockefeller Institute, published a paper showing that the aeration of ammonia even in "micro" amounts is so thoroughly established that it follows a definite law, namely, that of a mono-molecular reaction, and given certain factors the time necessary for complete distillation could be calculated. Furthermore, even for very small amounts of ammonia Van Slyke and Cullen conclude that "*the accuracy attainable is limited only by that of the measurements and standard solutions.*"

It might be assumed that this statement applies to the micro and not to the macro process under discussion, but it would be difficult to explain, if ammonia in micro amounts can be aerated over and absorbed, why larger amounts should not be distilled over if aeration is used in proportion.

In regard to the publications of my collaborators and myself, Falk gives the impression that only comparatively few satisfactory results were obtained, ignoring the fact that the aeration method has been used by us for regular work exclusively for eight years and has been checked by many assistants. This work comprises several thousand<sup>2</sup> duplicate and triplicate analyses which agree closely, but only protocols of which have been published. Thus it is evident that the failure of aeration results to agree indicates defective technic.

### Summary.

To insure accurate results in distilling ammonia by aeration it is necessary to use:

1. A sufficient volume of air.
2. As high a column but as low a volume of liquid as is convenient.
3. A saturated solution of pure sodium hydroxide in adequate excess.<sup>3</sup>

An impure alkali containing or producing sulfite is liable to cause error because of the sulfur dioxide evolved and carried over into the standard acid before the acid of the Kjeldahl mixture is completely neutralized.

4. Potassium hydroxide must not be used because the difficultly soluble potassium sulfate which separates may carry down ammonia by occlusion or as a double salt. Errors of 10% may be caused in this way but potassium sulfate as ordinarily used is not sufficient to produce appreciable error.

<sup>1</sup> *J. Biol. Chem.*, **24**, 117 (1916).

<sup>2</sup> Levene and Kober, *Am. J. Physiol.*, **23**, 328 (1909); Saccharine Report, U. S. Dept. of Agriculture, Referee Board of Consulting Scientific Experts, from the Herter Lab. The statements in these publications that the total nitrogen estimations were made according to the Kjeldahl-Gunning process are not quite correct; they were practically all distilled according to the aeration method.

<sup>3</sup> Kober and Graves, *THIS JOURNAL*, **35**, 1600 (1913).

5. The complete removal of the ammonia from the Kjeldahl mixture should be tested with Nessler's solution. The precaution of Van Slyke to run the aeration slowly or at half speed for the first minute or two may be an advantage.

#### Addendum.

After sending in this paper for publication I learn that recently a number of other investigators have tried the aeration method and found it accurate. I. K. Phelps and H. W. Daudt, from the Bureau of Chemistry, Washington, D. C., reported favorably on the method at the Urbana meeting of the Society. B. S. Davisson, E. R. Allen and B. M. Stubblefield<sup>1</sup> were able, with a powerful aeration, to remove and absorb small amounts of ammonia from large volumes of solution accurately, using only magnesium hydroxide as an alkali.

### PRESENCE OF NITRITES AND AMMONIA IN DISEASED PLANTS. ITS SIGNIFICANCE WITH REGARD TO CROP ROTATION AND SOIL DEPLETION.<sup>2</sup>

By P. A. BONCQUET.

Received July 3, 1916.

The present study was made independently from the discussion now at large concerning the presence of nitrites in plants.<sup>3</sup> It is not the intention of the writer to decide the above contentions, but only to make known some facts which may throw new light on the controversy.

**Nitrites in Diseased Beets.**—During previous work *Bacillus morulans*, Boncquet,<sup>4</sup> was found to be an inhabitant of the sieve tubes of sugar beets affected with Curly Leaf.<sup>5</sup> Moreover it was established that the organism was not confined to the disease of beets called Curly Leaf, but that it was connected with a great variety of irregular foliage types representing various forms of leaf wrinkling, curling and distortions.<sup>4</sup> The same organisms were also isolated in cultures from the interior of leaves of beets

<sup>1</sup> *J. Ind. Eng. Chem.*, **8**, 896 (1916).

<sup>2</sup> The writer is greatly indebted to the Spreckles Sugar Company for the splendid facilities placed at his disposal in the realization of this investigation.

affected with the diseases called Mottled Leaf, Black Leaf, and Black Tip of beets.<sup>1</sup>

As the biochemical investigations of *B. morulans* proved this organism to be a most vigorous nitrate reducer,<sup>2</sup> it was in logical sequence to test for nitrites any plant tissue in which the organism was found as a facultative parasite. These investigations were crowned with success every time the slightest irregularity revealed the presence of bacteria in the plant tissues. On the other hand, absolutely smooth and sterile tissue gave, without any exception, a perfectly negative result. Not even a trace of nitrite could be detected in perfect, normal leaves. In some cases, however, even a slight irregularity in the vein distribution indicated traces of nitrites which could be detected in the leaf juices.

**Ammonia in Diseased Beets.**—The reducing power of *B. morulans* Bonquet is not confined to the reduction of nitrates to nitrites, but the bacillus is found able to reduce nitrates as far as ammonia. In consequence of this, the same tissues which were found to contain nitrites were also tested for ammonia. The presence of the organism likewise decided whether the leaf juice contained ammonia or not. Under no circumstances was ammonia detected, where the leaf was found strictly nonpathological. Under some circumstances some leaves contained more ammonia than nitrites in comparison to other beets. This was especially true if the leaves had been separated from the crown of the plant, or if the plant had been taken from the soil and left to wilt. The reduction was sometimes found so far advanced that only ammonia could be detected, all nitrites having been reduced.

**Nitrites and Ammonia in Tobacco Leaves Affected with the "Mosaic Disease" (filtrable virus).**—An exceedingly small streptococcus was found to be connected with this disease. Its biochemical functions proved to be vigorous in reducing power. Nitrates in the test tubes were easily converted to nitrites and even ammonia. Thereupon the juices of diseased leaves were also tested for nitrites. It was found that normal tobacco leaves did not give the test for nitrites. Conversely, the juice of all diseased leaves gave a very strong nitrate reduction; ammonia was also detected.

**Nitrites in Potato Leaves and Tubers.**—A streptococcus called for the present *Streptococcus solani* n. sp. was found uniformly in certain potato vines and leaves. The fact that the micrococcus was found to be a most active nitrate reducer naturally suggested the presence of nitrites in the plant juices. It was found that all potato plants of the leaf type containing the micrococcus give a vigorous nitrite reaction in their expressed

<sup>1</sup> Ralph E. Smith and P. A. Bonquet, "Connection of a Bacterial Organism with Curly Leaf of the Beet Sugar," *Phytopathology*, 5, 335-342 (1915).

<sup>2</sup> Bonquet, *Loc. cit.*

leaf sap. Slight traces of ammonia were also detected. On the other hand, leaves and tissues of plants which did not possess any abnormalities and of a totally different leaf type, give negative results. This pathological condition of the potato has not been described distinctly from the pathological standpoint, owing to the fact that the plant appears normal in the broadest sense. The writer has at present a great deal of evidence that this condition is connected with the so-called "brown streak" and with the "blossom abortion" of potatoes, all of which appear to be different symptoms of one and the same disturbance, brought about by *Streptococcus solani*. The plants which gave the most pronounced nitrite test were growing very luxuriantly. The leaves were dark green, crinkled, however, and light revealed irregular patches of lighter green all over the leaf; more or less of the nature of those patches to be observed in the mosaic disease of tobacco. The tubers, however, were not affected with the regular "brown streak" but rather with a disturbance better called "brown or petrified heart." This petrification consists of the cells of the heart of the potato being slightly incrustated with a light cement. Patches of necrotic cells are distributed irregularly throughout the hard mass. Numerous conglomerates of streptococci were abundantly observed in and around the brown tissues. Although the nitrites were very abundant in the leaf tissues, the affected tubers gave only traces of nitrites. This absence of nitrites with the presence of an abundant bacterial flora is easily understood when chemical analysis revealed only traces of nitrates present in the tubers.

**Nitrates in Other Plants.**—Several other plants which showed abnormalities in leaf or stem structure were examined for their nitrite content. It was found that some individual alfalfa, bean and *Malva rotundifolia* plants gave a decided nitrite reaction. The intensity of the reaction ran parallel with the severity of the sickly conditions in which the plants were found. However, a yellow color was not always a sign that the plant contained nitrite or ammonia. It was rather the abnormal plant development from a structural standpoint, like the deformities of leaf, dwarfing, curling and distorting that manifested the disturbance.

All plant juices from plants where these abnormalities had been found, although obtained aseptically, were able to reduce nitrates to nitrites when inoculated in nitrite-free peptone tubes. At the same time a considerable growth of bacteria was obtained, which proved on subsequent inoculation to be very active nitrite reducers.

#### **Significance of the Presence of Nitrites in Plant Tissues.**

**Relation of the Internal Bacterial Flora to Soil Depletion and Crop Rotation.**—The presence of nitrites in plants, at least in all cases which the writer had under investigation, is due to the reducing power of the internal bacterial flora in the tissues. Nitrites have not been detected

in any plant tissue which was normal in the strictest sense of the word. The pathological disturbance is brought about by a partial and local nitrogen starvation of the tissues, and further by the mechanical laceration of local foci, where the bacteria in some cases, by their active growth, were forming metastatic ulcers.

The local and partial nitrogen starvation in the leaves around nitrate-reducing foci explains the mozaic nature of the leaf diseases in which an abundance of nitrite is detected. The foci of infection, found at the headgate of some secondary leaf veination, explains just why that region in the leaf which is under the control of the infected headgate, suffers most from starvation and why it is pale yellow while other regions of the leaf, not controlled by a diseased headgate in the veination, are abundantly supplied with nitrates and consequently develop the heavy green color so characteristic of nitrogen abundance.

The mechanical laceration of infected foci is the cause of a local arrest of growth in the veins and this arrest of growth brings about leaf distortion. In some other cases the internal bacterial flora is uniformly distributed throughout the plant tissues. In consequence of this the symptoms are also uniform, and result in dwarfing and arrested growth as in "little leaf" diseases.

The pathological condition due to the disturbance of a nitrate-reducing bacterial flora in the tissues, may even be without any visible symptoms. Nevertheless, in these cases the nitrite-containing juices extracted aseptically from diseased plants when inoculated in nitrite-free peptone tubes, always brings about a vigorous nitrate reduction, with an abundant growth of nitrate-reducing bacteria. Tissues free from nitrate on inoculation give a sterile tube with no tract of nitrite to be detected.

**Significance to Soil Depletion and Crop Rotation.**—Further studies and field observations have led the writer to believe that the nitrite content of plants and consequently the internal bacterial activity which brings the nitrate-reduction about, has a fundamental bearing on certain cases of soil depletion. This is especially believed to be true in potato fields. A field was observed which had been planted with potatoes for more than fifteen years. Nearly every vine was affected with nitrogen starvation due to internal bacterial reduction.

On the other hand, the soil in which the potatoes were growing was abundantly supplied with nitrates. The analysis showed more than sixty parts per million of soluble nitrates. In this abundance of plant food the potatoes gave a poor yield. It seems, especially from observations on beet fields, that the virulence of nitrate-reducing bacteria as invaders of plant tissues is increased by lack of crop rotation and consequently reduces the yield in some cases to such a point that the reduction is attributed to soil depletion.

### Summary.

Nitrites in plants in the cases observed were due to the reducing power of the internal bacterial flora. This reduction is the cause of nitrogen starvation of plants affected with some peculiar diseases. This nitrogen starvation may occur even when plants are growing on a soil where nitrates are abundant. The internal bacterial flora of plants with its nitrogen-reducing power may be a direct factor in soil depletion where crop rotation is not practiced, owing to the increased virulence and invading power of reducing bacteria. It is believed that lack of crop rotation provides soil organisms a better opportunity to establish themselves in the veins and tissues of plants by means of adaptation.

### NEW BOOK.

**Annual Reports of the Progress of Chemistry for 1915.** Issued by the Chemical Society.  
Vol. XII. London, 1916. Pp. viii + 268. Sold by D. Van Nostrand Company.  
\$2.00 net.

In 1905 the Chemical Society of London inaugurated the publication of this series of annual reports of the progress of chemistry. Issued usually in the late spring, they aim at giving an epitome of the most important work of the preceding year. For the busy chemist who would know what is taking place in other branches of chemistry than his own special field, they are invaluable; within his field he will find them at least interesting and suggestive. Prepared so soon after the close of the year, they naturally lack perspective, and they may often give undue prominence to topics for which the reviewer has a particular bias, but this detracts little from their value. The reviewers of the different fields are for the most part specialists and investigators, which lends interest and value to their work. The contents of the present volume are: General and Physical Chemistry, H. M. Dawson. Inorganic Chemistry, E. C. C. Baly. Organic Chemistry: Part I, Aliphatic Division, J. C. Irvine; Part II, Homocyclic Division, F. L. Pyman; Part III, Heterocyclic Division, A. W. Stewart. Analytical Chemistry, G. Cecil Jones. Physiological Chemistry, F. G. Hopkins. Agricultural Chemistry and Vegetable Physiology, N. H. J. Miller. Mineralogical Chemistry, T. V. Barker. In time past the American Chemical Society has published occasional similar reviews in *THIS JOURNAL*. Such duplication of preparation is unwise to say the least, but it is a pity that some arrangement cannot be made whereby such reviews in the English language may be put in the hands of every member of both societies, and we should add that the Society of Chemical Industry ought also to coöperate in the work.

#### THE OCCLUSION OF HYDROGEN BY A PALLADIUM CATHODE.

BY DONALD P. SMITH AND FREDERICK H. MARTIN.

Received August 14, 1916.

The occlusion of hydrogen by palladium, whether from the gas directly or during electrolysis, has been the subject of numerous investigations. In particular, the changes in the electrical resistance of the metal brought about by this occlusion have been studied by Graham,<sup>1</sup> Dewar,<sup>2</sup> Knott,<sup>3</sup> Bruchietti,<sup>4</sup> Krakau,<sup>5</sup> McElfresh,<sup>6</sup> Fischer,<sup>7</sup> Sieverts<sup>8</sup> and Wolf.<sup>9</sup>

As a result of these investigations it has been established that an increase in the specific resistance of the metal results from the occlusion and that, at least between thirty and about nine hundred and eighty volumes, the increase in resistance is approximately proportional to the hydrogen taken up.

With regard, however, to the relation between the resistance and the

quantity of occluded gas, which obtains for the high degrees of occlusion reached in palladium cathodes when electrolysis is long continued, we have only the observations of Fischer.<sup>1</sup> These are remarkable in that the last portions of gas, which, since they are again spontaneously evolved as soon as the current is interrupted, he termed "supersaturation" hydrogen, produce no effect upon resistance, although they cause an expansion of the metal proportionally greater than that produced by the occlusion in its earlier stages. Since the increased effect of the "supersaturation" hydrogen upon the volume was also found by Thoma,<sup>2</sup> this lack of effect upon resistance raises certain questions as to the nature of the states of "saturation" and "supersaturation."

In order, if possible, to obtain further information upon these questions and upon the phenomena of occlusion generally, the following experiments were undertaken. They consisted in observing the changes in the electrical resistance and in the cathode potential of palladium wires during their cathodic occlusion of hydrogen from 2 *N* sulfuric acid. As a control of the conditions of electrolysis, the applied voltage and the current were also observed, and occasional measurements were made of the anode potential.

### Experiments.

The electrolytic cell consisted of separate cathode and anode vessels, the former of which is shown in Fig. 1. Here A is the inlet for the electrolyte and B the outlet. The palladium wire *e, f, g, h*, about 10 cm. long, is fused at each end to two other palladium wires, X and Y, which pass through the rubber stoppers C, C and are soldered outside to copper wires of 3.26 mm. diameter, which form the leads of a Kelvin bridge. D is a siphon which connects through an intermediate vessel with the reference electrode. To make possible the observation of the cathode potential during electrolysis, without the introduction of an error due to the ohmic fall of potential, this siphon terminates in a small orifice held directly against the cathode. The principle is that of the capillary-tip siphon of Luggin and Haber,<sup>3</sup> and the modifications necessary to keep the wire cathode in place during its expansion with absorption of hydrogen will be clear from Fig. 1a. To make the distribution of current at the cathode symmetrical the latter is connected to battery through the branched lead *j, j*.

In order to diminish changes in the temperature or composition of the electrolyte in the constricted cathode chamber, the liquid was made to flow through the cell during electrolysis at the rate of about four liters in twenty-four hours, while to guard against its depolarizing influence,

<sup>1</sup> Dissertation, Leipzig, 1905; *Ann. phys.*, [4] 20, 503 (1906).

<sup>2</sup> *Ibid.*, 3, 69 (1889).

<sup>3</sup> Haber, *Z. physik. Chem.*, 32, 207 (1900).

all air was displaced by nitrogen from the closed system of vessels through which the electrolyte circulated. The cell and a glass coil through which the electrolyte first passed were contained in a large oil thermostat which maintained a temperature of  $25 \pm 0.01^\circ$ . The platinum anode was enclosed in a porous cup to preclude the possibility that platinum might find its way to the cathode.<sup>1</sup>

The measurements of electrical resistance had an accuracy of about one part in 6000 for the higher resistances encountered in the later portions of the experiments with small palladium wires, where alone results of interest were obtained, while the measurements of e. m. f. were made with the potentiometer. Potentials refer to a mercurous sulfate electrode with 2 *N* sulfuric acid, which varied during the investigation by less than one millivolt.

The electrolyte used throughout was 2 *N* sulfuric acid, for the preparation of which chemically pure acid was redistilled in quartz and diluted with water of conductivity between 1.0 and  $1.2 \cdot 10^{-6}$ . The concen-

Fig. 1.—Cathode vessel.

tration, which corresponded to a specific gravity of 1.0605 at  $21^\circ$ , was occasionally controlled by titrating against normal hydrochloric acid, obtained by the method of Hulett and Bonner.

During the course of the experiments palladium from three different sources was employed. One sample, G, of Table II, was a piece of foil obtained from a German dealer and drawn into wire for the present purpose; another lot, A, was obtained ready-drawn from an American dealer

<sup>1</sup> See J. Tafel, *Z. physik. Chem.*, 50, 641 (1905); J. Tafel and B. Emmert, *Ibid.*, 52, 349 (1905).

and the third variety, P, was prepared in this laboratory from commercial palladium by employing in succession the customary methods for the separation of this metal, precipitations with hydrogen sulfide, ammonium thiocyanate and mercuric cyanide being repeated.

Before use each wire, from whatever source, was ignited *in vacuo* at  $830^{\circ}$  for from four to ten hours to expel any occluded gas and to anneal the metal. Evacuation to a pressure of 1 mm. of mercury, or less, was effected by means of a lift pump, a vessel of finely divided silver being interposed between the pump and wire in order to guard against the vapor of mercury, which Ramsay<sup>1</sup> has shown to exert an inhibitive action upon the occlusion of hydrogen by palladium. Except in one instance a new wire was taken for each experiment.

The initial reading of resistance was made as soon as possible after the cell had filled with electrolyte, and before electrolysis had begun. It was found that no change occurred even in the course of several days, until the charging circuit had been closed. The other measurements were made at such intervals as may be seen from Table I, in which are given in full the observations taken in one of the six experiments with varied charging current. In four other experiments a constant current was employed. Saturation was in general considered, to have been attained when the curve of resistance as a function of current-time (see Fig. 3), had become horizontal within the limits of measurement, but in several instances the charging was much prolonged, and in Expt. 5, electrolysis was continued for six days after the attainment of apparent constancy, without causing any further change.

The principal results with regard to resistance may be summarized as follows:

(1) All palladium wires increased in resistance during electrolysis by more than 56%, finally reaching a value which remained unaltered by prolonged charging, but which appeared to vary irregularly from wire to wire.

(2) Wires of 0.1 mm. diameter or less, and the ribbon of Expt. 12, which was 0.018 mm. thick and 0.57 mm. wide, showed a further increase of resistance after the interruption of electrolysis.

(3) With the small wires and ribbon there was also found a change of resistance whenever the intensity of the charging current was altered either during the later stages of occlusion or after the attainment of saturation.

(4) The larger wire of Expt. 11 could not be made to exhibit the effects noted under (2) and (3).

The variability of the saturation resistance, referred to under (1), is shown in the fifth column of Table II, where the highest resistance attained with each wire is expressed as per cent. increase of the original resistance.

The effect mentioned in (2) may be seen from the last column of Table II, and is further illustrated by Fig. 2, where each curve shows the change of resistance which occurred after the interruption of electrolysis in the case of a wire which had already reached a constant resistance with the current flowing.

The dependence of resistance on current, noted in (3), is displayed by Fig. 3, where are given portions of the curves of resistance, as dependent upon current-time, for four wires. At A on each curve may be seen the

Fig. 2.—Change of resistance after interruption of current.

drop in resistance induced by an increase of current, while at B occurs an increase of resistance produced by diminution of current. In the case of No. 3 the current was raised at A from 0.8 to 1.1 milliamp. and was reduced at B to 0.2 milliamp.

The conduct of the large wire, mentioned in (4), is shown by Curve 11 of Fig. 2. When this wire was again charged, after the loss of resistance shown in the figure, it recovered exactly its former maximum resistance in six hours and retained it unaltered until the current was again interrupted forty-three hours later. The resistance curve obtained after this second interruption was entirely similar to that shown.

Fig. 3.—Dependence of resistance upon current during electrolysis.

The results of the observations made upon the cathode potential were as follows: The potential, in every case, rose steadily so long as electrolysis was continued. Upon the interruption of the current at the end of the first charging of a palladium wire there always occurred the series of changes shown in the first part of Fig. 4, consisting of a sharp drop, followed by a pronounced recovery and then by a gradual decline. When a wire was repeatedly charged to constant resistance, the recovery of potential became less marked with each succeeding interruption of elec-

trolysis, as may be seen from the eight successive curves for the same cathode given in Fig. 4. The initial drop of potential, preceding the re-

Fig. 4.—Changes of potential and resistance for successive interruptions.

covery, appeared to consist of two parts. For the first reading, taken as soon as possible after the interruption, instead of corresponding to chance

Fig 5.—First readings of potential after interruption of current, Expt. 5.

positions upon the falling branch of the curve, showed marked regularity, as may be seen from Fig. 5. Here the points upon Curve *a* represent the first readings for successive interruptions of electrolysis during the first charging of Wire No. 5, while Curves *b*, *c* and *d* correspond to three subsequent chargings of the same wire. The regularity with which these values increase with increasing occlusion, together with the form of the potential-time curves, seen best in Nos. 4, 5 and 7 of Fig. 4, seem to show that the point *A* of these last is a well-

defined potential, determined by the state of occlusion in the surface of the metal.

For comparison two similar experiments were made with copper wires of 0.1 mm. diameter, drawn from electrolytic copper. In these the initial resistance was observed, and the charging circuit was closed, before the introduction of the electrolyte. No change of resistance was found either during electrolysis or after its interruption, nor did the wires show brittleness or any other change upon their removal from the cell. The potential during electrolysis altered in the manner shown by Curves *a*, *b* and *c* of Fig. 6, which correspond to successive chargings with the same wire. After the interruption of the current the potential fell off in a perfectly regular manner.

A wire of commercial nickel of 0.26 mm. diameter also failed to show any change of resistance with currents up to 4.5 milliamperes, and was apparently unaltered in other respects.

#### Discussion.

The foregoing results confirm those obtained by previous observers in that, with progressing occlusion of hydrogen, the resistance of palladium increases steadily and reaches a constant value. With regard to the proportional increase at saturation the results are, however, extremely divergent. For, while Fischer found increases which varied only between 68 and 69%, and McElfresh obtained the value 67% for both of the wires which he studied, Knott's results run from 63 to 83%, and those here reported from 56.6 to 74.7%. The values found for small wires are undoubtedly too high, owing to the effect mentioned under (2) in the summary of resistance results above, and the circumstance that observations of the saturation resistance had necessarily to be made during momentary interruption of the charging current. Moreover, since it has been shown that the presence of small amounts of alloy-forming impurities exerts a marked influence upon the occlusion<sup>1</sup> of hydrogen by palladium, it is likely that differences of purity between the various wires account in great part for the discrepancies shown, and it may be seen from Table II that the smallest increases of resistance found in the present

Fig. 6.—Potential of copper during electrolysis.

<sup>1</sup> Graham, *Proc. Roy. Soc. London*, 17, 500 (1869); Berry, *J. Chem. Soc.*, 99, 463 (1911); Sieverts, *Z. anorg. Chem.*, 92, 329 (1915).

investigation were obtained with the carefully purified metal, and the largest with that which was probably of poorest quality.

The possibility that the previous history of the palladium used affects its conduct in this matter, which is suggested by the well-known variability in the velocity and extent to which the metal occludes "molecular" hydrogen, should not be overlooked, but the results of these experiments show no indication of such an influence. Indeed, while observations upon this point were only incidental, the conduct of Wire No. 11 suggests rather that such an effect was absent. For this wire, which was of purified metal, and of sufficient diameter to be unaffected by the disturbing factors discussed in the next paragraph, gave reproducible results, the maximum resistance of 0.4080 ohm, which it maintained during two days of electrolysis on first being charged, being exactly recovered and maintained in each of the two subsequent chargings.

The principal new observation of the present experiments is to be found in the change of resistance with change of charging current, which has been noted under (2) and (3) in the summary of resistance results above, and which is further evidenced by a dependence of the saturation resistance upon the current, such as is illustrated by the following observations from Expt. 12: the resistance having become constant at 4.3560 ohms with a current of 0.2 milliamp., fell in the course of an hour and a half to 4.3120 ohms, when the current was increased to 0.8 milliamp., and again became constant. When the current, some eight hours later, was lowered to 0.3 milliamp., the resistance rose to 4.3440 ohms. This inverse response of resistance to current in a saturated wire was found invariably with the small wires and ribbon. It should be noted that, as may be seen clearly from the curves of Fig. 3, an increase of current produced an uninterrupted decline of resistance to a new constant value, while a decrease of current usually caused the resistance to pass through a maximum.

Two possible explanations of these effects suggest themselves. The first is that, during electrolysis, there is formed upon the wire a conducting layer of some product of electrolysis, and that the thickness or conductivity of this layer responds immediately to any change of current or impressed potential.

There are considerations, however, which appear to make this explanation untenable. In the first place, if one regards the change of resistance after interruption of the charging current in connection with the accompanying change of potential, it is evident from the curves exhibited in Fig. 4, which represent the changes of both quantities for successive interruptions with the same cathode, that while the character of the potential curve undergoes great modification between the first interruption and the last, the character of the resistance curve remains unaltered. If

the changes of resistance were indeed due to processes occurring in the portion of the electrolyte which immediately surrounds the wire, we should not expect their character to remain the same while the changes of potential suffered such radical alterations.

In the next place, the modification of the potential curves with successive interruptions is alone a sufficient indication of changes occurring in the wire, or in its surface, rather than in the electrolyte. For it is scarcely conceivable that persistent alterations could be produced in the electrolyte.

Finally, if the effect were due to changes in the electrolyte, a similar effect might be expected with copper cathodes, when subjected to the same treatment. Yet none was apparent, the potential of the copper varying regularly, and without the rise and subsequent fluctuations shown by that of palladium, while its resistance remained unaltered.

It seems necessary to conclude, therefore, that the change of resistance observed after interruption of the charging current is produced by changes in the cathode or its surface. It also appears that these changes are not confined to the immediate surface of the metal, which plays a part in determining the potential, for in that case we should again expect some parallel between the variations of potential and those of resistance.

If, then, the change of resistance after interruption of electrolysis is to be explained by processes occurring within the cathode, it is yet evident that these processes cannot be merely a continuation of those which have occurred during charging; for no matter how long or how often the wire has been charged to the attainment of steady resistance, a further increase of resistance takes place when the current ceases. The processes are also immediately responsive to any changes of current, and are evidently reversible.

As a tentative explanation, which agrees at least qualitatively with all of the facts observed, the following seems worthy of consideration. The steady rise of resistance observed during the progress of occlusion is due to combination of hydrogen with palladium to form an alloy of higher resistance than the pure metal. When, with steady current and applied voltage, this combination has come to equilibrium, the wire possesses the resistance of the saturated alloy, diminished by a conductance due to the uncombined hydrogen, or to some portion of the latter. Upon the interruption of the current, after this state has been reached, the gradual disappearance of the conducting hydrogen produces an increase of resistance, at first rapid, but diminishing in rate until a constant value has been attained. So long as the charging current continues without variation the loss of conducting hydrogen is made good by further occlusion, but any change of current causes either the rate of supply or the rate of loss to predominate, with corresponding loss or gain of resistance,

until a steady state has again established itself. This accords, evidently, with the fact that the lower the current at which the steady state sets in, the higher is the corresponding resistance.

On comparing the conduct, after the interruption of electrolysis, of wires of different sizes, shown in Fig. 2, it appears that the increase of resistance is greatly dependent, both as to magnitude and duration, upon the dimensions of the wire. With the 0.32 mm. wire, No. 11, the effect could not be found. In the 0.1 mm. wires, Nos. 5, 6 and 9, the increase was from 0.10 to 0.15 volt, and was complete in less than four hours, after which the resistance usually remained nearly constant for many hours. In the 0.05 mm. wire, No. 7, the increase amounted to almost 0.9 volt, and required some twenty-eight hours for its completion. With the ribbon of No. 12, however, which was 0.018 mm. thick, and in ratio of surface to volume was equivalent to a wire of 0.035 mm. diameter, the effect again fell to a very small magnitude. Since the form of the ribbon was much more favorable than even that of the smallest wire to rapid escape of hydrogen, it might be supposed that this process made its influence felt in the case of the ribbon before the rise of resistance had come to an end. But doubt is thrown upon this explanation of the behavior of the ribbon by the fact, also apparent from Fig. 2, that a decline of resistance began relatively early also in the large wire, No. 11, and in one of the 0.1 mm. wires, No. 9. Whatever the cause of the divergent conduct of the ribbon, it is at any rate evident that dimensions have a marked influence, and hence the process which is responsible for the rise of resistance must be supposed to take place chiefly near the surface.

If the effect is to be explained as due to conductance by the occluded hydrogen, it seems necessary, in view of this superficial character, to conclude further that the conducting hydrogen is of a form which exists only for a brief time and passes then into a nonconducting form, or one of relatively small conductivity, or else to suppose that a uniform distribution by diffusion had not been attained even in the numerous cases in which the resistance became constant within forty-eight hours, and remained so during days of continued electrolysis. For, unhindered diffusion assumed, a single form of uncombined hydrogen, if there were only one, must have been uniformly distributed through the wire when the steady state was attained, and the loss of conductance on interrupting the current would have been proportionally as great for thick wires as for those of smaller diameter. While there exist many grounds, from the work of other observers as well as from these experiments, for believing that the diffusion of hydrogen in palladium is sufficiently rapid to have insured uniform distribution in all of the experiments under discussion, the conclusion just indicated with regard to the condition of the occluded hydrogen is obviously in need of support by further experiments, and its

consequences need not be drawn at present. A particular reason for caution will be found below.

With regard to the observations upon the cathode potential, which have already been summarized, it should be pointed out that the indications as to the initial drop of potential are somewhat doubtful. For if, in any experiment, the electrode wire did not rest closely against the siphon tip of Fig. 1a, and in consequence an appreciable ohmic fall was included in the potentials observed before the interruption of electrolysis, the effect must have been to produce such an instantaneous drop upon the interruption of the current as that found, and the magnitude of this drop must have increased with the current, as was the case. Although inspection of the cell before and after each experiment showed the wire to be closely held, it is, therefore, not certain that the first, falling part of the potential curves of Fig. 4, to the point A, corresponds to any process directly related to occlusion. The second, more slowly falling portion of the curve, from A to the minimum, appears to be merely the usual decay of polarization after the cessation of electrolysis.

The recovery of potential, however, seems to warrant further study for its indications as to the diffusion of hydrogen from the interior. It varied greatly in character and magnitude, sometimes showing the regularity seen in Curve 1, Fig. 4, and in other instances consisting of a series of fluctuations, and is probably due to the cause to which Helmholtz<sup>1</sup> attributed irregularities which he observed in platinum cathodes, namely, the existence within the metal of regions of different hydrogen concentration. The explanation agrees qualitatively with many of the observations, such as an exceptionally large and rapid recovery found with the ribbon of Expt. 12, and a very small recovery for the 0.32 mm. wire, and the fact that the recovery seemed to be most regular when a constant current had been employed in charging. But diffusion at a constant rate does not seem to be alone adequate to account for several such observations as may be illustrated by the first interruption of Expt. 7. Here the applied voltage and the cathode potential had risen steadily during the previous electrolysis, and hence possessed, at the time of interruption, values higher than any which had gone before. Yet upon interruption the potential, after falling from 1.2180 volts to 0.4479 volt, or lower, rose in the course of nine hours to 0.4840 volt. Since it would seem that under the conditions mentioned, and with a constant coefficient of diffusion, the concentration of hydrogen at the time of interruption must either have diminished continuously from the electrode surface inward, or must have been uniform throughout the wire, it is not readily seen how a reversal in the course of the potential curve can be explained, unless it is supposed that owing either to local differences in the rate of

<sup>1</sup> *Pogg. Ann.*, 150, 494 (1873).

diffusion or to its variation with time, there existed at some depth within the wire concentrations higher than that obtaining immediately within the surface. The occurrence of the recovery in such cases is, therefore, not improbably related to the fact observed by Lessing<sup>1</sup> that the rate of diffusion of hydrogen through palladium declines for some time before becoming constant.

The gradual disappearance of the recovery with repeated interruptions, seen in Fig. 4, is most readily accounted for as due to slow equalization of hydrogen concentrations throughout the metal. If this is the correct interpretation, it can hardly be supposed that saturation had been reached in most of the experiments here recorded, for in the experiment of Fig. 4, which was that conducted with the thin ribbon, conditions were the most favorable to speedy saturation, and yet five repetitions of charging were required before the disappearance of the recovery. On the other hand, if saturation had not been reached in the other experiments, it is difficult to understand the constancy of resistance long maintained in many instances, and particularly the reproducibility of this constant resistance already pointed out in connection with Expt. 11. The reconciliation of these apparently discordant indications must await the completion of further experiments.

The uncertainties regarding the attainment of saturation evidently do not affect the observations upon the inverse response of resistance to charging current, and the probability that this is due to conductance by occluded hydrogen, although they have direct bearing upon the question of the form in which this hydrogen is present.

The results with copper and nickel wires seem to show that these metals occlude very little hydrogen, if any, under the conditions of these experiments, although both are known to occlude considerable amounts of "molecular" hydrogen at higher temperatures.

Since the experiments thus far described were all conducted in cells of one type, it seemed desirable to make observations under somewhat different conditions, particularly with regard to the distribution of current at the cathode.

A cell of half-liter volume was employed, in which the cathode wire was supported upon a stirrer which revolved at 100 r. p. m., so that each side of the cathode in turn was presented toward the anode. The platinum points upon the stirrer, to which the cathode was fused, connected with a Wheatstone bridge through mercury seals which served also to close the cell from the air. The resistance of the leads was eliminated by compensating until the original resistance read was that estimated for the palladium wire, so that the observations, while affected with a small constant error, are of high relative accuracy. The arrangements were otherwise

<sup>1</sup> *Verh. deutsch. physik. Gesell.*, 4, 569 (1906).

the same as those described above, except that provisions for the measurement of potential were omitted.

The electrolyte was 2 *N* sulfuric acid, prepared as before, and the wires studied were from an American source. They were about 11 cm. long and of 0.05 mm. diameter.

After charging with a steady current of 1.5 milliamp. until the resistance had become constant, electrolysis was interrupted and the observations were made of which the results are displayed in Fig. 7. Here Curve 1 is for a first interruption after 71 hours' charging of Wire No. 1, while the other curves refer to three successive interruptions with

Fig. 7.

Wire No. 2, made after 68, 51 and 22 hours' charging. Curve 1, for which the ordinates are given in brackets, would extend above the figure if drawn to the same ordinates as the other three, to which the unbracketed numbers apply. The rise of resistance in No. 1 was, therefore, greater and much more rapid than any of those observed with No. 2.

The results dispose of the possibility that the supplementary rise of resistance after the interruption of electrolysis might have been due to the peculiar distribution of current at the cathode in the earlier experiments. The differences shown between the first interruptions, Nos. 1 and 2a, and between the successive interruptions of No. 2, are much greater than any previously found between wires of the same diameter. This is probably to be attributed to the fact that the preliminary annealing *in vacuo*, to which all of the earlier wires were subjected, was here omitted.

A study of these effects by another method has been undertaken.

### Summary.

1. Observations have been made of the changes in the electrical resistance and in the cathode potential of palladium wires, both during their occlusion of hydrogen electrolytically evolved, and after the interruption of electrolysis.

2. The proportional increase of resistance at apparent saturation has been found to vary widely, even with wires from the same lot of carefully purified palladium.

3. The resistance of saturated wire of 0.1 mm. diameter or less, observed during momentary interruptions of electrolysis, has been found to vary in a well-defined manner with the polarizing current; and the resistance after the interruption of electrolysis has been shown to undergo changes which are reversible and reproducible.

4. Saturated wire of 0.32 mm. diameter has been found not to exhibit these changes.

5. Considerations are given which make it probable that the changes of resistance in the smaller wires are due to processes occurring within the metal, and not far removed from its surface.

6. The tentative conclusion is suggested that hydrogen occluded at the cathode surface exists for some time in a transitional state in which it possesses an electrical conductance of its own, and passes gradually into another form which has much less conductance, or none.

7. Characteristic changes have been observed, after the interruption of electrolysis, in the cathode potential of saturated palladium wire, and certain connections have been noted between the manner and magnitude of these changes and the conditions of electrolysis.

8. A few observations have been made upon copper wires which show that this metal does not suffer any measurable alteration of electrical resistance, under the same conditions which produce a high degree of occlusion in the case of palladium.

9. A single experiment has been made upon nickel wire, which appears to show that it too is unable to occlude sufficient hydrogen, under the conditions of these experiments, to produce any perceptible alteration of its electrical resistance.

PRINCETON, N. J.

## THE ACTION OF MAGNESIUM ON SOLUTIONS OF POTASSIUM CHLORIDE.

By FREDERICK H. GETMAN.

Received September 18, 1916.

It has long been known that metallic magnesium reacts very slowly with distilled water at ordinary temperatures, the products of the reaction being magnesium hydroxide and hydrogen. An apparently similar, though more energetic, reaction has been shown to occur when magnesium

is introduced into an aqueous salt solution. On the other hand, when magnesium is introduced into a solution of one of the caustic alkalies no reaction takes place.

In an attempt to determine the difference of potential between metallic magnesium and various magnesium salts, the attention of the author was directed for the first time to the unusual reaction between magnesium and saline solutions. After reviewing the literature of the subject,<sup>1</sup> it became evident that none of the explanations of the phenomenon which have been advanced is wholly satisfactory. Undoubtedly the best explanation is that suggested by Kahlenberg based upon the assumption that solutions are chemical combinations of solvent and solute in varying proportions. While this assumption offers a ready explanation of all of the phenomena described and consequently is superior to the explanations advanced by earlier investigators in this field, it is open to the objection that it involves a step backward to the older theories of solutions. The modern theory of solutions has proven to be so comprehensive a generalization that it does not seem unreasonable to assume that it can be invoked to explain the action of metallic magnesium on saline solutions.

With this end in view, the present investigation was undertaken.

**Theoretical.**—The reaction between magnesium and water may be represented by the following equation:

or writing the reaction in terms of ions, we have

Since, for a definite temperature, the ionic product of water is constant,  $c_{\text{H}^+} \times c_{\text{OH}^-} = \text{const.}$ , it follows that the rate of the reaction should decrease owing to the increase in the concentration of hydroxyl ions furnished by the dissolved magnesium hydroxide. When the solubility product of magnesium hydroxide is exceeded, then the reaction should proceed at a uniform rate, provided that the effective surface of the metal is not reduced by the accumulation of precipitated magnesium hydroxide. In general, aqueous solutions react more energetically with magnesium than pure water alone. This suggests that the dissolved substance may function as a catalyst in the reaction. The possibility that the solute might function as a catalyst was suggested by Tommasi<sup>2</sup> in connection with his experiments on the action of magnesium on solutions of potassium chloride. In commenting on this suggestion, Kahlenberg<sup>2</sup> says: "It would scarcely be helpful to dismiss the matter by saying that in these

<sup>1</sup> Tommasi, *Bull. soc. chim.*, [3] 21, 885 (1899); Lemoine, *Compt. rend.*, 29, 291 (1899); Mouraour, *Ibid.*, 130, 140 (1900); Kahlenberg, *THIS JOURNAL*, 25, 380 (1902); Roberts and Brown, *Ibid.*, 25, 801 (1903).

<sup>2</sup> *Loc. cit.*

diverse solutions the rate of evolution of hydrogen is increased by the catalytic action of the solute when hydrogen is liberated more rapidly than from water, and that the rate is diminished by the negative catalytic action of the solute, when the formation of hydrogen takes place less rapidly than from water." As a matter of fact, Kahlenberg's experiments with a wide variety of solutes, failed to reveal but three cases where the rate of the reaction between magnesium and water was lessened. Glycerol, mannite and cane sugar each produced a distinct retardation of the reaction, but it is conceivable that this effect may be traceable to the presence of several hydroxyl groups in each of these compounds. Whatever the cause of the retarding action of these substances, the fact seems to be well established that dissolved substances, as a rule, tend to promote rather than to retard the reaction between magnesium and water. A further consequence of the catalytic theory is, that the dissolved substance should remain unaltered throughout the reaction and be recoverable in its original amount at the end of the reaction.

**Materials.**—The magnesium used in this investigation was obtained in the form of wire 3.3 mm. in diameter. Analysis showed it to contain 99.66% of magnesium, together with a residue consisting of aluminium and iron. Spectroscopic examination of the wire with a grating spectroscope confirmed the results of chemical analysis. The potassium chloride was obtained from a reliable source and, after recrystallization, was found to be of a high degree of purity. In addition to ordinary distilled water, so-called "conductance water" was used. This was prepared in the usual manner by successive redistillation of ordinary distilled water, first from chromic acid and then from alkaline potassium permanganate, the final distillate being condensed in block tin and stored in a receiver of Jena glass. The water obtained by this process was found to possess a specific conductance of about  $3 \times 10^{-6}$  reciprocal ohms.

### Experimental.

The present investigation is limited to the study of the action of metallic magnesium on aqueous solutions of a single solute, potassium chloride. The experimental work may be conveniently considered in the following order: (a) measurement of the volume of hydrogen obtained from water under varying conditions, (b) measurement of the volume of hydrogen obtained from solutions of potassium chloride of different concentrations, (c) determination of the difference of potential between magnesium and solutions of potassium chloride, (d) study of the concentration of the hydrogen ion in the presence of magnesium in both pure water and solutions of potassium chloride, and (e) determination of the concentration of potassium chloride in a solution before and after the action of magnesium.

(a) **Volume of Hydrogen from Water.**—A form of apparatus similar to that shown in Fig. 1 was used in measuring the volume of hydrogen

resulting from the action of metallic magnesium on water alone or on aqueous solutions of potassium chloride. It consisted of a graduated gas-measuring tube, B, of 50 cc. capacity and a leveling tube, A, the two tubes being connected by means of a piece of rubber tubing fitted with a pinchcock, E. In carrying out an experiment with this apparatus, E was closed and, after removing the rubber stopper and tubing at D, A was filled with water or with the solution to be studied. The pinchcock E was then opened and the liquid in A was allowed to flow out until any air bubbles which might be present in the tubing were removed. After again closing E, the tube B was filled full of the liquid to be studied, a piece of magnesium wire of known dimensions was dropped in, and the stopper D was quickly inserted, taking care to avoid the inclusion of air. On inverting the tube B, the piece of magnesium wire could be readily caused to fall into place at C, the end of the glass tubing projecting through the stopper serving to hold it in a vertical position as shown in the illustration. The pinchcock E was then opened and the tubes A and B clamped in such relative positions that the level of the liquid in the former was slightly higher than that in the latter. Readings of the volume of gas disengaged were made with the liquids in the two tubes at the same level. The pieces of magnesium wire used were exactly 50 mm. in length and were carefully polished in a lathe to an average diameter of 3.25 mm. before introducing into the liquid in the tube B. It was assumed that the effective surface

Fig. 1.

of the wire was its total superficial area minus the area of the end in contact with the rubber stopper. That this assumption was justifiable was proven by the fact that only a slight tarnish was observed on the ends of wires which had been immersed for several days. The effective surface of magnesium in each of the following experiments may thus be taken to be 518.9 sq. mm. In the subjoined tables,  $t$  denotes the interval of time in hours from the beginning of the experiment,  $v$  denotes the volume of gas evolved in cubic centimeters and reduced to  $0^{\circ}$  and 760 mm., and  $\Delta v / \Delta t$  gives the rate at which gas is evolved,  $\Delta t$  being reckoned from the initial time as zero.

336	2.34	0.007
384	2.48	0.006

The water used in the first two experiments was freed from dissolved air, while that used in the last experiment was saturated with air from which the carbon dioxide had been removed by passing it successively through a solution of potassium hydroxide and a column of soda lime. The data recorded in Tables I and II indicates that magnesium reacts initially at nearly identical rates with ordinary distilled water and with that which has been freed from dissolved gases, and that ultimately the two rates become equal. On the other hand, the data of Table III shows that the presence of dissolved air augments the volume of hydrogen liberated in a given interval of time. The results obtained with distilled water confirm the results of Kahlenberg<sup>1</sup> and Bryant,<sup>2</sup> the latter of whom states that magnesium reacts equally well with both boiled and unboiled water. The experiments of Roberts and Brown,<sup>1</sup> however, led to the conclusion that magnesium is without action on distilled water, boiled free from dissolved gases, and cooled out of contact with air. A further deduction drawn by the last-mentioned authors from their experiments was that magnesium reacts with water which has been boiled and subsequently charged with oxygen. This conclusion is fully confirmed by the data recorded in Table III. From the evidence at hand, it seems justifiable to conclude that metallic magnesium reacts slowly with the purest distilled water and that the rate of reaction is augmented by the presence of neutral dissolved gases.

(b) **Volume of Hydrogen from Solutions of Potassium Chloride.**—In view of the fact that magnesium reacts at approximately the same rate with ordinary distilled water as with conductance water, the former was used in preparing the solutions of potassium chloride.

Two distinct series of experiments were carried out and the agreement between the results was as close as could be expected when the inherent defects of the method are taken into consideration. The solubility of the evolved hydrogen in the solution and the difficulty of removing the last

<sup>1</sup> *Loc. cit.*<sup>2</sup> Bryant, *Chem. News*, 80, 211 (1899).

adhering bubbles of gas from the surface of the magnesium wire constituted the chief defect in the method and introduced an appreciable error for which no correction was attempted. The curves shown in Fig. 2 are plotted from the experimental data, with the exception of that for  $N$  KCl, which is calculated from Kahlenberg's data, on the assumption that the amount of hydrogen evolved is proportional to the surface of magnesium exposed in the solution. The full line curves show the relation between time and the volume of hydrogen disengaged, while the dotted curves represent the variation in the rate of gas evolution with time. It will be observed that the rate of reaction between magnesium and water is greatly accelerated by the presence of potassium chloride. Furthermore, it is evident that the increase in gas evolution is not proportional to the increase in concentration of the solution. All of the curves show a tendency to become rectilinear with time, indicating that the reaction has attained a constant rate. None of the curves show the inflection which is characteristic of the curves of Roberts and Brown,<sup>1</sup> notwithstanding the fact that readings were taken every twenty minutes during the earlier stages of the reaction where this effect was observed. Direct comparisons with the data of the above investigators could not be made because of the insufficient information as to the dimensions of the magnesium used in their experiments.

(c) **Difference of Potential between Magnesium and Potassium Chloride Solutions.**—Determinations of the difference of potential between magnesium and solutions of several electrolytes were made by Kahlenberg.<sup>1</sup>

The measurements were made at  $20^{\circ}$  against the normal calomel electrode, the potential of which was assumed to be 0.56 volt. The following table summarizes the results obtained, the value of each difference of potential representing the mean of four determinations in which different bars of magnesium were used:

TABLE IV.		
Electrolyte.	Concentration.	Diff. of potential.
NaCl.....	2 (mols per liter)	1.163 (volts)
NaOH.....	1	1.111
KOH.....	1	1.140
KOH.....	0.1	1.105
MgSO <sub>4</sub> .....	1	1.366

It was observed that in the solution of sodium chloride, the e. m. f. changed but slightly with time; in the caustic alkali solutions the e. m. f. slowly diminished on standing, while in the solution of magnesium sulfate it showed a tendency to increase. In discussing these results, Kahlenberg says: "The difference of potential between magnesium and the solutions would be expected to be higher in the case of solutions that are vigor-

<sup>1</sup> *Loc. cit.*

Fig. 2.

ously attacked than in solutions in which the action is slight. The experimental data are in accord with this." Similar determinations of differences of potential between magnesium and solutions of potassium chloride were made in the present investigation. The data given in this subjoined tables were obtained from measurements of the e. m. f. of cells of the following type:

the current flowing outside of the cell in the direction of the arrow. The cell was immersed in a thermostat maintained at  $25^\circ \text{C.} \pm 0.05^\circ$ , at which temperature the potential of the calomel electrode was taken to be 0.6186 volt. Two different magnesium electrodes were used in these experiments, care being taken to remove all traces of oxidation by polishing with emery cloth immediately before immersing in the solution. The results tabulated represent the mean of several determinations with each of the two electrodes:

TABLE V.—0.1 N KCl.

Time.	Diff. of potential
0 (min.)	1.1007 (volts)
10	1.0948
20	1.0920
30	1.0893
40	1.0868
50	1.0860
120	1.0840
250	1.0690
450	1.0638
1200	1.0589

TABLE VI.

Concentration.	Diff. of potential.
0.1 (mol. per liter)	1.0962 (volts)
0.05	1.0760
0.02	1.0517
0.01	1.0199
0.005	1.0069
0.001	0.9870
0.0005	0.9170
0.0001	0.8856

It will be seen from Table V that when magnesium is immersed in 0.1 N KCl, the difference of potential between the metal and the solution decreases with the time. This effect is undoubtedly caused by the gradual accumulation of the products of the reaction upon the surface of the electrode and a consequent lessening of its rate of solution. When the difference of potential is plotted against the time, a curve is obtained which is similar to that expressing the relation between the rate of evolution of hydrogen and the time as shown in Fig. 2. The values of the differences of potential given in Table VI are based upon measurements of electromotive force which were made as soon as possible after introducing the magnesium electrodes into the respective potassium chloride solutions. They may, for all practical purposes, be regarded as the differences of potential between an untarnished surface of magnesium and the different solutions of potassium chloride given in the table. As will be seen, the difference of potential decreases with decreasing concentration, a result which is not unexpected, when it is remembered that the rate of solution of magnesium is conditioned by the amount of salt present.

An interesting phenomenon was noted in connection with the study of the electromotive behavior of magnesium in solutions of potassium chloride. When the surface of the electrode was cleaned by immersion in acid, it was found that the difference of potential between it and the solution was invariably lower than when the surface was cleaned by means of emery cloth. The influence of the preliminary treatment on the subsequent behavior of the electrode is clearly shown by the data of Table VII.

TABLE VII.—0.1 *N* KCl.

Electrode.	Potential after treatment with		Difference.
	Emery.	Acid.	
I.....	1.0957	1.0666	0.0291
I.....	1.0958	1.0423	0.0535
II.....	1.0935	1.0524	0.0411
II.....	1.1000	1.0530	0.0470

While the value of the difference of potential established between a freshly polished magnesium electrode and 0.1 *N* KCl was practically constant and reproducible, the corresponding values obtained with electrodes previously immersed in acid were always numerically smaller and varied considerably. It will be observed that the differences of potential established by electrodes which have been treated with acids are comparable with the final values of Table V. This tends to confirm the suspicion that the surface of an electrode which has been immersed in acid is enveloped by an adsorbed film of hydrogen which cannot be removed by prolonged washing.

(*d*) **Concentration of the Hydrogen Ion.**—Attention has already been called to the fact that when magnesium is immersed in water, or in a solution of potassium chloride, an alkaline reaction ensues almost immediately. It is evident that any satisfactory explanation in this reaction must take into account the changes which occur in the concentration of the hydrogen ion as the reaction proceeds. With this end in view, determinations of the concentration of the hydrogen ion were made at definite intervals of time in reacting mixtures of water and magnesium and of potassium chloride solutions and magnesium. A hydrogen electrode consisting of a strip of platinum foil coated with platinum black and saturated with hydrogen under a definite pressure was used to determine the concentration of the hydrogen ion. When such an electrode is immersed in a solution which is normal with respect to the hydrogen ion, and is connected with a similar electrode, immersed in a solution of unknown hydrogen-ion concentration, *c*, the resulting e. m. f., *E*, can be calculated by means of the well-known formula of Nernst, *viz.*,

$$E = RT/nF \log_e 1/c.$$

Since it is more convenient to use the calomel electrode than the normal hydrogen electrode, the above expression may be written

$$E = RT/nF \log_e 1/c + \delta,$$

where  $\delta$  denotes the difference between the potential of the normal hydrogen electrode and that of the calomel electrode.

At a temperature of  $25^\circ$ , using a calomel electrode containing 0.1  $N$   $\text{KCl}$ , the formula becomes, on transforming to Briggsian logarithms,

$$E = 0.0595 \log 1/c + 0.33,$$

the value of  $\delta$  being 0.33 volt under these conditions.

A hydrogen electrode similar to that described by Hildebrand<sup>1</sup> was prepared and was found to attain equilibrium quickly and also to be both constant and reproducible. The hydrogen used was prepared by the action of granulated zinc on hydrochloric acid, and was washed by passing successively through solutions of potassium hydroxide and potassium permanganate. As in the foregoing experiments, the magnesium used was in the form of wire polished to an average diameter of 3.15 mm. and cut in 40 mm. lengths, thus giving a total surface of 411.6 sq. mm. Owing to the fact that in these experiments the solution was stirred before taking each reading, it may be assumed that the entire surface of the wire represents the effective surface. An enclosed type of Lippmann electrometer, sensitive to 0.0001 volt, was employed to determine the point of balance on the bridge wire, according to the familiar method of Poggendorff. Before beginning a series of measurements, care was taken to insure the complete saturation of the hydrogen electrode at atmospheric pressure. By passing a current of hydrogen through the electrode at such a rate that about one bubble per second escaped from the immersed end of the electrode, it was found that complete saturation could be secured in ten minutes, and that by continuing the passage of gas at the same rate, the constancy of the electrode could be maintained indefinitely. The volume of water or of solution used in all of the experiments was 25 cc. and care was taken not to immerse the hydrogen electrode to a greater depth than was necessary to prevent the free escape of hydrogen. Having secured a completely saturated electrode, connection with the calomel electrode was established by dipping the siphon tube of the latter into the contents of the beaker. Having measured the e. m. f. of the combination as quickly as possible, the freshly polished magnesium wire was introduced and, after an interval of five or ten minutes, the e. m. f. was again determined. As soon as the point of balance on the bridge wire was obtained, connection with calomel electrode was broken by closing the stopcock in the siphon tube and then removing the latter from the

<sup>1</sup> Hildebrand and Harned, *Eighth Intern. Congr. Appl. Chem.*, 1, 217; *THIS JOURNAL*, 35, 847 (1913).

solution in the beaker. This procedure minimizes errors due to diffusion at the liquid junction. No attempt was made to introduce a correction for liquid potentials since such a correction would in every case be negligible in comparison with the experimental error. The solution in the siphon tube of the calomel electrode was renewed before the beginning of each experiment, thus insuring a connecting solution which was strictly 0.1 *N* with respect to potassium chloride. The experimental data are

Fig. 3.

represented by the curves shown in Fig. 3. The influence of increasing amounts of potassium chloride in accelerating the reaction between magnesium and water with a consequent diminution of the hydrogen-ion concentration, is clearly shown. The rapidity with which the e. m. f. changes in the early stages of the reaction rendered it extremely difficult to secure satisfactory readings during the first five or ten minutes of an experiment. It will be observed that the curves of Fig. 3 all show a tendency to become horizontal with increasing time and that this tendency becomes more pronounced as the amount of potassium chloride is increased. This result furnishes weighty evidence in favor of the proposed explanation of the reaction between magnesium and water and the function of potassium chloride therein. According to this explanation, magnesium is assumed to dissolve in water by virtue of its high solution pressure, forming magnesium hydroxide. This latter substance undergoes ionization, thereby increasing the concentration of hydroxyl ions in the water and causing a corresponding decrease in the concentration of the hydrogen ions. The process will continue until the water becomes saturated with magnesium hydroxide, after which the concentrations of the hydroxyl and hydrogen ions will remain constant. The addition of increasing amounts of potassium chloride should not only accelerate the velocity of the reaction but also should increase the solubility of the magnesium hydroxide formed, with a consequent further depression of the limiting concentration of the hydrogen ion.

(e) **Concentration of Potassium Chloride before and after Reaction.**—

If the action of potassium chloride in the reaction between magnesium and water is purely catalytic, its amount should remain unaltered. As has already been stated, Tommasi<sup>1</sup> found this to be the case in his investigation of the action of magnesium on solutions of potassium chloride and, as a result, he suggested that the potassium chloride should be considered as a catalyst promoting the reaction between magnesium and water. With a view to verifying the statement of Tommasi that the initial weight of potassium chloride remains unchanged throughout the reaction, the following experiment was performed. A piece of freshly polished magnesium wire was immersed in distilled water containing a known weight of potassium chloride. The reaction was allowed to proceed for several days until the rate of evolution of hydrogen became very slow. Then, after scraping off the accumulated magnesium hydroxide from the wire as completely as possible, the entire reaction mixture was filtered and the wire and residue washed repeatedly with boiling water. The object of this last operation was to remove the last traces of adhering potassium chloride from the wire and the residual magnesium hydroxide. The filtrate was then treated with a solution of barium

<sup>1</sup> *Loc. cit.*

hydroxide and the precipitated magnesium hydroxide was removed by filtration. The excess of barium was next removed by means of a solution of ammonium carbonate and the resulting filtrate carefully evaporated to dryness. After freeing the residue from ammonium salts by cautious heating, it was raised to the temperature of a full Bunsen burner for twenty minutes. The weight of the ignited residue was then determined, after allowing it to cool in a desiccator. The amount of potassium chloride present initially was 0.1868 g. while the weight of the residue at the conclusion of the experiment was 0.1886 g. While it may be conceded that the experiment established the fact that there is negligible adsorption of potassium chloride by the surface of the magnesium wire and the magnesium hydroxide produced by the reaction, it is evident that the various steps involved in the recovery of the salt would in all probability bring about the decomposition of any compound which it might have formed with the products of the reaction. So far as the writer is aware, however, no compounds of potassium chloride and magnesium hydroxide are known.

**Discussion of Results.**—The proposed explanation of the reaction between magnesium and water and of the role of potassium chloride in accelerating this reaction has been confirmed by several distinct lines of experimentation of which perhaps the most satisfactory is that involving the determination of the change in concentration of the hydrogen ion as the reaction progressed. The function of potassium chloride in the reaction may be likened to other well-established cases of so-called "salt-action." For example, Ostwald<sup>1</sup> showed that when a 0.4 *N* solution of potassium nitrate was added to a solution of cane sugar containing a 0.05 *N* solution of nitric acid, the coefficient of velocity of inversion of the sugar was raised from 29.9 to 33.9. From this and similar experiments he was led to the conclusion that while the presence of a neutral salt containing an ion in common with the inverting acid lowers the concentration of the hydrogen ions of the latter, it also exerts a marked stimulating influence on the remaining hydrogen ions. Quite another type of salt action is that described by Van Name and Edgar.<sup>2</sup> They showed that the rate of solution of a number of different metals in aqueous solutions of iodine is greatly increased by the presence of potassium iodide. In the Silliman lectures delivered at Yale University in 1911 by Arrhenius,<sup>3</sup> he says: "It has been proved that salts exert a certain influence which is sometimes very great, especially on the velocity of reaction." While in the present investigation the influence of only one salt on the reaction has been studied,

<sup>1</sup> Ostwald, *J. prakt. Chem.*, [2] 31, 307 (1885).

<sup>2</sup> Van Name and Edgar, *Am. J. Sci.*, [4] 237 (1910).

<sup>3</sup> "Theories of Solutions," p. 165, Yale Univ. Press, 1912.

it is believed that the explanation here given is of general application and that it is not necessary to invoke the assistance of the older chemical compound theory of solution.

### Summary.

In this paper the action of magnesium on solutions of potassium chloride has been investigated. The experimental work has involved (a) the measurement of the volume of hydrogen obtained by the action of magnesium on water prepared in a variety of ways, (b) the measurement of the volume of hydrogen obtained from solutions of potassium chloride of different concentrations, (c) the determination of the differences of potential between magnesium and solutions of potassium chloride, (d) the determination of the concentration of the hydrogen ion in both pure water and solutions of potassium chloride, and (e) the determination of the concentration of potassium chloride in a solution before and after the action of magnesium. The evidence furnished by these several lines of experimentation has led to the conclusion that the reaction between magnesium and water may be represented by the equation

and that the presence of the dissolved salt merely accelerates the reaction catalytically.

## OXIDATION-REDUCTION REACTIONS WITHOUT THE ADDITION OF ACID.

### III. FERROUS CHLORIDE AND POTASSIUM PERMANGANATE.

#### A New Method for the Preparation of Colloidal Hydrous Ferric Oxide.

BY MARKS NEIDLE AND JOHN N. CROMBIE.

Received October 6, 1916.

The most familiar reaction involving the oxidation of ferrous ion by permanganate ion, is that between potassium permanganate and ferrous sulfate in the presence of an excess of sulfuric acid, and may be formulated by either of the following equations:

The data necessary for predicting whether a mixture of aqueous solutions of ferrous chloride and potassium permanganate contains a sufficient concentration of hydrogen ion to render the normal reaction possible, and to make it go practically to completion are not available. Nor was it possible to gain this information from the results of the oxidation-

reduction reactions<sup>1</sup> already studied, for, in the latter, potassium dichromate was employed, which gives a concentration of hydrogen ion greater than that given by equivalent solutions of ferrous chloride or potassium permanganate. From our knowledge that hydrated manganese dioxide is formed when permanganate reacts with certain substances, *e. g.*, sugar, oxalic acid, manganese sulfate, in neutral or slightly alkaline solution (and even in weakly acid solution),<sup>2</sup> we might expect a similar result in the reaction with ferrous chloride or ferrous sulfate, without the addition of acid. A few preliminary experiments, however, pointed to the contrary, indicating that the ionic equation for the reaction between ferrous chloride and potassium permanganate, without the addition of acid, is the same as that in which an excess of acid is added. Then, it was possible to predict that one of the products is colloidal hydrous ferric oxide, while in the corresponding reaction with ferrous sulfate, the colloid is precipitated.

**Stoichiometric Relations.**—Ferrous chloride solutions, approximately normal, half-normal, fifth-normal and tenth-normal, were prepared by dissolving the commercial C. P. salt in the proper amounts of water, and filtering off the insoluble residue. These solutions were titrated by potassium permanganate of approximately the same normalities: first, with the addition of an excess of acid, and second, without the addition of acid.

Twenty-five cubic centimeters of ferrous chloride solution were taken in all titrations. In those with acid, 10 cc. of concentrated hydrochloric acid, 50 cc. of preventative solution, and water to make a volume of 400 cc. were added to the ferrous chloride and the titration conducted in the usual way, *i. e.*, until the first appearance of pink throughout the solution.

In the titrations without the addition of acid, the permanganate was immediately run into the ferrous chloride contained in a beaker. The first few drops produced a light yellow color, which gradually changed to a clear deep brown as more permanganate was added. Potassium ferricyanide was used as an outside indicator, and the end point was considered reached when a brown color was obtained, which did not turn green on standing for a few minutes. With a little practice, the end points were easily detected with a fair degree of precision. The titrations with the normal solution, however, presented a little more difficulty than the others, because of the intense brownish red color produced as the permanganate was added to the ferrous chloride.

It will be seen from the results, given in Table I, that the volume of permanganate required in a titration depends upon the manner of its addition. This was evidently due to the collateral reaction between

\* Neidle and Witt, *THIS JOURNAL*, 37, 2360-68; 38, 47-52.

<sup>2</sup> C. W. R. Powell, *J. Proc. Roy. Soc., New S. Wales*, 48, II, 223-41 (1914).

the permanganate and the chloride ion. We therefore decided to run similar titrations, using ferrous sulfate instead of ferrous chloride.

**Titration of Ferrous Sulfate by Potassium Permanganate with and without the Addition of Acid.**—The procedure was identical with that followed in the ferrous chloride titrations, except that in those with acid, 5 cc. of concentrated sulfuric acid were substituted for the hydrochloric acid, and no preventative solution was employed. The ferrous sulfate solutions, in the titrations without acid, at first behaved exactly like those of ferrous chloride, but later gave a precipitate as indicated in Table II.

TABLE II.

Normality (approximate).	FeSO <sub>4</sub> . Cc.	Titrations with acid. KMnO <sub>4</sub> . Cc.	Titrations without addition of acid.	
			KMnO <sub>4</sub> . Cc.	Remarks.

		24.80	24.80	
0.2	25.00	22.97	22.95	Solution became cloudy when end point was nearly reached, and on standing a short time after completion of titration, a brown gelatinous precipitate formed.
		23.00	22.97	
0.5	25.00	25.63	25.60	Cloudiness did not appear until a short time after the completion of titration. Turbidity gradually increased and a precipitate finally formed.
		25.67	25.63	

**Discussion of Results.**—Since the ferrous sulfate titrations gave the same results (Table II, Columns 3 and 4), whether acid was used or not, we may conclude that the stoichiometric relations in the reaction between ferrous ion and permanganate ion are the same with and without the addition of acid. We may also conclude that, even in 0.1 *N* concentrations, ferrous sulfate and potassium permanganate react practically instantaneously.

The results of the ferrous chloride titrations, without acid, show the

same variations as found by Birch<sup>1</sup> and Friend<sup>2</sup> in their studies on the action of permanganate on ferrous salts in presence of hydrochloric acid. Birch attributes the larger amounts of permanganate to the loss of elementary chlorine. He also observes that "the results are, if anything, slightly better in concentrated than in dilute solution." This is also the case in the ferrous chloride reaction, without acid, as is seen from Column 5, Table I. Our data thus show that the greater the concentrations of the solutions, the less does the chloride ion interfere with the titrations. This may be explained by the greater speed of reaction between elementary chlorine formed in the side reaction and ferrous ion at the higher concentrations, and the consequent smaller proportionate loss of elementary chlorine.

The latter will also explain why the discrepancy in the results, due to the difference in the manner of adding the permanganate, decreases with increasing concentration. Friend has observed that the results in titrating ferrous salts by permanganate in the presence of hydrochloric acid are high when the permanganate is added rapidly, and more nearly theoretical when it is added slowly. He ascribes this discrepancy to the formation of an intermediate perchloride of manganese. We are inclined to attribute it to the presence of large local excesses of permanganate in the rapid titrations, resulting in considerable oxidation of chloride ion and loss of elementary chlorine.

The products in the ferrous sulfate-permanganate reaction are potassium sulfate, manganese sulfate, ferric sulfate and colloidal hydrous ferric oxide. Ferric sulfate, or rather the ferric ion, protects the colloid while the other salts are good colloid precipitants. A definite concentration of ferric ion is necessary to protect the colloid against precipitation by the sulfate ion. The amount of ferric ion in a ferric sulfate solution gradually diminishes because of hydrolysis.<sup>3</sup> Furthermore, colloidal hydrous ferric oxide accelerates the hydrolysis of ferric salts.<sup>4</sup> These considerations immediately furnish an explanation of the gradual appearance of a turbidity and ultimate precipitation in the ferrous sulfate-permanganate titrations without acid.

#### Products of the Ferrous Chloride-Potassium Permanganate Reaction.

—An amount of commercial C. P. ferrous chloride, containing an equivalent weight of ferrous iron, was dissolved in about a liter of water and filtered. An equivalent weight of permanganate ( $\frac{1}{5}\text{KMnO}_4$ ) was dissolved in about 600 cc. of water, and the resulting solution added in small portions—to avoid oxidation of chloride ion—to the ferrous chloride solution which

<sup>1</sup> *Chem. News*, 99, 61, 73 (1909).

<sup>2</sup> *J. Chem. Soc.*, 95, 1218 (1909).

<sup>3</sup> Schneider, *Ann.*, 257, 362 (1890).

<sup>4</sup> Goodwin and Grover, *Phys. Rev.*, 11, 193 (1900).

was shaken vigorously during the addition. Considerable heat was generated by the reaction, which yielded a perfectly clear, deep, brownish red solution. This solution, diluted to two liters, will be referred to as the "reaction mixture."

The reaction mixture became turbid after several weeks. The turbidity gradually increased, until, after nearly five months, two layers formed, the upper one being a perfectly clear yellow solution, and the lower one a brown ochery suspension, which could not be filtered off but did separate out on centrifuging for many hours. Boiling the original mixture gave a brown gelatinous precipitate, which was filterable. This precipitate readily dissolved in water to a solution, which was perfectly clear red by transmitted light, and turbid by reflected light, and from which the colloid could not be separated by centrifuging for many hours at about 2000 revolutions per minute.

**Dialysis.**—Immediately after its preparation, 400 cc. of the reaction mixture were introduced into a parchment paper membrane and dialyzed with intermittent changing of the diffusate. The dialysis was continued for thirty-five days, and the perfectly clear reddish brown colloidal solution, which now suffered no change on boiling, was analyzed for iron, manganese, potassium and chlorine. The manganese and potassium were barely detectable, and therefore were not determined. The ratio of iron to chlorine in gram equivalents ( $\frac{1}{3}$  Fe, 1 Cl) was 26.3, and the colloidal solution contained 68.4% of the iron in the original mixture. We have thus obtained the common hydrosol of hydrous ferric oxide, protected, as usual, by a small amount of hydrochloric acid.

The percentage of the total iron in the mixture, obtainable in the form of the hydrosol, depends on the nature of the membrane and the method of dialysis. By continuous dialysis in the cold, using a parchment paper membrane, 82.1% of the total iron remained in the colloidal solution. The equation for the reaction points to only 53.3% of iron in the form of the hydrous oxide. The additional 15.1% obtained in intermittent dialysis and 28.8% in continuous dialysis, is due to hydrolysis of the ferric chloride. It has been mentioned that the reaction mixture gradually becomes turbid, and finally separates into two layers. Until the latter stage is reached, dialysis will readily yield a perfectly clear colloidal solution. After that, the colloidal solution obtainable by mixing the two layers and dialyzing, is slightly turbid in reflected light, though perfectly clear in transmitted light.

**Addition of an Excess of Permanganate to Ferrous Chloride.**—A slight excess of permanganate has no apparent effect other than a slight change in color, and, on dialysis, it rapidly diffuses through the membrane, leaving a clear hydrosol. A large excess does not cause an immediate change, but an odor of chlorine is observed, and the entire solution gels—within

an hour for 0.5 *N* solutions, and after several days for 0.1 *N* solutions. When such solutions have gelled, dialysis will not yield a hydrosol.

**Discussion of Results.**—Since all the manganese and potassium in the reaction mixture diffuse through the dialysis membrane, it may be concluded that they are present in the mixture as chlorides. Hence the products of the reaction are the chlorides of potassium, manganese and ferric iron, and colloidal hydrous ferric oxide. The reaction may now be written,

The ionic reaction, with acid, is usually formulated by the equation

but is possibly better represented by the equation

If the concentration of hydrogen ion is very high, due to the presence of a strong acid, the concentration of hydroxyl ion will be kept at an exceedingly low value, as required by the ionic product constant for water. When no acid is employed, our results show that sufficient hydrogen ion for the reaction is furnished by the dissociation of the water, and by the hydrolysis of the ferrous chloride and potassium permanganate. But here hydroxyl ion accumulates, and soon the solubility product constant of ferric hydroxide is exceeded, when colloidal hydrous ferric oxide is formed.

The complete reaction between ferrous chloride and potassium permanganate may be represented ionically as follows:

The turbidity which appears in the reaction mixture, gradually in the cold and rapidly in the hot, is due to the hydrolysis of the ferric chloride. The ferric chloride, or rather the ferric ion, protects the colloid against precipitation by the manganese and potassium chlorides. Hydrolysis of the ferric chloride decreases the concentration of ferric ion, and, when it is reduced below the value necessary for protection, the colloid coagulates. This coagulation is, however, reversible, for the turbid reaction

mixture, on dialysis, will yield a practically clear sol. The reversibility in this case is due to the greater diffusion velocities of manganese and potassium chlorides as compared with ferric chloride. As the manganese and potassium chlorides diffuse, the residual ferric ion peptizes the coagulated colloid, and the sol is again formed.

### Summary.

The stoichiometric relations in the permanganate-ferrous sulfate and permanganate-ferrous chloride reactions are the same with or without the addition of acid. In the permanganate-ferrous chloride reaction, the collateral oxidation of chloride ion is practically avoided by adding the permanganate gradually and with vigorous stirring.

The products of the permanganate-ferrous chloride reaction are the chlorides of potassium, manganese and ferric iron, and colloidal hydrous ferric oxide, while in the permanganate-ferrous sulfate reaction, the corresponding sulfates are formed, and also hydrous ferric oxide, which is precipitated by the sulfate ion.

A gram equivalent of permanganate, dissolved in about 600 cc. water, was slowly added to a gram equivalent of ferrous chloride, dissolved in about a liter of water, and the resulting clear, deep brownish red solution diluted to two liters. This solution remained perfectly clear for several weeks, then gradually became more and more turbid, until finally a suspension settled out. Until the latter stage is reached, dialysis yields a perfectly clear brownish red hydrosol of hydrous ferric oxide. After a suspension settles out, dialysis will give a hydrous ferric oxide hydrosol which is slightly turbid in reflective light, but perfectly clear in transmitted light.

## FURTHER STUDY OF THE ATOMIC WEIGHT OF LEAD OF RADIOACTIVE ORIGIN.

By THEODORE W. RICHARDS AND CHARLES WADSWORTH, 3D.

Received October 20, 1916.

The recent independent and almost simultaneous investigations upon the atomic weights of lead from radioactive minerals have proved with very little room for doubt that the substance derived from this source has a much lower atomic weight than ordinary lead.<sup>1</sup> This conclusion is so important in its theoretical relations that its every aspect should be carefully investigated. Accordingly, the present paper represents further

<sup>1</sup> Richards and Lambert, *THIS JOURNAL*, 36, 1329 (1914); Hönigschmid and St. Horovitz, *Compt. rend.*, 158, 1798 (1914); M. Curie, *Ibid.*, 158, 1676 (1914); Soddy and Hyman, *J. Chem. Soc.*, 105, 1402 (1914); also especially, Hönigschmid, *Sitzb. h. Akad. Wiss., Wien, IIa*, 123, 1 (Dec., 1914).

research in this direction, embodying determinations of the atomic weight of new samples of varied origin. The outcome entirely supports the earlier conclusion.

Four samples from widely separated sources were studied in the present research, namely, radio-lead from Australian carnotite, from American carnotite, from Norwegian cleveite, and Norwegian bröggerite.

The first of these samples was obtained in large quantity from the Olary mines of South Australia, through the kindness of Mr. S. Radcliff and Mr. E. R. Bubb, of the Radium Hill Company, of Sydney, New South Wales. The carnotite, an impure vanadate of uranium and potassium, mixed with much ilmenite and mica, was crushed and fused with excess of salt cake. The powdered product was extracted with cold water in agitators, dissolving the uranium and rare earths and leaving a suspension of barium, radium and lead sulfates, which was allowed to settle in lead-lined vats. After digestion with sulfuric acid to remove the iron, the separated sulfates were converted into carbonates by boiling with 20% sodium carbonate solution. The carbonates were dissolved in hydrochloric acid and the metals were reprecipitated as sulfates, which, after washing, were fused with sodium carbonate in graphite crucibles. Two kilograms of metallic lead thus reduced served as the basis of one of our present samples, as well as of the work now being continued in this laboratory.

The preliminary purification above described was carried out in Australia.<sup>1</sup> Our subsequent work with the sample is briefly described in a recent paper on the density of radio-lead,<sup>2</sup> but because so much depended upon the purification of materials in work of the sort under consideration, further details are desirable. Three different purified samples derived from the Australia lead were prepared as follows: In each case the metallic lead was dissolved in nitric acid, leaving practically no residue. Two portions of the nitrate thus obtained were taken; the first for the preparation of Samples A and B, and the second for the preparation of Sample C.

The first portion was precipitated with 20% hydrochloric acid from dilute solution, the precipitate being separated from the mother liquor by suction and dissolved in pure warm water to which enough acid had been added to prevent precipitation of the basic salt. Lead sulfide was precipitated from this solution by thoroughly scrubbed hydrogen sulfide gas, and after separation and washing was dissolved in pure nitric acid. The small portion oxidized to sulfate during this latter process was boiled with sodium carbonate for several hours, and the precipitate of lead carbonate, washed free from sodium, was dissolved in nitric acid and united to the

<sup>1</sup> A fuller description of the details is to be found in the paper by S. Radcliff, *Jour. and Proc. of the Roy. Soc. of New South Wales*, 47, 145 (1913).

<sup>2</sup> *THIS JOURNAL*, 38, 223 (1916).

main portion of the nitrate, which was recrystallized four times from pure water and precipitated as chloride from a warm solution in a quartz dish with hydrogen chloride. The precipitate was centrifuged, dissolved in water in a large platinum can and recrystallized four times, each time having added a few drops of hydrochloric acid to prevent the formation of basic salt. The second mother liquor gave no test for nitrate. This chloride, dried over caustic alkali, formed Sample A, and after two additional recrystallizations a smaller specimen constituted Sample B.

The second portion of the original nitrate made from the Australian sample was purified in a much simpler fashion. Avoiding the troublesome precipitation with hydrogen sulfide, we recrystallized the nitrate five times successively by adding concentrated nitric acid to its aqueous solution; then the radio-lead was converted into chloride, and by precipitation with excess of hydrochloric acid this salt also was recrystallized five times. This was Sample C of the chloride, a portion of which before the last crystallization had served to prepare Sample D of the metallic radio-lead used for determining the density.<sup>1</sup>

The next sample, designated F, was prepared from American carnotite by the Standard Chemical Co., of Pittsburgh, and came to us through the kindness of Dr. C. H. Viol, of this company, and of Professor W. D. Harkins, of the University of Chicago. After one or two recrystallizations as nitrate and three consecutive separations as chloride, this material had been reduced to metal by fusion with alkaline tartrate and carbonate, and reached us in this form. Harkins had determined its grating spectrum, and found no lines foreign to ordinary lead. Recrystallization as nitrate and chloride having been so efficacious in the case of Sample C, we continued the same method here, recrystallizing this sample thrice successively in the form of each of these salts. The limitation in the amount of material prevented further purification.

Two other samples of especial value and significance were obtained through the kindness of Dr. Ellen Gleditsch, of Kristiania. Both came from primary rocks—Norwegian pegmatite dykes. The purification of one of these, from cleveite, has already been described;<sup>2</sup> the source of this material, which occurred in cubic crystals and was carefully selected, was near Langesund, Norway. It was recrystallized first as nitrate and then as chloride three times each, in the usual manner; and the pure substance, dried in a vacuum over caustic alkali, was designated as Sample G.

Yet another sample, designated H, was prepared from lead sulfide, also kindly sent by Dr. Gleditsch, obtained from selected crystals of Norwegian octahedral bröggerite from Roade, near Moss, Norway. This was purified in precisely the same way as lead from cleveite.

<sup>1</sup> *Loc. cit.*, p. 224.

<sup>2</sup> Richards and Wadsworth, *THIS JOURNAL*, 38, 1659 (1916).

In addition to these four samples of radio-lead enough ordinary lead was carefully purified to serve as the basis of control-analyses. The purest "test lead" of commerce, free from silver, was dissolved in nitric acid, and recrystallized four times as nitrate and four times as chloride.

Throughout this work the usual care taken in atomic weight investigations was not forgotten. The nitric acid, hydrochloric acid, water and silver were all purified in methods already often described, and throughout the work on the nitrate and chloride of lead (except in the preparation of the nitrate for Sample A), the material was treated exclusively in vessels of platinum or quartz. In the case of Sample A, vessels of a good modern, slightly soluble glass, were employed.

None of our preparations after ignition in hydrochloric acid was entirely free from a trace of the insoluble black residue usually left by even carefully purified fused lead chloride when it is dissolved in water. This difficulty has been already met with by Baxter and his assistants, as well as in the earlier work on radio-lead.<sup>1</sup> In many cases the amount of contamination was almost if not wholly negligible; in others, on the other hand, it was appreciable. The amounts found in the two analyses of ordinary lead detailed below were, respectively, 0.26 and 0.30 mg., whereas the amounts found in the nine analyses of radio-lead were, respectively, 0.84, 0.21, 1.95, 0.00, 0.05, 0.47, 0.04, and 0.00 mg. These quantities, found by collecting the black residue on a Gooch-Munroe crucible before precipitation of chlorine with silver, were subtracted from the initial weight of the fused lead chloride. It is noticeable that in general those preparations which contained appreciable amounts of the residue were slightly lower than the others as regards the final atomic weight obtained, but this conclusion rests on only a few cases and may have no significance. In any case the error produced by this slight residue (which consisted mainly of carbon, with a trace of silica) could not have been important. The residues were of a much smaller order than the differences between the atomic weights of the various samples, and the main outcome of the work would have been unaffected if they had been entirely disregarded.

The black residue may be entirely eliminated by adopting a method which has been in use for a long time for freeing fusible salts from silica, namely, the preliminary fusion of the salt, filtering off the residue, and recrystallizing before the analysis is commenced.<sup>2</sup> Hönigschmid and St. Horovitz<sup>3</sup> have shown also that by distillation in quartz this residue remains behind, a fact which we have recently verified.

<sup>1</sup> Richards and Lambert, *THIS JOURNAL*, 36, 1336 (1914).

<sup>2</sup> See Stas, "Untersuchungen Über die Gesetze der Chemischen Proportionen. Über die Atomgewichte und Ihre Gegenseitigen Verhältnisse," Leipzig, 1867, p. 275; Richards, *THIS JOURNAL*, 24, 376 (1902); see also Baxter and Hartmann, *Ibid.*, 37, 117 (1915).

<sup>3</sup> Hönigschmid and St. Horovitz, *Sitzb. k. Akad. Wiss. Wien, IIa*, 123, 16 (1914).

The method of analysis was essentially similar to that so often described. The lead chloride was fused in a platinum boat in pure hydrogen chloride; this gas was displaced by nitrogen while the substance was cooling; and finally the pure dry salt in its boat was pushed into the weighing bottle, stoppered in pure dry air with the help of the familiar "bottling apparatus," and weighed at leisure. The weighed salt was placed in a large Erlenmeyer flask with glass stopper very carefully ground. Enough water was then added to form a fiftieth-normal solution of the salt and the flask and contents, with the addition of a drop of pure nitric acid to prevent the formation of basic salt,<sup>1</sup> were gently warmed on an electric stove, at about 50°, until complete solution was obtained. The boat was then removed, and the residue filtered off, both boat and residue being carefully washed and the filtrate being collected directly in the precipitating flask.

The chlorine contained in this solution was then precipitated in the usual fashion by an amount of silver calculated as nearly as possible to correspond with it. Especially in the early determinations of a previously untested sample the exact amount was not attained, and more silver or more chloride had to be added, but in most of the subsequent cases the precipitation was found at once to be almost complete. These small quantities of silver, or those corresponding to the additional chloride, were, respectively, added to or subtracted from the weight of silver originally taken in each case, and the finally corrected weight is given in the table. As the magnitudes of these small quantities are purely accidental, their detailed recital is unnecessary. The precipitation was carried on in a dark room, under red light, and the usual precautions were taken. The attainment of exact equivalence of silver and chlorine was tested in a nephelometer in the customary fashion.

The balance used was a good one, and the weights were, of course, carefully standardized. All the weighings were reduced to the vacuum standard (adding 0.060 mg. for each gram of lead chloride and subtracting 0.030 mg. for each gram of silver) and all other precautions usual in this sort of work were carefully maintained.

The first two determinations on ordinary lead were only preliminary, in order to gain practice with the method, and are not included in the table below. They yielded as values for the atomic weight, respectively, 207.15 and 207.16. All the other analyses which were brought forward to conclusion are recorded in the tables. Probably the first analysis in the second table of Sample A of Australian carnotite was somewhat erroneous, but the effect on the average, in which it was included, is unimportant. The tables are self-explanatory. The atomic weights of silver and chlorine are taken as 107.88 and 35.459, respectively.

<sup>1</sup> See Baxter and Grover, *THIS JOURNAL*, 37, 1027 (1915).

Average, 206.084

The results of these analyses show that the different samples of radio-lead all give lower values for the atomic weights than ordinary lead, but that the material from each source gives a different value, precisely as had been previously found in the earlier investigations in this and other laboratories. Summarized, the results were as follows:

## ATOMIC WEIGHT OF RADIO-LEAD.

Ore.	Geographical origin.	Atomic wt.
Galena (?)	American ordinary lead	207.18
Carnotite	Colorado, U. S. A. (?)	207.00
Carnotite	Radium Hill, N. S. W., Australia	206.34
Bröggerite	Moss, Norway	206.12
Cleveite	Langesund, Norway	206.08

In this table results have been arranged in order of the atomic weight. Ordinary lead gave the maximum value (essentially equal to that found by Baxter and Grover<sup>1</sup>; and Norwegian cleveite gave the minimum value (essentially equal to that found by Hönigschmid in bröggerite,<sup>2</sup> 206.06).

It seems reasonable to suppose that the other samples were composed of mixtures of these two kinds of lead, but that is by no means certain, for there may be yet a third variety. The Norwegian bröggerite gave a result so near to that of the cleveite that we may assume the substance to be almost of the same kind, with but very slight admixture of an im-

<sup>1</sup> Baxter and Grover, *THIS JOURNAL*, 37, 1027 (1915).<sup>2</sup> Hönigschmid and St. Horovitz, *Sitzb. k. Akad. Wiss, Wien, IIa*, 123, 1 (Dec., 1914).

purity; but the two carnotites give widely divergent results. The lead from Australian carnotite was known to have originated partly from an admixture of galena; therefore it was to be expected that the atomic weight would be greater than the minimum value for radio-lead. Its value, 206.34, would be given approximately by a mixture of three parts of radio-lead like that obtained from Norwegian cleveite with one part of ordinary lead—a reasonable supposition, since, as stated above, the Australian carnotite was known to have contained galena. The American carnotite, Sample F, represented by Analyses 5 and 6, is more puzzling. This has an atomic weight which would be given by a mixture of only one part of radio-lead with 5 or 6 of ordinary lead, a condition which seems to indicate the admixture of very large amounts of galena with the sample in question. Since the source is uncertain one cannot say whether or not this inference is satisfactory. The alternative would be the assumption of an admixture of a third kind of lead with yet higher atomic weight, such as that possibly indicated by the work of Soddy and Hyman.<sup>1</sup>

Two physical properties of the several preparations under consideration have especial interest, namely, the magnitude of the radioactivity and the nature of the spectrum.

One of us, in collaboration with Dr. Lemberg, had already concluded that the radioactivity is not proportional to the decrease in atomic weight in samples of radio-lead coming from different sources, and our present experience fully confirms this conclusion. The radioactivity of the several samples was determined by the rate of fall of a gold-leaf spectroscope arranged in the usual fashion so as to measure quantitatively the rate of fall of the gold leaf by means of a small telescope. Equal weights of the several samples of lead chloride spread out in a thin layer were tested in succession. The rate of the fall of the instrument in the absence of any radioactive substance was subtracted from that in the presence of each. Alpha radioactivity was excluded by thin aluminum foil; that which was measured was due almost entirely to beta-rays. The results are given by the following table:

TABLE.

Source of radio-lead.	Time of fall in seconds.	Rate of fall.		
		Per minute.	Natural.	Corrected.
Australian Carnotite.....	9.45	0.1053	0.0287	0.0766

If the radioactivity were dependent upon the presence of radium G (the supposed end product of the decomposition, a form of metallic lead),

<sup>1</sup> *Loc. cit.*

<sup>2</sup> Calculated from data from another electroscope.

the rate of fall for cleveite would be the greatest and that for American carnotite the least. But the results are precisely the other way about. There can be little question, then, that radioactivity is not due to the isotope which gives the low atomic weight. Probably it is due to radium E, since in all of our samples the half-value of the radioactivity was attained in about five days—the half life of radium E. The maximum value, approached asymptotically, is nearly reached in a month.

The spectrum of radio-lead as thus far studied by Hönigschmid, by Merton and by Harkins, as well as by Baxter (who kindly photographed the ultraviolet spectrum of one of the samples of lead prepared by one of us with the help of Dr. Lember) has always been found to be essentially like that of ordinary lead. In the present research we thought it worth while once more to test this question and especially to extend the inquiry to the visible portion of the spectrum—most of the tests in the past having been made in the ultraviolet region. We found difficulty in eliminating traces of copper, silver and calcium too small to be detected by ordinary analysis, either quantitative or qualitative. The extreme delicacy of the spectrum in a Féry spectrometer was shown by the fact that Sample C of Australian lead, which gave distinct silver lines, nevertheless showed no trace of this metal when dissolved in nitric acid and tested nephelometrically with bromide for the presence of silver, although the latter test is a very sensitive one. The amount of silver giving these strong lines must, therefore, have been at least as small as is represented by the very slight solubility of silver bromide in the presence of excess of bromine ion—far too little to affect the atomic weight. After eight recrystallizations as nitrate and two as chloride, the product gave in every respect precisely the same spectrum as the purest ordinary lead prepared by Baxter and Grover, except for a vanishingly small trace of two of the most prominent silver lines.

The details of the spectroscopic testing were as follows: To make the electrodes, electrolytic crystals were dried on pure filter paper and fused in a current of pure hydrogen in a hard glass (or silica) tube constricted at one end to the desired size. The molten metal was allowed to run into the constricted part of the tube. If the glass adheres to the metal the surface of the lead must be carefully freed from fragments when the glass is removed, preparatory to use in the spectroscope.

Between two electrodes thus prepared, 2 mm. apart, were flashed sparks from a large induction coil. As usual, a large condenser, placed in parallel with the coil, increased the strength of the spark; and a small self-inductance (consisting of a number of turns of coarse insulated wire) served to eliminate air lines. The spark must be intermittent, otherwise the leaden electrodes will melt; its light was focused on the slit of the spec-

troscope by means of a double convex spherical-cylindrical lens, of quartz or glass, as the need required.

The photographs of the ultraviolet region in the Féry spectrometer were very kindly made by Professor Baxter. Photographs of the visible portion of the spectrum were made by us in the Gibbs Laboratory (by means of a less technically complete, but nevertheless fully satisfactory, spectrometer). The range of this latter spectroscopy was between wave lengths 3300 and 7800—the permeability of glass limiting the effect on one end and the sensitiveness of the specially prepared plate on the other. All the latter work of loading and developing had to be done in complete darkness. To make assurance doubly sure, a further study of the visible spectrum was made, in collaboration with Mr. Norris F. Hall, with the help of the Hilger wave-length spectrometer, comparing visually in the same field of view the spectra of pure ordinary lead and the best purified specimen from Australian carnotite. Every line was scrutinized between the range 4000 and 7600, especial pains being taken in the red and yellow portions, the least satisfactory from a photographic point of view. No discernible differences between the two spectra were observed.

The lead kindly sent us by Professor Harkins was also found to be identical in every respect to the other two samples, except for a faint trace of copper. The lead made from the Norwegian cleveite had been less often crystallized; it showed a distinct trace of silver, and minute traces of copper and calcium; but (so far as we could tell) no impurity in amount sufficient to affect the atomic weight.

Because no lines were detected between wave lengths 7800 and 2200 in any of the samples which were not due either to ordinary lead or to unimportant traces of well-known impurities, the conclusion previously reached by Richards and Lambert is supported, namely, that radio-lead possesses the same spectrum as ordinary lead. The present confirmation is especially interesting because of the support of the presumably almost pure radio-lead obtained from the preparations of Dr. Gleditsch.

Since the atomic weight is variable, but the spectrum of these samples all the same, one must conclude that a part of the atom exercising an important effect upon the atomic weight is without influence upon the spectrum or the volume. The dual nature thus postulated is, of course, in accord with the interesting hypothetical assumptions which have been advanced on various sides concerning the possible make-up of the atom; but our present research can go no further than support the idea of duality without defining exactly of what the two parts may consist. Nothing in the outcome is in any way inconsistent with the suggestive disintegration hypothesis, independently advanced by Soddy and Russell in England and by Fajans in Germany.

We are glad to acknowledge our indebtedness to the Carnegie Institution of Washington for generous support in this investigation.

### Summary.

In this paper the atomic weight of four different samples of radio-lead not hitherto tested, as well as one sample of ordinary lead (used to control the others) was determined. The results were as follows:

Ordinary lead.....	207.18
Radio-lead (Colorado).....	207.00
Radio-lead (Australia).....	206.34
Radio-lead (obtained from bröggerite from Norway).....	206.12
Radio-lead (obtained from cleveite from Langesund, Norway).....	206.08

That the most carefully selected sample should give the lowest result is strong evidence that the higher results obtained from other samples were due merely to the accidental admixture of ordinary lead. As before, no new lines were found either in the ultraviolet or visible spectrum of any of these samples. Hence the atom of lead may be supposed to have a dual structure. Each sample, except the ordinary lead, possessed radioactivity, but the magnitude of this radioactivity seemed to bear no relation to the lowering of the atomic weight.

## THE SYSTEMATIC DETECTION OF THIOCYANATES.

BY LOUIS J. CURTMAN AND BEN R. HARRIS.

Received September 23, 1916.

**Nature of the Problem.**—One of the most striking reactions in qualitative work, is the red color produced when ferric salts and thiocyanates are brought together in solution. While the production of this red color serves as an exceedingly sensitive test for iron, as a test for thiocyanates this reaction is not only of a much lower order of sensitiveness,<sup>1</sup> but is also interfered with by many acids. Arsenates, phosphates, oxalates, tartrates, fluorides<sup>2</sup> and borates<sup>3</sup> hinder the free course of the reaction; ferrocyanides mask the red color, while iodides, acetates and nitrites offer the most serious interferences by forming colorations with ferric salts similar to the color of ferric thiocyanate.

<sup>1</sup> This was to be expected; for, Kruss and Moraht (*Ber.*, 22, 2056 (1899)) have demonstrated that the maximum color is produced when ferric chloride and potassium thiocyanate are brought together in the proportion of 1 : 12, respectively, a condition that is not reproducible when unknown and minute amounts of thiocyanate have to be dealt with. Quantities of thiocyanates in excess of this ratio also produce the maximum color, so that in testing for iron it is always possible to produce the deepest color attainable in a given case.

<sup>2</sup> Stokes and Cain, *Bull. Bur. of Standards*, 3, No. 1, 115 (1907).

<sup>3</sup> Prescott and Johnson, *Qual. Chem. Anal.*, 1918, p. 155.

**Determination of the Sensitiveness of the Test.**—To determine the sensitiveness of the test for thiocyanates, which depends upon the formation of ferric thiocyanate, a definite volume of a standard solution of potassium thiocyanate was treated in a test tube, with 0.5 cc. 2 *N* ferric chloride solution,<sup>1</sup> the whole diluted to 5 cc., shaken, allowed to stand one minute and observed. The results obtained are given in Table I.

TABLE I.

No.	Mg. SCN.	Result.
1-2	5-3	Deep blood red
3-4	1-0.5	Deep red
5-6	0.4-0.3	Brownish red
7	0.2	Light brownish red
8	0.1	Reddish yellow (limit)

An inspection of Table I will show that 0.1 mg. of thiocyanate may be detected with the ordinary amount of care.<sup>2</sup> The addition of three drops of concentrated hydrochloric acid had practically no effect on the color.

For a reason stated below,<sup>3</sup> numbers 1, 3 and 8 of Table I were repeated, using ferric nitrate and 3 drops of 10% nitric acid in place of ferric chloride and hydrochloric acid, respectively. Results identical with those recorded in Table I were obtained.

It may be of interest to state that while in the detection of minute amounts of iron, the test may be considerably intensified by extracting the ferric thiocyanate with ether, this procedure is of no value when conditions are reversed. In Experiments 3-8, Table I, colorless ether layers were obtained when the solutions were shaken first with 2 and then with 5 cc. of ether, the aqueous layers retaining their original colors. This is probably due to the fact that in the test for iron there is invariably added a large excess of thiocyanate, while in the experiments noted above this was not the case.

**Extent of Interferences.**—To determine the extent to which iodides, acetates and nitrites interfere with the test for thiocyanates, a series of experiments was conducted. The procedure was the same as that followed in the determination of the sensitiveness of the test. The results obtained are recorded below in Tables II, III and IV.

TABLE II.  
Interference of Iodides.

No.	Mg. I.	Result.
1	30	Blood red
2-3	20-15	Dark brownish red
4-5	10	Light brownish red
6	8.5	Light brownish red
7-8	7	Yellowish red (limit)
9	0.0	Very faint yellow

TABLE III.  
Interference of Acetates.

No.	Mg. C <sub>2</sub> H <sub>3</sub> O <sub>2</sub> .	Result.
1-2	100-50	Deep blood red
3-4	30-25	Reddish brown
5-6	20	Light reddish brown
7-8	18	Reddish yellow (limit)
9-10	0.0	Very pale yellow

<sup>1</sup> This solution contained 0.5 cc. conc. HCl per liter.

<sup>2</sup> This figure is also given by A. A. Noyes, *Qual. Chem. Anal.*, 1915, p. 101.

<sup>3</sup> See number eight under "Comments on the Procedure."

TABLE IV.  
Interference of Nitrites.

No.	Mg. NO <sub>2</sub> .	Result.
1	100	Brownish red ppt.
2-3	50-35	Dark reddish brown
4-6	25-17	Brown
7-8	14	Light brown (limit)
9-10	11	Brownish yellow

**Comments.**—It is evident that iodides rank first in the degree of interference. It may be of interest to note that the colorations produced both by large and small amounts of iodide are almost identical in tint with those produced by certain corresponding quantities of thiocyanate, whereas the colorations produced by small amounts of acetate and of nitrite resemble the color of ferric thiocyanate less closely. It is for this reason, that it was difficult to determine the "limit" interferences of these acids. The limit data, especially in Table IV, are therefore only approximate. In the tables, the limit of interference is that quantity of the substance which produces a coloration equivalent to that formed under similar conditions by 0.1 mg. of thiocyanate. The ferric chloride solution mentioned contained 0.5 cc. of concentrated hydrochloric acid per liter to retard hydrolysis. This free acid decomposed the nitrite, hence, a special, nearly neutral 2 *N* ferric chloride solution was used in the determination of the interference of nitrites. Even this solution caused a slight evolution of the oxides of nitrogen. The coloration given by iodides was unaffected by the addition of three drops of concentrated hydrochloric acid. The same quantity of acid, however, bleached to a greenish yellow, the coloration given by acetates.

**The Available Methods for the Detection of Thiocyanates in the Presence of Iodides.**—A search of the literature failed to disclose a direct method for the separation of iodides from thiocyanates.<sup>1</sup> The liberation of iodine and its removal by means of carbon disulfide or some similar solvent is the only means for this purpose. Of the many liberators of iodine, *e. g.*,  $\text{KMnO}_4$ ,  $\text{H}_2\text{O}_2$ ,  $\text{K}_2\text{Cr}_2\text{O}_7$ ,  $\text{KNO}_3$ ,  $\text{Cl}$ -water and  $\text{FeCl}_3$ , only the last named was suitable; for, while they all adequately liberated the iodine,

<sup>1</sup> After the completion of this work, our attention was called to a paper by Benedict and Snell (THIS JOURNAL, 27, 738), entitled "A Method for the Detection of the More Common Acids," in which the separation of thiocyanates from iodides is effected by digesting the precipitate of  $\text{AgI}$  and  $\text{AgSCN}$  "in the cold with a mixture of three volumes of 2 *N* sodium chloride and one volume of 5 *N*  $\text{HCl}$ ." To determine whether this method possessed any advantage over the one proposed by us, test experiments were made, a description of which appears in Note 4, page 2625. While this paper was in press, Weber and Winkelman (THIS JOURNAL, 38, 2000) published a paper in which the separation of  $\text{I}$  and  $\text{SCN}$  is effected by heating their silver salts with sodium formate in alkaline solution. By this process the  $\text{AgSCN}$  is reduced giving metallic silver and sodium thiocyanate while  $\text{AgI}$  is not reduced.

they also oxidized the thiocyanate to cyanide and sulfate, thus vitiating the subsequent ferric thiocyanate test. Even the use of ferric chloride did not yield satisfactory results, owing to the fact that the extraction with carbon disulfide was cumbersome and that the removal of the excess of iron which it was necessary to introduce at the beginning, entailed serious difficulties.

Advantage was also taken of the fact that nascent hydrogen reacts with thiocyanates to give hydrogen sulfide.<sup>1</sup> The evolution of hydrogen sulfide would thus serve as a suitable, though indirect, means for the detection of thiocyanates in the presence of iodides, acetates and nitrites, subsequent to the removal of all other sulfur compounds capable of liberating hydrogen sulfide under similar conditions. This method was tried but was abandoned on account of the excessive sensitiveness of the test and because of its inability to indicate the quantity of thiocyanate present.

The procedure finally adopted and described in detail below depends upon the fact<sup>2</sup> that silver iodide is for all practical purposes inert in a hot 5% sodium chloride solution, while silver thiocyanate is transposed to sodium thiocyanate and silver chloride<sup>3</sup> by this treatment.<sup>4</sup> Acetates and nitrites are held in solution by making the preliminary silver precipitation in a boiling, sufficiently dilute solution. The precipitate consisting of silver iodide and thiocyanate<sup>5</sup> is filtered and subjected to the sodium chloride treatment. Other interfering acids are previously removed by precipitating them with a solution of a mixture of barium and calcium nitrates<sup>6</sup> and a solution of cobalt nitrate.<sup>7</sup>

### Procedure.

The solution contained in a 200 cc. beaker is rendered *just* alkaline with sodium hydroxide.  $\text{Ba}(\text{NO}_3)_2 + \text{Ca}(\text{NO}_3)_2$  and  $\text{Co}(\text{NO}_3)_2$  are added in excess in the order named. About 3 g. of washed asbestos fiber are introduced, the mixture boiled for  $\frac{1}{2}$  minute with stirring, filtered on a

<sup>1</sup> Fresenius, "Manual of Qual. Chem. Anal.," Well's translation, p. 372 (1898).

<sup>2</sup> A number of experiments was made to test this point. See also Nos. 1 and 2, Table V.

<sup>3</sup> Some of the  $\text{AgCl}$  so formed is dissolved by the excess of  $\text{NaCl}$ .

<sup>4</sup> As this transposition was similar to that employed by Benedict and Snell (see Note 1, p. 2624) experiments were made to ascertain which of the two was the more efficient. Two separate precipitates each consisting of a mixture of 500 mg. of  $\text{I}$  as  $\text{AgI}$  and 1 mg. of  $\text{SCN}$  as  $\text{AgSCN}$  were treated, respectively, by the two procedures. The conditions were kept uniform as to volume and the quantity of  $\text{FeCl}_3$  added. With the Benedict and Snell method a solution having an orange-yellow color was finally obtained; whereas our procedure gave as the final result a dark brownish red solution affording unmistakable evidence of the presence of  $\text{SCN}$ .

<sup>5</sup> Silver chloride and bromide are also filtered off at this point.

<sup>6</sup> 50 g.  $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$  were dissolved in 100 cc. water. This solution was then saturated with  $\text{Ba}(\text{NO}_3)_2$ .

<sup>7</sup> This solution contained 25 g.  $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  in 100 cc.

fluted filter and washed with hot water till the washings are only faintly pink. The filtrate and washings, received in a 150 cc. beaker, should have a volume of about 100 cc. The filtrate is rendered acid with 5 drops 10%  $\text{HNO}_3$  and  $\text{AgNO}_3$  solution<sup>1</sup> added in excess. The reaction mixture is boiled for one minute with stirring to prevent loss by bumping, filtered<sup>2</sup> and washed with hot water till the washings are no longer pink. The precipitate, together with part of the filter paper to which the precipitate adheres, is returned to the beaker in which the silver precipitation was made, 10 cc. of 5%  $\text{NaCl}$  solution are added, the mixture kept near the boiling point for 3 to 5 minutes with vigorous stirring, filtered on a very small filter and washed twice with hot water, catching filtrate and washings in a 50 cc. evaporating dish. The combined filtrate and washings are concentrated by evaporation to about 4 cc., transferred to a test tube, acidified with 1 drop 10%  $\text{HNO}_3$  and finally treated with 0.5 cc. 2 *N* ferric nitrate.

**Comments on the Procedure.**—1. The  $\text{Co}(\text{NO}_3)_2$  precipitates sulfides, cyanides, ferrocyanides and ferricyanides, thereby materially reducing the size of the silver precipitate and supplying a separation of thiocyanates from ferrocyanides. The nitrates of Co, Ba and Ca were employed in preference to the chlorides to render the silver precipitate as small as possible.

2. The asbestos fiber is added to facilitate the filtration of cobalt cyanide, ferrocyanide and ferricyanide. The asbestos also serves to indicate the presence of an excess of  $\text{Co}(\text{NO}_3)_2$  which is not otherwise visible. If allowed to drop gently and float on the surface of the liquid, the asbestos will acquire a pink color when cobalt is present in excess. Furthermore the asbestos prevents bumping when the mixture is boiled.

3. The silver precipitate may well be washed by decantation, the bulk of the precipitate being retained in the beaker for the  $\text{NaCl}$  treatment.

4. In test analyses 12–24 where the silver precipitate consisted almost exclusively of 1 mg. of thiocyanate as  $\text{AgSCN}$  in a volume of 110 cc., there was visible only a faint opalescence which required a second filtration. Care should be taken always to obtain a perfectly clear filtrate from the silver precipitate, refiltering if necessary. It is safer in any case to refilter because the pink color resulting from the presence of Co, may mask the opalescence.

5. It is imperative that the silver precipitate be washed free of cobalt because the pink color of the latter may be mistaken for ferric thiocyanate in the final test.

6. A confirmatory test was always made with  $\text{HgCl}_2$  solution. With small amounts of  $\text{SCN}$ , the decolorization with  $\text{HgCl}_2$  is even a better indication of the presence of the acid than the original red or reddish color.

7. Since thiosulfates are only incompletely precipitated by barium, on the addition of silver nitrate, first a yellow and finally a black precipitate of  $\text{Ag}_2\text{S}$  separates out. But as evidenced by test analyses 14, 30 and 32, Table V, this precipitate does not interfere with the general procedure.

8. The final test is made in a volume of 5–6 cc. Before the test can be made, however, the solution as a rule will have cooled sufficiently to cause some of the dissolved  $\text{AgCl}$  to separate out, thus causing the solution to become turbid. The addition

<sup>1</sup> 6.45 g.  $\text{AgNO}_3$  were dissolved in 100 cc. of water, yielding a solution containing 50 mg. Ag per cc.

<sup>2</sup> A 9 cm. S. & S. No. 590 filter is required for this purpose.

of  $\text{FeCl}_3$  augments this turbidity; hence the use of  $\text{Fe}(\text{NO}_3)_3$ . The cloudiness, however, may be diminished and in most cases entirely removed by warming, the rise in temperature causing the  $\text{AgCl}$  to redissolve.

**Test Analyses.**—To test the efficiency of the method a large number of test analyses was made. The results are given in Table V.

**Comments on Table V.**—Following the procedure, thiocyanate was found in test analysis No. 26, although none was introduced. This result, however, does not militate against the method for the reason that thiocyanate, although not originally added, was nevertheless formed in solution from the interaction of sulfides and cyanides or of the polysulfide in the sulfide solution, and cyanides. It was therefore considered necessary to avoid the simultaneous presence of sulfides and cyanides in further experiments. The same may be said of thiosulfates as evidenced by the result obtained in test analysis 28. Prescott and Johnson<sup>1</sup> state that thiocyanate is formed in the fusion of cyanides with thiosulfates; and what holds true for a fusion may be supposed to take place also when the salts are boiled together in solution, though probably in a much lesser degree. The negative results obtained in test analyses 30 and 31, in which the above precautions were observed, showed the method to be thoroughly trustworthy.

**Approximation of the Quantity of Thiocyanate.**—In the course of the work it was observed that with amounts of thiocyanate greater than 4 or 5 mg., the depth of color was such as to make it impossible to approximately estimate with the naked eye the amount of thiocyanate present. Between the colors produced by 5 and 250 mg., there was only a very slight difference in opacity. Between 25 and 250 mg. of thiocyanate there was no discernable difference in the coloration. It was therefore deemed desirable to devise means whereby the quantity of ferric thiocyanate might be roughly estimated. The volume of mercuric chloride solution<sup>2</sup> required to discharge the red color affords such means. Attempts to bleach the color completely by comparison with a blank were unsuccessful because of the disproportionately large amount of mercuric chloride required to remove the last tinge of red. Mercuric chloride solution was therefore added only to the point when a certain brown tint was reached; beyond this stage, the bleaching was exceedingly slight with each addition of 0.3 cc. of mercuric chloride, whereas up to this point considerable changes in color were produced by the same small quantities of mercury solution. With very large amounts of thiocyanate the changes on first adding the mercuric chloride are not visible; but this state of no apparent change is easily distinguished from that alluded to above, by

<sup>1</sup> "Qualitative Chemical Analysis," p. 272 (1908).

<sup>2</sup> It was found necessary to use a highly concentrated solution because dilution alone discharges the red color. To dissolve 27 g.  $\text{HgCl}_2$  in 100 cc. of water, it was necessary to add 10 g.  $\text{NaCl}$ . The resulting solution contained 200 mg.  $\text{Hg}$  per cc.

<sup>1</sup> The solution used was prepared by saturating with H<sub>2</sub>S a definite volume of a standard solution of NaOH and then adding to the saturated solution an equal volume of the same NaOH solution.

<sup>2</sup> The silicate solution used was prepared by fusing a known quantity of C. P. silicic acid with sodium carbonate.

the presence of a blood red color in the latter as against a brown color in the former. The results recorded in Table VI show that the volume of mercuric chloride solution required to bleach the red color to the point when no further considerable change takes place on adding 0.3 cc., is roughly proportional to the quantity of thiocyanate present. This reaction therefore furnishes a basis for an approximate estimation of thiocyanates.

TABLE VI.

No.	Mg. SCN.	Cc. HgCl <sub>2</sub> solution used.
1.....	5	0.6
2.....	50	5.4
3.....	100	9.9
4.....	250	18.6

**Significance of the Results.**—It has been stated by Kern<sup>1</sup> and confirmed by us that in the presence of thiocyanates, palladium chloride may fail to give a reliable indication of the presence of iodides and that palladium nitrate may fail to give a reliable separation of iodides from chlorides and bromides. The need for a test for thiocyanates in the presence of iodides is therefore evident. Moreover, it is hardly necessary to state that in the presence of alkali halides only, the entire preliminary procedure may be dispensed with in testing for thiocyanates. To the solution, acid with dilute nitric acid, it is only necessary to add silver nitrate, and after filtering to treat the precipitate with sodium chloride solution.

#### Summary.

1. The sensitiveness of the ferric thiocyanate test for thiocyanates has been determined.
2. Data are supplied showing the extent of the interference of iodides, acetates and nitrites.
3. A procedure has been devised for the systematic detection of thiocyanates depending upon the ability of a 5% sodium chloride solution to transpose silver thiocyanate.
4. Numerous tests analyses show the reliability of the method.

### FREE ENERGY AND HEAT CAPACITY.

By JAMES M. BELL.

Received November 20, 1915.

In a recent paper, T. W. Richards<sup>2</sup> writes as follows:

"I was able to show, in cases of certain typical reversible galvanic cells, that when free energy change increases with rising temperature, total energy change decreases, and *vice versa*."

And appended to this is a footnote as follows:

<sup>1</sup> *Chem. News*, 32, 242 (1875).

<sup>2</sup> *THIS JOURNAL*, 36, 2433 (1914).

"That is to say, expressed mathematically  $dA/dT = -n.dU/dT$ , in which A represents free energy, U total energy and  $n$  a number, which was often found to be about 2. Of course  $dU/dT$  is nothing more or less than the change of heat capacity during the reaction. J. M. Bell has questioned the sufficiency of the evidence, but he has neglected to note that although Marignac's data (upon which I relied) were perhaps absolutely not very accurate, they are relatively one to another much more to be depended upon; and in this question relative accuracy alone is concerned. *J. Phys. Chem.*, 9, 402 (1906)."

In the paper<sup>1</sup> referred to by Richards, I showed that the possible errors, whose magnitude Marignac<sup>2</sup> was careful to state, were in some cases so great as to leave an uncertainty in the quantity sought ( $dU/dT$ ) greater than the quantity itself. That there were large errors seems to be admitted by Richards, who, however, now makes the claim that Marignac's data were relatively to one another much more to be depended upon. In reply to this, there are here offered two statements of fact which refute the claim.

(1) Marignac makes no such claim about his own data, for in comparing results<sup>3</sup> by taking differences (exactly as Richards does) he frankly admits a possible error of two units in the third decimal place for each solution, or a possible error of four units in the third decimal place for the differences. If the numbers were relatively accurate, the error should cancel out. Where the signs of the errors are unknown, the possible error in the final result must be considered as the accumulation of all the possible errors. Marignac clearly recognized this point.<sup>4</sup>

(2) In determining the heat capacity of a solution of the composition  $\text{CuSO}_4.200\text{H}_2\text{O}$ , Richards takes the mean of two values given by Marignac:<sup>5</sup> 0.9503 between  $18^\circ$  and  $23^\circ$ , and 0.9528 between  $22^\circ$  and  $53^\circ$ . The very fact that the mean was taken indicates that they were considered as duplicates. They differ by more than two units in the third place of decimals; whereas, in my paper I showed that with an error of one unit in the third place of decimals, there was an uncertainty in the quantity to be determined greater than the quantity itself. The wide difference between numbers considered by Richards as duplicates at once refutes his claim of greater relative accuracy, for this relative accuracy could not be greater than the degree of duplication of results.

UNIVERSITY OF NORTH CAROLINA,  
CHAPEL HILL, N. C.

<sup>1</sup> This reference should be *J. Physic. Chem.*, 9, 381 (1905).

<sup>2</sup> *Ann. chim. phys.*, [5] 8, 415 (1876).

<sup>3</sup> *Loc. cit.*, p. 421.

<sup>4</sup> On page 415 of his paper (*loc. cit.*) Marignac says of individual results: ". . . . la troisième (décimale) peut être déjà affectée d'une erreur de 1 ou 2, rarement de 3 unités." And on page 421 of the same paper he says of differences: ". . . . la limite des erreurs d'observation celles-ci pouvant bien s'élever, entre les deux expériences à  $\frac{80}{10000}$  ou  $\frac{40}{10000}$ ."

<sup>5</sup> *Loc. cit.* p. 418.

### A Reply to the Foregoing Communication.

Of course I heartily agree with Professor Bell in regard to the general proposition suggested by the foregoing note. There is great need of caution that the limits of accuracy of the data should not be overstepped in any conclusion drawn from them. My footnote, to which he takes exception, is not happily expressed. It was, moreover, too brief to express the exact state of the case. Accordingly, I beg leave to withdraw the wording of the four lines concerning Dr. Bell, with apologies to him, and to substitute for these four lines the following more complete and accurate statement:

"Dr. J. M. Bell has questioned the sufficiency of the evidence. It must be admitted that Marignac's data, upon which I depended, leave something to be desired; but, nevertheless, a careful comparison of the figures seems to show that large errors were comparatively rare.<sup>1</sup> This being the case, it seems to me that although such a single comparison among these data as that adduced by Dr. Bell might be subject to an important chance of mistake, nevertheless, when a number of results (with a range as wide as those employed in my reasoning) combine in pointing toward any given verdict, the chances are much in favor of the correctness of the verdict. Marignac's own use of his data justifies this opinion."

A few quotations from Marignac's remarks, following his tables of results, may make this point clear.

"Mais on peut espérer que les erreurs d'expériences se compensant en grande partie sur un aussi grand nombre de déterminations, les conséquences tirées de leur ensemble seront suffisamment justifiées....."

"Mais à côté de ces observations générales, ces expériences prouvent que l'accroissement de la chaleur spécifique est très rapide pour certaines solutions. Ce fait est surtout remarquable pour le sulfate de cuivre, et il m'est impossible de l'attribuer à une erreur, car j'ai fait trois fois, à trois époques différentes, la série entière des déterminations relatives à ce sel, dans les deux conditions de température et je suis toujours retombé sensiblement sur les mêmes nombres dont j'ai indiqué la moyenne....."

"Il est impossible de méconnaître un certain degré de parallélisme dans les diverses séries de sels. Les bases se rangeraient le plus souvent à peu près dans le même ordre....."

<sup>1</sup> Full discussion of this comparison of Marignac's figures would require too much space for the present note. On tabulating his results at different temperatures for the most dilute solutions containing bivalent metals (which alone came into consideration), it appears that an error of even as much as 1 in the third decimal place was probably not frequent. The mean deviation from the average in all these cases (except that of copper sulfate, which received special discussion) is only 0.0003, and one might well conclude that most of the individual values are probably within 0.05% of the truth. Marignac's cautious temperament apparently led him to claim less than he was entitled to claim.

"La différence entre les chaleurs moléculaires du sulfate et du chlorure de potassium est exactement la même que celle qu'on observe entre le sulfate et le chlorure de sodium. . . . ."

"Il y a identité presque absolue de chaleur moléculaire pour les solutions de sulfate et de chromate de potasse, et de même pour celles d'acide sulfurique et d'acide chromique." . . . . etc.<sup>1</sup>

These quotations show that Marignac, while fully recognizing the possibility of occasional wide deviations, had considerable confidence in his final results, and thought them worthy of employment in parallel comparisons involving a number of data. I used Marignac's values (the best data available) for a kind of comparison not unlike that described in the above quotations, and in a spirit essentially in accord with his. I cannot help thinking that they still deserve this degree of confidence. It should be noted, also, that the special case cited by Dr. Bell is one of the very least significant of all those which I used. If all the cases had been so little decisive as this one, I should agree with Dr. Bell, and should never have drawn the conclusion in question. This is a case of statistical reasoning, which depends not upon a few cases, but rather upon the consensus of all.

Further discussion of the matter may well be postponed until Marignac's figures have been verified or disproved by new experimental determinations, already begun.

## THE INFLUENCE OF PRESSURE ON SOLUBILITY.

BY HERBERT F. SILL.

Received September 8, 1916.

### Introduction.

Experimental values for the terms involved in the equation  $T dA/dT = Q$  have been applied with good agreement for the processes of fusion and of vaporization in one-component systems. The same is true for vaporization of mixtures (isothermal distillation).

For the important case of change of state in two-component solid-liquid systems (solution and precipitation) complete experimental data have heretofore been lacking.

When both the influence of pressure and of temperature on the solubility of a substance are known, as well as the volume change involved, the relationship  $dA/dT$  is obtainable as the product  $ds/dT dp/ds$  ( $V_2 - V_1$ ). The significance of these terms may be stated as follows:

Let a large amount of saturated solution at the temperature  $T$  be in contact with the solute at the pressure  $p$ . Then  $dp$  represents the increase in pressure necessary to cause one gram more of the solute to pass into

<sup>1</sup> Oeuvres Complet, II, 630, 632. *Ann. chim. phys.*, [5] 8, 421-425 (1876).

solution isothermally and  $dT$  represents the increase in temperature necessary to produce the same result at constant pressure.

Thus far the only accurate measurement of the influence of pressure upon solubility has been made by E. Cohen, Inouye, and Euwen,<sup>1</sup> in an apparatus designed by them and covering a range of 1500 atmospheres. The substances employed were sodium chloride and mannite and their solubilities in water were determined at the constant temperature  $24.05^{\circ}$  and pressures from one to 1500 atmospheres as follows:

Pressure (atmospheres).	Solubility in parts per hundred.	
	NaCl.	Mannite.
1	26.41	17.12
250	26.60	17.30
500	26.76	17.45
1000	27.02	17.63
1500	27.20	17.69

The values for the solubilities obtained by them, when plotted against the pressure, yield smooth curves, concave toward the pressure axis and indicating by their trend a point of maximum solubility for this temperature, at about 2500 atmospheres pressure.

It appears from the table that for these substances a considerable range of pressure is necessary in order that the solubility change may be sufficient to permit a satisfactory calculation of the value  $dp/ds$ .

These investigators did not attempt a comparison of these pressure solubility data, with any experimental values for the other thermodynamic factors

With view to establishing complete data for a case of solution the following experiments were made involving the design and construction of a new type of "pressure bomb" which is extremely simple in operation and permits the withdrawal of the sample for analysis without reducing or otherwise changing the pressure. This was not possible with the apparatus employed by Cohen, Euwen and Inouye, as it was necessary for them to relieve the pressure and open the bomb in order to take the sample for analysis. This was of no disadvantage for the systems employed by them, since during the few minutes required for the above manipulation the solution remained supersaturated to the full degree of the previous equilibrium conditions.

In the case of certain other systems such as ether-water, upon whose investigation the writer is now engaged, the composition of the layers would not remain unchanged during the time necessary to remove the sample after relieving the pressure.

#### The Pressure Bomb.

This was of the nature of a modified U-tube, the two arms of which were made from "Shelby Steel tubing" of 25 mm. bore and 63 mm. external diameter.

<sup>1</sup> *Z. physik. Chem.*, 75, 291 (1910).

The left hand or "reaction chamber" (Fig. 1) was 30 cm. and the right hand or "mercury chamber" 28 cm. in length. These were filed at the ends to a hexagonal form to permit being held with a wrench when the screw-plugs were tightened.

Fig. 1.

The ends of the capillary tubing are threaded and screwed into a steel disc, C, of the same dimensions as the washer and between the two is inserted a rubber washer, B, 3 mm. in thickness and forming a smooth cylindrical surface with the steel disc and washer.

The screw disc is slightly hollowed conically on its outer face to prevent trapping of air when inserted and rests on the shoulder D. When the plug is screwed tight the rubber is forced against the capillary tube and the wall of the bomb chamber.

Connection with the pump is made through the piece of steel capillary E joined to the  $2\frac{1}{2}$  meter flexible copper capillary F by means of the brass coupling G. The bomb is supported in the thermostat by a clamping device so constructed that the whole can rotate freely on the adjustable axis arm H, which can be raised or lowered on the support J. The latter stands within and toward the left end of an oval tank. Through the use

Both chambers were reamed smooth on the inside and turned at each end on the inside for a distance of 40 mm. to a diameter of 31 mm., thus forming a 3 mm. shoulder at D (Fig. 2). These ends were threaded to a depth of 28 mm. for the reception of screw-plugs. The latter were 28 mm. long and provided with enlarged hexagonal heads. The connection between the two chambers and with the Cailletet pump and with the outlet valve is affected by means of capillary steel tubing of 1.5 mm. bore and 6 mm. external diameter. The steel tubing passes first through a 7 mm. hole in the center of the screw-plug, then through a steel washer, A, 6 mm. thick, which fits rather snugly but will slide readily.

of the long flexible copper capillary F, which bends around in a large loop, the bomb can be rotated with little resistance through an angle of more than ninety degrees when connected with the pump, which stands to the right of the tank.

The Cailletet pump, together with its pressure gage, was one of those used in the numerous investigations on compressibility by T. W. Richards and others, and was kindly loaned to the writer for the purpose of the work here presented. The calibration of the gage is fully described in a recent article<sup>1</sup> on the "Compressibilities of Certain Hydrocarbons, Esters, Amines and Organic Halides," and is therein designated as Gage A.

The charging of the bomb is effected as follows:

The upper screw plugs P and K are removed and the apparatus—thoroughly cleaned and dried on the inside—is rotated so that the reaction chamber is in a vertical position and clean mercury is poured in to a depth of about 3 cm., after which the chamber is filled nearly to the top with saturated solution together with a suitable excess of the solid solute. The screw plug P, bearing

Fig. 2.

Fig. 3.

the discs, outlet valve, etc., is then inserted with the valve closed and screwed down until mercury appears in the right-hand or mercury chamber. A further amount of mercury is then added, sufficient to half fill the mercury chamber, and the screw-plug P tightly screwed down with a wrench. The outlet valve R is now opened sufficiently to allow a few drops of the solution to escape and insure the expulsion of any air which may have been enclosed, whereupon the valve is tightly closed.

The apparatus is next rotated to the right to allow the mercury chamber to stand vertical and mercury is added to within a centimeter of the shoulder D.

Above the mercury is added a layer of the pump liquid (castor oil was employed in the measurements to be described) to a height about where the screw threads begin. The screw-plug K bearing the short piece of steel capillary E, with its discs and washer, is now inserted in the mercury chamber and screwed down tightly. This forces oil up the capillary and causes it to fill and overflow the conical cavity in the lower

coupling piece.

The upper coupling piece is then held above the lower one and oil from

<sup>1</sup> Richards, Stull, Matthews and Speyers, *THIS JOURNAL*, 34, 972 (1912).

the pump is forced through the long copper capillary and out of the conical tip, whereupon the coupling ring is tightly screwed down. Pressure is now applied from the pump in order to test for leaks and the joints further tightened if necessary.

The apparatus is again rotated to the right so as to place the reaction chamber in a horizontal position. The outlet tube L, made from the steel capillary tubing, is unscrewed, rinsed and dried, replaced and closed at the end by means of a piece of rubber tubing, plugged with a piece of glass rod. This is to prevent the entrance of water from the bath when the apparatus is submerged.

The mercury in the reaction chamber is caused to flow back and forth by means of a simple tilting mechanism. A pulley wheel is placed above the lower end of the horizontal reaction chamber and connected eccentrically with the latter through a brass strip which functions in the manner of a driving rod.

The pulley is so geared that the tilting occurs about every six seconds.

In the following measurements the thermal regulation and the stirring of the bath were connected in the manner described by T. W. Richards.<sup>1</sup>

The regulator was adjusted to  $25^{\circ}$ , measured by means of a Reichsanstalt thermometer graduated in twentieths of degrees, of which the corrections were given to hundredths of degrees. By the use of a reading-lens readings accurate to this fraction could be readily made. A Beckman thermometer graduated in hundredths showed, during all the measurements made, which extended over some seventy hours, a fluctuation of two to three thousandths of a degree.

This excellent constancy is doubtless to be attributed to the use of the hydrogen generator which kept the mercury-platinum contact in an atmosphere of this gas and to the vigorous stirring which was employed.

The first system investigated was sodium chloride and water. This was done with a view to trying out the apparatus and also in order to obtain a comparison with the results obtained by Cohen, Euwen and Inouye.

C. P. sodium chloride was reprecipitated from a saturated water solution by means of HCl gas generated from C. P. acid by the addition from a dropping funnel of C. P. sulfuric acid. The precipitated salt was washed several times by decanting with small amounts of water, dried and heated for an hour at  $350^{\circ}$ . A solution containing about a gram of this product remained colorless on addition of phenolphthalein and turned pink on the addition of one drop of 0.05 *N* sodium hydroxide solution.

The bomb was charged in the manner described and the tilting mechanism set in operation.

In Expt. 1 no pressure was applied from the pump. The tilting was con-

<sup>1</sup> Stähler, "Handbuch der Arbeitsmethoden in der anorganischen Chemie," III,

tinued for two hours and the first sample withdrawn, after which the apparatus was tilted for an additional hour and the second sample taken. The identity in the analytical results on the two samples indicates that saturation was complete in the first case, hence in the following measurements on this system the tilting was suspended at the end of two hours.

In Experiments 2, 3 and 4, pressure was first applied to a point several kilograms beyond the final pressure desired. During the following two or three minutes the dissipation of the heat of compression caused the pressure indicated by the gage to slowly diminish.

When the gage reading had become practically constant the pressure was adjusted to the value given in the table and was maintained at this point throughout the experiment.

In Experiment 4, at 750 kg. pressure it was found that, owing to oil leakage at the pump connections, frequent manipulation of the pump was necessary in order to keep up the pressure. The measurements were, therefore, not carried beyond this point.

One of the samples from Expt. 4 became accidentally contaminated after its withdrawal and was not analyzed.

The procedure connected with the taking of the samples was as follows: After the tilting had been suspended the reaction chamber was placed in a vertical position and allowed to stand for fifteen minutes to permit the solid substance to settle. This step is probably not necessary since the slight loosening of the valve which permits the slow expulsion of the liquid would scarcely allow any solid particle to escape.

The bomb was next turned back to the position shown in Fig. 1. This left the end of the outlet tube sufficiently above the surface of the water in the bath to permit the attachment of the weighing bottle which was to receive the sample for analysis.

The outlet tube and the protective rubber tube were thoroughly dried with filter paper and the rubber tube removed.

The weighing bottle was provided, in addition to its glass stopper, with a flat one-hole rubber stopper about 1 cm. in thickness. This rubber stopper was slipped over the end of the outlet tube and the weighing bottle then pushed into the rubber stopper. By this means any loss by evaporation during the withdrawal of the sample was prevented.

The valve was now slightly loosened until the gage began to show a decrease in the pressure indicating the escape of liquid through the valve. The original pressure was at once restored by means of the pump and was kept up during the slow egress of the sample (about 20 drops per minute) into the weighing bottle. When 3-4 cc. of the solution had escaped the valve was tightened, the weighing bottle removed from the rubber stopper and its glass stopper at once inserted and the weighing made.

The analysis of the sample was effected without transferring from the

weighing bottle. The latter was placed in a tall beaker to protect it from the action of steam and the solution evaporated to dryness on the water bath, after which the residue was heated in an air bath for one hour at  $350^{\circ}$ , cooled in a desiccator, and weighed.

TABLE IV.—SOLUBILITY-PRESSURE DATA FOR SODIUM CHLORIDE AT  $25^{\circ}$ .

Expt. No.	Pressure kg. per sq. cm.	Wt. of sample.	% NaCl found.	% water.
1.....	1	4,100	26.44	73.56
	1	3,339	26.44	73.56
2.....	250	3,505	26.58	73.42
	250	3,408	26.58	73.42
3.....	500	3,629	26.76	73.24
	500	2,076	26.68	73.32
4.....	750	4,012	26.82	73.18

The divergence in the results of the analysis of the two samples for Expt. 3 cannot be accounted for.

If the average of the two values (26.72%) be taken, a smooth pressure-solubility curve results for the four points.

The accurate determinations by Andrea of the ordinary solubility (*i. e.*, at atmospheric pressure) of sodium chloride at different temperatures resulted in the values 26.37% and 26.53% for the temperatures  $20^{\circ}$  and  $30^{\circ}$ , respectively. A straight line interpolation for  $25^{\circ}$  gives the value 26.45%, which is one point higher than the result contained in Table IV. The temperature coefficient of solubility  $ds/dt$  calculated from Andrea's data is therefore 0.46/10 or 0.016%.

From the data of Table IV it is seen that an increase in pressure of 249 kg. alters the solubility by only 0.14%.

In both instances it is apparent that a slight variation in the analytical results will produce an immense effect on the ratios  $ds/dt$  and  $dp/ds$ . A satisfactory calculation of the relation  $dA/dt$  as the product  $ds/dt \cdot dp/ds$  ( $V_2 - V_1$ ) is therefore not possible for this substance.

In considering the choice of a solute for which complete thermodynamic data could be readily established, barium hydroxide suggested itself on account of its moderate solubility, its much larger temperature coefficient of solubility than that of NaCl, and the ease and accuracy of its analysis by titration.

Moreover, being an alkaline substance, there is no danger of contamination of the solution through action on the iron.

Data for the heat of solution were found and for the temperature coefficient of solubility and for the specific volume of the solid substance, but owing to the absence of data for the specific volume of its solutions from which the volume change  $V_2 - V_1$  could be calculated, it was not possible to estimate whether its pressure coefficient of solubility were large or small. Instead of first making the density determinations, the measurements with the pressure apparatus were carried out in the manner de-

scribed, except that the samples of solution withdrawn under pressure were titrated with 0.04 *N* hydrochloric acid carefully standardized against anhydrous sodium carbonate and with burets standardized by weight. The solution chamber was charged by preparing a hot solution of barium hydroxide of a concentration twice as great as that possessed by the saturated solution at twenty-five degrees. This hot solution was filtered (to remove carbonate) directly into the bomb and the screw-plug inserted. On cooling, the excess of solid solute separated. The material used was pure crystallized octohydrate and was not analyzed further.

The results are contained in Table V. The equilibrium for atmospheric pressure and for 250 kg. per sq. cm. (245 megabars)<sup>1</sup> was approached from both sides. In Expt. 1, hot water was added to the bath to bring it to a temperature of 30° and the bomb tilted for one-half hour. The bath temperature was then lowered to 25° (where it was maintained by the automatic regulation) and the bomb tilted for three hours at which time the sample was removed.

In Expt. 2 the bath was cooled to 20° and the bomb tilted for one-half hour, after which the temperature was raised to 25° and the tilting continued for three hours as before. The good agreement of the analyses shows that equilibrium was reached in both cases.

In Expts. 3 and 4 the same procedure was followed, except that the tilting at 25° was continued for 2 hours only. The difference in the analyses, although small, is somewhat beyond the probable analytical error and indicates that the tilting had not been quite long enough continued, hence in the subsequent calculation the average value, 8.791, is used.

In Expt. 5 the tilting was continued for 2.5 hours.

TABLE V.—SOLUBILITY OF  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$  AT 25° AND VARYING PRESSURES.

### The Heat of Solution.

The molar heat of solution of  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$  in large amounts of water has been determined by de Forcrand and by Thomsen<sup>2</sup> as  $-14500$  cal. and  $-15210$  cal., respectively. These values correspond to  $-46.0$  cal. and  $-48.2$  cal. per gram of solute. On account of this divergence and the fact that the heat of solution of substances at or near the saturation point may be very different from the values for dilute solutions, two deter-

<sup>1</sup> Megabar =  $10^6$  dynes = 1.02 kilograms per sq. cm.

<sup>2</sup> Landolt-Börnstein Tabellen.

minations were made, the first starting with a solution already 54% saturated and using an amount of solute such as to bring its concentration to 64% saturated. The second determination continued from the latter point and brought the solution to 74% saturated.

The measurements were made in a Richards "adiabatic calorimeter."

During the process of solution the lowering of the temperature within the calorimeter vessel was kept pace with by the addition of colder water to the outside vessel whose contents were kept rapidly stirred.

At no time did the thermometer readings inside and outside differ by more than one-hundredth of a degree.

The initial solution (No. 1) was prepared by diluting a saturated solution and filtering into the calorimeter vessel after which a sample was pipetted out for analysis.

Barium hydroxide (150 g.) was dissolved at 60° and filtered clear into a flask which was then stoppered and allowed to cool. The fine crystals of  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$  separating out were quickly filtered in four Gooch crucibles and then rotated rapidly in a centrifuge until no more liquid could be separated. The upper portion of the contents of each crucible, which doubtless contained some carbonate formed during the rotating, was removed with a spatula and the remainder shaken out onto three thicknesses of filter paper and folded up in the latter to form a flat package. This was pressed vigorously between more sheets of filter paper and the contents of the package then transferred to a stoppered bottle. By this means the formation of carbonate was reduced to a negligible amount, as is shown by the fact that a sample of the product, dissolved in previously boiled water, left but a scarcely perceptible turbidity.

A sample of this product was transferred to a weighing bottle, weighed and titrated, with the result that the preparation was found to contain 6% of saturated solution which the treatment with the centrifuge and the filter paper failed to remove.

For each of the two measurements 3 g. of this preparation were roughly weighed into a small thin glass bulb which was sealed and placed in the calorimeter vessel along with the solution. When all was in readiness the bulb was broken by means of a stirrer. The time required for complete solution as indicated by the stationary temperature was eight to ten minutes, moderate stirring being employed.

A sample was withdrawn from the calorimeter vessel by means of a 10 cc. pipet, weighed and titrated. From the result of this titration the total increase in the octohydrate content of the solution was computed. From this amount was deducted the weight of octohydrate in the 6% of saturated solution which had been present in the sealed bulb and which had had no appreciable thermal effect. This correction amounts to  $6\% \times 8.3\% = 0.5\%$ .

The remainder gives the amount of solid octohydrate which had actually passed into solution during the calorimeter measurement.

These figures are contained in the fifth column of the following table:

TABLE V.

Solution No.	% hydrate.	Degree of saturation.	Grams of sol. used.	Grams solid hydrate dissolved.	Temperature change
1.....	4.502	54%	360	2.948	—0.381°
2.....	5.280	64%	352	3.228	—0.437°
3.....	6.155	74%	...	.....	.....

The heat of solution per gram of solid hydrate added in bringing a 54% saturated solution to 64% saturation as calculated from these data is 48.3 calories and in bringing the latter solution to 74% saturation, 49.1 calories, account being taken of the heat capacity (10 cal.) of the calorimeter, stirrer, glass fragments, etc. A straight-line extrapolation gives the value 51.2 cal. for the heat of solution at the saturation point.

The heat capacity of the solutions may vary from that of water by 1-2%, but in the absence of any data no account could be taken of this possible difference.

#### The Volume Change.

A simple and accurate means of determining the volume change was suggested by the observations made in the course of the previous work that barium hydroxide solutions could be easily kept at a high degree of supersaturation. From this fact it appeared that a dilatometer measurement in which a supersaturated solution of known composition should be precipitated by inoculation would yield the desired value.

The successful use of mercury as a stirrer in the pressure-solubility experiments led to its adoption for the same purpose in hastening the approach to equilibrium in the dilatometer.

Fifty cc. of mercury were placed in a three and one-half liter round-bottomed flask whose neck was constricted at the opening to such a diameter as would accommodate a No. 1 one-hole rubber stopper. Through the stopper passed a glass tube of 5 mm. bore graduated in tenths of cubic centimeters. As the graduation marks were about six millimeters apart, hundredths of cubic centimeters could be readily calculated.

The octohydrate (400 g.) was dissolved in four liters of water by heating and the warm solution filtered into a four-liter flask which was stoppered and placed in the thermostat of 25° for several hours. The solution, which was calculated to be about 10% supersaturated at this temperature, remained perfectly clear. A sample (about 10 cc.) was pipetted out, weighed, and titrated and found to contain 9.199% of octohydrate.

The dilatometer flask containing the mercury, together with the rubber stopper and graduated tube, were counterpoised on a balance and the flask filled to the top with the supersaturated solution.

The rubber stopper was now inserted, causing a little of the solution to be expelled through the hole. The volumetric tube was then pushed through the stopper, the displacement of the liquid by the tube thereby raising the level to a convenient point on the scale.

The whole apparatus was weighed and found to contain 3540 g. of solution.

A small soda-lime tube was attached to the upper end of the volumetric tube and the flask immersed in the thermostat bath for half a day. During the last two hours of this period readings of the level in the tube were made and after each reading the mercury was swirled about in the flask.

The meniscus reading remained unchanged during the two hours and the solution entirely clear.

A minute particle of solid octohydrate about one-half millimeter in diameter was taken with a forceps and dropped down the tube and was seen to fall through the solution and rest on the bright mercury surface at the bottom of the flask. Flakes of octohydrate soon began to appear and the solution level to rise in the graduated tube. The process was hastened by agitating the mercury every few minutes.

At the end of six hours a large deposit of octohydrate had separated and an increase in volume of 1.28 cc. had taken place. No further rise in the meniscus level could be observed after an additional half hour.

Since the stirring had been only for a few seconds at intervals of from three to six minutes instead of being continuous as in the pressure-bomb experiments, it was not to be supposed that complete equilibrium had been established. The fact that no measurable increase in volume had occurred during half an hour indicated, however, that a sample of the solution could be safely removed for analysis.

The stopper and tube were accordingly removed and a sample drawn into a 10 cc. pipet, transferred to a weighing bottle, and weighed.

Although the solid octohydrate settles quickly, leaving the solution clear, the precaution was taken of attaching to the pipet a 5 cm. piece of glass tubing, constricted in the middle and packed below the constriction with a plug of cotton.

The titration analysis of the sample showed 8.487% of  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ .

The total of the solid phase which had separated was accordingly

$$3540(0.09199 - 0.08487) = 25.205 \text{ grams,}$$

$$\text{and the specific volume change } (V_2 - V_1) \text{ was } \frac{1.28}{25.205} = 0.0508.$$

#### The Temperature Coefficient of Solubility.

This value was calculated from the solubility data of Rosenstühl and Rühlmann.<sup>1</sup> This table gives the percentage of BaO in the saturated

<sup>1</sup> Taken from the Landolt-Börnstein tables, 1912, p. 459.

solution for temperatures at intervals of  $10^{\circ}$ . The following table shows these values and equivalent values for  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ :

	BaO.	$\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ .
$10^{\circ}$	2.17%	4.46%
$20^{\circ}$	3.36%	6.91%
$30^{\circ}$	4.75%	9.77%
$40^{\circ}$	6.85%	14.09%

When these four points are plotted and a smooth curve drawn, the curve-reading for the solubility at  $25^{\circ}$  is 8.30%, agreeing with the value obtained by direct measurement (Table V).

Hence the Rosenstühl-Rühlmann data may serve as a basis for the calculation,

$$\frac{ds}{dt} = \frac{9.77\% - 6.91\%}{10^{\circ}} = 0.288\%.$$

The application of the complete data to the equation

$$T \frac{(p_2 - p_1)(v_2 - v_1)}{t_2 - t_1} = Q$$

gives for the left-hand side

$$298 \times 0.288 \times \frac{244}{0.491} \times 10^6 \times 0.0508 = 2.16 \times 10^9$$

and for the right-hand side

$$51.2 \times 4.189 \times 10^7 = 2.14 \times 10^9.$$

The agreement is seen to be excellent.

The writer wishes to acknowledge his thanks to Prof. T. W. Richards, of Harvard University, for valuable advice and assistance in the devising of the pressure bomb employed in this investigation. This apparatus is owned by the Carnegie Institution of Washington and is now being used for other work under the auspices of the Institution.

## STUDIES ON THE COBALTAMMINES. I.

### VARIOUS IONIZATION TYPES AS DETERMINED BY THE FREEZING-POINT LOWERING IN AQUEOUS SOLUTION, TOGETHER WITH CONDUCTANCE MEASUREMENTS.<sup>1</sup>

BY WILLIAM D. HARKINS, R. E. HALL AND W. A. ROBERTS.

Received August 14, 1916.

The present investigation was undertaken as a starting point in the study of the structure of the cobaltammines. The first point necessary

<sup>1</sup> The temperature readings were taken to one-twenty thousandth of a degree by means of a 50 couple thermoelement, and a double combination potentiometer specially designed for this work by Dr. W. P. White, and we wish to express our indebtedness to him for this aid.

to establish was the type of salt for the different groups under which the cobaltammines may be classified, *i. e.*, the number of ions which they give in aqueous solution. That it is essential that such an investigation should be undertaken, is indicated by the great divergence, amounting to 100% or more, between the results of various investigators in this field, such as that which exists between the results on freezing-point lowering as obtained by E. Petersen<sup>1</sup> and by Werner and Herty,<sup>2</sup> and by the discrepancies which exist between the various results obtained by any one individual investigator.

Petersen criticized the empirical conductivity comparison method employed by Werner for determining the number of ions from his conductivity data, and proposed, by substituting for  $\gamma$  in the Equation  $i = 1 + (n - 1)\gamma$ , the value obtained for it from the conductivity ratio  $\lambda/\lambda_0$ , to determine  $n$  by giving it different integral values (1, 2, 3, etc.), and finding which one would fit for the value of  $i$ , determined from freezing-point depressions. This work was done during the latter part of the controversy between Werner and Jørgensen, and the materials for it were furnished by the latter. Petersen used as his  $\lambda_0$  merely the value of  $\lambda$  derived from his conductivity measurements at the lowest concentration used (1 mol of salt to 3200 liters of water), and did not extrapolate his results to obtain the real  $\lambda_0$ . With the exception of some three of the salts, he was unfortunate, too, in his choice of compounds, as he used substances which hydrolyze quite readily, and were therefore of little value in determining the point in question. About four years later, Werner and Herty replied to Petersen, severely criticizing his work, and gave freezing-point data on a few salts. Table I summarizes the results on the only salt on which both Petersen and Werner and Herty give freezing-point data.

TABLE I.—SUMMARY OF PETERSEN'S AND WERNER AND HERTY'S FREEZING-POINT DATA ON CROCEO COBALTAMMINE.

Petersen. Dinitrotetrammine cobalt nitrate.				Werner and Herty. Dinitrotetrammine cobalt chloride.			
Conc. N <sup>3</sup> X 10 <sup>3</sup> .	Depression, $\Delta t$ .	$\Delta t/N$	$i$ .	Conc. N X 10 <sup>3</sup> .	Depression, $\Delta t$ .	$\Delta t/N$ .	$i$ .
5.0	0.030	6.00	3.23	4.35	0.015	3.45	1.74
10.0	0.058	5.80	3.12	4.72	0.017	3.60	1.82

While their results on conductivity were in fair agreement, the disparity in the freezing-point measurements was so great that Werner's criticisms on Petersen's method, suggesting, as the cause for the difference, an error in determining the real zero on his Beckmann thermometer because of solubility of the freezing-point vessel in the water, can really

<sup>1</sup> *Z. physik. Chem.*, **22**, 310 (1897); *Ibid.*, **39**, 249 (1902).

<sup>2</sup> *Ibid.*, **38**, 331 (1901).

<sup>3</sup> N represents the equivalent concentration per 1000 g. of water and  $\Delta t$  the lowering of the freezing point.

serve as no explanation at all. He very justly pointed to the fact that, owing to the small solubility of the salts, the difficulties encountered in freezing-point determinations would lead to uncertain conclusions. When it is considered that the limit of accuracy of the ordinary Beckmann thermometer is  $0.001^{\circ}$ —and the ordinary Beckmann apparatus was evidently used by both Werner and Petersen—and notes the temperature depressions recorded in Table I, it is not difficult to account for a difference of 5–10% in their measurements. But the disparity amounts to almost 100%—great enough so that while Werner interpreted the croceo salt as one giving two ions in aqueous solution, Petersen designated it a tetraionic salt.

The method of determining freezing-point lowerings by the use of a fifty junction copper-constantan thermoelement<sup>1</sup> can be applied with accuracy to low concentrations of solution, and the use of the interferometer for analysis, while interfered with by the color of the cobalt-ammines, permits the determination of the concentration of the equilibrium mixture of these complex salts. We therefore decided to determine the freezing-point lowerings of a few of them, choosing for our work those which showed the least tendency to instability in aqueous solution. The well-known series described by Werner<sup>2</sup> meets this requirement very well, and includes salts of the different types of ionization.

We therefore prepared the following salts:

Hexammine (luteo) cobalt chloride.....	$\text{Co}(\text{NH}_3)_6\text{Cl}_3$
Nitropentammine (xantho) cobalt chloride.....	$(\text{NO}_2)\text{Co}(\text{NH}_3)_5\text{Cl}_2$
Chloropentammine (purpureo) cobalt chloride.....	$\text{ClCo}(\text{NH}_3)_5\text{Cl}_2$
Dinitrotetrammine (croceo) cobalt chloride.....	$(\text{NO}_2)_2\text{Co}(\text{NH}_3)_4\text{Cl}$
Dinitrotetrammine (flavo) cobalt nitrate.....	$(\text{NO}_2)_2\text{Co}(\text{NH}_3)_4\text{NO}_3$
Trinitrotri­ammine cobalt.....	$(\text{NO}_2)_3\text{Co}(\text{NH}_3)_3$
Potassium tetranitrodiammine cobaltate (Erdmann's salt).....	$(\text{NO}_2)_4\text{Co}(\text{NH}_3)_2\text{K}$
Ammonium tetranitrodiammine cobaltate.....	$(\text{NO}_2)_4\text{Co}(\text{NH}_3)_2\text{NH}_4$
Sodium cobaltic nitrite.....	$(\text{NO}_2)_6\text{CoNa}_3$

While some of the salts of this series are rather unstable and hydrolyze readily at higher temperatures, at zero degrees no trouble was experienced, except with dinitrotetrammine cobalt chloride, and with this only on exposure to bright light, and with sodium cobaltic nitrite. To dispense with any error from hydrolysis, all analyses of the equilibrium mixtures were made on the same day as, and immediately following, the determination of the freezing-point lowerings. Only rather limited data on these salts could be obtained, owing to their slight solubility. However, determinations could be made at a sufficient number of concentrations to

plot the curve for  $\Delta t/N$  against a function of the concentration, and to permit comparison of this with the curve of some simple salt.

### Preparation of the Salts.

**Chloropentammine Cobaltic Chloride**,  $[\text{Co}(\text{NH}_3)_5\text{Cl}]\text{Cl}$ , was prepared by Sørensen's method.<sup>1</sup> 20 g. of cobalt carbonate were dissolved in the least amount of 1:1 HCl possible. The filtered and cooled solution was added to a mixture of 250 cc. of concentrated ammonia solution and 50 g. of  $(\text{NH}_4)_2\text{CO}_3$  dissolved in 250 cc. of water. This was then put in a large flask and a rapid stream of air passed through it for three hours. 150 grams of  $\text{NH}_4\text{Cl}$  were added and the solution evaporated on a water bath until it became a crystal pulp. The  $(\text{NH}_4)_2\text{CO}_3$  was decomposed by HCl and the solution made alkaline by the addition of 10 cc. excess  $\text{NH}_4\text{OH}$ . Complete precipitation of the salt was accomplished by the addition of 300 cc. of concentrated HCl. After heating on the water bath for an hour to decompose any aquopentammine the salt was collected on a filter and washed with dilute HCl.

For purification the salt was dissolved in a weak solution of ammonia by heating on a water bath. It was precipitated by concentrated HCl heated on the water bath and filtered. This process was repeated four times. After final washing with dilute HCl, redistilled alcohol and ether it was dried in a desiccator and heated to constant weight at forty degrees in an air bath. Scarcely any loss of weight occurred during the heating. An analysis was made by treating a sample with  $\text{H}_2\text{SO}_4$  and weighing as  $\text{CoSO}_4$ , and gave 0.2113 g. of  $\text{CoSO}_4$ . The amount calculated from the formula was 0.2115.

**Hexammine Cobaltic Chloride**,  $\text{Co}(\text{NH}_3)_6\text{Cl}_2$ , was prepared by Jörgensen's method.<sup>2</sup> 10 grams of chloropentammine cobaltic chloride, 100 cc. of 20% ammonia and 8 grams  $\text{NH}_4\text{Cl}$  were placed in a pressure flask which held about 110 cc. The flask was put in a water bath and heated with shaking every hour until no trace of the pentammine could be seen. This required on the average about five hours. After cooling the contents of the flask were poured into an open vessel and the ammonia removed by suction in a vacuum desiccator. The flask contained mostly hexammine with a little chloropentammine and aquopentammine. When the ammonia had been removed, the mixture was diluted to 300 cc. and 50 cc. concentrated HCl were added. It was heated on the water bath for an hour, 0.5 of its volume of concentrated HCl was then added, and the solution cooled and filtered. For purification the hexammine, which is rather soluble in water, was removed from the pentammine by extracting with cold water. The reprecipitation was carried out as above. It was washed and dried in the same way as the pentammine.

**Nitropentammine Cobaltic Chloride**,  $[\text{Co}(\text{NH}_3)_5\text{NO}_2]\text{Cl}_2$ , was prepared as recommended by Jörgensen. 20 grams of chloropentammine cobaltic chloride were dissolved in 200 cc.  $\text{H}_2\text{O}$  and 50 cc. of 10% ammonia on the water bath. The solution was filtered, acidified with HCl and then heated for some time with 25 grams  $\text{NaNO}_2$ . Complete precipitation was accomplished by the addition of 250 cc. concentrated HCl. It was filtered, washed many times with dilute HCl, alcohol and ether and then dried.

**Dinitrotetrammine (croceo) Cobalt Chloride**.—The method recommended by Jörgensen<sup>2</sup> was followed. Cobalt carbonate was dissolved in the requisite amount of hydrochloric acid; ammonium chloride, sodium nitrite, and ammonium hydroxide were added, and air was drawn through the solution for several hours. The precipitated salt was separated on a Hirsch funnel, and washed repeatedly to remove the small quantities of xantho chloride contaminating it, until no test for the xantho salt was

<sup>1</sup> *Z. anorg. Chem.*, **5**, 369 (1894).

<sup>2</sup> *Ibid.*, **17**, 455 (1898).

given by ammonium oxalate. To convert this mixture of croceo chloride and nitrate to the pure chloride, it was dissolved in water weakly acidified with acetic acid, and a large amount of ammonium chloride was added; the solution was cooled, and allowed to stand for a few hours. The salt which separated was washed thoroughly first with water, and finally with 90% alcohol. It was dried, and recrystallized from water very weakly acidified with acetic acid. Although Jörgensen recommends recrystallization without acid, it was found impossible to do this without some hydrolysis, and the consequent precipitation of a varying amount of an oxide of cobalt. 150 g. of the pure salt were prepared. The air-dry salt was brought to constant weight at 80°.

**Dinitrotetrammine (flavo) Cobalt Nitrate.**<sup>1</sup>—The first preparation was carbonato-tetrammine cobalt sulfate,<sup>2</sup> which was made by dissolving cobalt carbonate in the requisite amount of sulfuric acid, adding ammonium carbonate and ammonium hydroxide, oxidizing by drawing air through the solution for a few hours, concentrating on the water bath with frequent addition of a little ammonium carbonate, cooling to 0°, and filtering on a platinum cone. This material was then converted into the flavo salt by dissolving in dilute nitric acid, adding sodium nitrite, heating on the water bath for a few minutes, cooling, and leaving in the ice chest for several hours. The acid flavo nitrate which separated was washed with dilute nitric acid, and changed to the neutral salt by further washing with alcohol to neutral reaction. The salt was recrystallized from hot water, very weakly acidified with acetic acid, and was separated on a platinum cone. 140 g. of the pure salt were prepared. The air-dry salt was brought to constant weight at 50°.

**Trinitrotetrammine Cobalt.**<sup>3</sup>—Cobalt carbonate was dissolved in just the requisite amount of hydrochloric acid, and the solution was poured into a solution containing ammonium chloride, sodium nitrite, and ammonium hydroxide. The cobalt was oxidized by drawing air through the mixture for a few hours. After standing for a week in open dishes, the solution had lost its odor of ammonia and had decreased in volume by half. The solid material which had separated consisted of a yellow slime and dark brown crystals. To remove all traces of chloride, repeated washing was necessary, and it was found expedient to do this by decantation, as the crystals were practically chloride-free. This salt was finally dissolved in boiling water containing a little acetic acid, and crystallized by cooling to 0°. The air-dry salt was brought to constant weight at 80°. An analysis for cobalt showed 23.76%; theoretical, 23.77%.

**Potassium Tetranitrodiammine Cobaltate.**<sup>4</sup>—Cobalt carbonate was converted into the chloride, ammonium chloride was dissolved in the solution, the mixture heated to 50°, and a very concentrated solution of potassium nitrite at the same temperature added. The temperature was maintained at 50° for half an hour. After some hours, a fine yellow powder and dark brown crystals had separated from the solution. Most of the powder was removed by decanting off the original solution, and washing the crystals with cold water in the same manner; the remainder, by dissolving the crystals in hot water, and filtering off the practically insoluble powder. The salt obtained on cooling the solution was recrystallized from pure water, and brought to constant weight at 50°. An analysis for cobalt showed 18.61%; theoretical, 18.65%.

**Ammonium Tetranitrodiammine Cobaltate.**—The procedure was similar to that used in the preparation of the preceding salt, with the exception that sodium nitrite was used in place of potassium nitrite. An analysis for cobalt showed 20.16%; theoretical, 19.98%.

<sup>1</sup> *Z. anorg. Chem.*, **17**, 455 (1898).

<sup>2</sup> *Ibid.*, **2**, 282 (1892).

<sup>3</sup> Jörgensen, *Loc. cit.*

<sup>4</sup> *J. prakt. Chem.*, [2] **23**, 249 (1881).

**Sodium Cobalt Nitrite.**<sup>1</sup>—The method recommended by Biltz was followed in this preparation. The air-dry salt was brought to constant weight at 50°. An analysis made by weighing the sodium and cobalt as sulfates showed for the cobalt 14.03%. This salt is described in the literature<sup>2</sup> as one of varying amounts of water of hydration. On the basis of the formula  $(\text{NO}_2)_6\text{CoNa}_3$ , the theoretical percentage of cobalt is 14.60; for  $(\text{NO}_2)_6\text{CoNa}_3 \cdot \text{H}_2\text{O}$ , 13.97. The freezing-point data were figured on the basis of the latter formula. However, the difference in values obtained, using one formula or the other, is of little significance, as the decomposability of the salt in aqueous solutions renders any determination at best merely an approximation.

### Freezing-Point Data.

The method followed in this work was the same as will be described in a later paper. On account of the color of the solutions, the analysis with the interferometer proved rather troublesome, and probably a

Fig. 1.—Values of  $\Delta t/N$  for the freezing-point lowerings of hexamine (luteo) cobalt chloride and of lanthanum nitrate.

method based on conductivity measurements would be even more satisfactory. The difficulties experienced in the analysis account largely for the slight irregularities of the individual points on the curves as plotted. All data are calculated on the basis of weight normality.

**Hexamine Cobalt Chloride.**—This is one of the most stable salts of the series. Table II comprises the data on this salt, and the values obtained by Werner. Table III includes our data at rounded concentrations, the corresponding  $i$  values for lanthanum nitrate, and the apparent ionization as obtained from the

<sup>1</sup> Biltz, "Laboratory Methods of Inorganic Chemistry," 1909, p. 149.

<sup>2</sup> Moissan, *Chim. Minerale*, 4, 206 (1905), and the references listed.

conductivity measurements of Roberts at  $0^{\circ}$ . The latter are calculated on the basis of volume normality; but the concentrations are small enough so that very little change would be made by recalculating on the basis of weight normality. Fig. 1 shows the curve of  $\Delta t/N$  plotted against the logarithm of the concentration, and the corresponding curve for lanthanum nitrate. Fig. 2 plots our values on a smaller scale, in order to include Werner and Herty's data. The freezing-point lowerings, are smaller throughout than those shown by lanthanum nitrate. However, the agreement is such as to leave no doubt that the

**Nitropentammine and Chloropentammine Cobalt Chloride.**—Fig 3 shows the curves for these salts in relation to the curve of cobalt chloride. It will be seen that they are very much steeper over the range possible to investigate than that of the cobalt chloride. The points taken by Werner and Herty on the xantho salt are also plotted. Table IV collects our data, and that of Werner and Herty; Table V includes the data at rounded concentrations, the *i* values of cobalt chloride, and the ionization values determined by Roberts' conductivity measurements at 0°. The salts, especially the purpureo, show high ionization values. Evidently they are quite comparable to cobalt chloride, and are therefore of the three ion type.

**Dinitrotetrammine Cobalt Salts. Croceo Chloride and Flavo Nitrate.**—Fig. 4 plots the curves of these salts, shows the points determined by Werner and Herty, and gives also the curve for potassium iodate, as a representative di-ionic salt. The difference in the slope of the curves for the croceo and flavo salts is only slightly greater than that between potassium chloride and potassium nitrate (Fig. 5 of the following paper).

<sup>1</sup> The data given by Werner and Herty, *Z. physik. Chem.*, 38, 352 (1901), have been recalculated on the basis of 1.858 for the molal lowering.

Fig. 3.—Values of  $\Delta t/N$  for nitropentammine (xantho) cobalt chloride and chloropentammine (purpureo) cobalt chloride. The black circles give the results of Werner and Herty.

Fig. 4.—Values of  $\Delta t/N$  from the freezing-point lowerings of dinitrotetrammine (croceo) cobalt chloride, dinitrotetrammine (flavo) cobalt nitrate, two isomeric compounds, and of potassium and ammonium tetranitrodiammine cobaltates, a series of univalent salts. The black circles give the values of Werner and Herty. The bottom line in each of these four plots represents a value of 3.30 for  $\Delta t/N$ .

**Croceo and Flavo Salts.**—These interesting isomeric inorganic salts are evidently di-ionic, and correspond very closely to the ordinary di-ionic salts in their freezing-point lowerings.

**Trinitrotri-amine Cobalt.**—The insolubility of this salt renders accurate freezing-point determinations very difficult. The greatest temperature depression noted, as shown in Table VIII, was a little more than  $0.005^\circ$ . This, in conjunction with the difficulty of analyzing the equilibrium mixture, as mentioned above, serves to explain the discrepancies in the  $i$  values given in the table. It is interesting to note that this is the only case in which our values are in agreement with those of Petersen. So far as can be shown by freezing-point measurements, the salt is a non-electrolyte.

**Sodium Cobaltic Nitrite.**—The instability of this salt in aqueous solution rendered any accurate determination of the freezing-point depression an impossibility. The salt was dissolved and introduced into the freezing-point jars as quickly as possible, and the temperature depression noted as soon as equilibrium was attained. With the introduction of the salt, the temperature fell rapidly for a short time, and from then on, slowly

but continuously. The attainment of equilibrium evidently occurred when this slow change commenced, and the temperature reading was taken at this point. The concentration of the freezing-point mixture was controlled by a gravimetric determination of the cobalt and sodium as sulfates. The  $i$  values indicate that the salt is tetra-ionic.

The values of the apparent ionizations of the cobaltammines, as determined by the conductivity and freezing-point methods, are nearly the same, with one exception, and that is in the case of the salt of highest type, hexammine cobaltic chloride, a tetra-ionic salt, which gives a value for the freezing-point lowering 1.2% higher at 0.005  $N$ , and 6.7% higher at 0.050  $N$ . These deviations are in the same direction as those found in this laboratory between the two sets of results for lanthanum nitrate, a salt of the same type. These are given in Table XII

TABLE XII.—VALUES OF THE APPARENT IONIZATION OF LANTHANUM NITRATE AS CALCULATED FROM FREEZING-POINT AND CONDUCTIVITY DATA.

Concn. in equivalents.	Apparent ionization.		Per cent. deviation.
	Conductivity.	Freezing point.	
0.005	85.83	88.9	3.58
0.01	81.77	85.4	4.44
0.05	69.91	75.4	7.86
0.1	64.38	71.6	11.21
0.2	58.51	68.8	14.46

With both of these tri-univalent salts the value of the apparent ionization calculated from the freezing-point results rapidly increases above that determined by conductivity as the concentration of the solution increases. This suggests that the cause of this change is to be sought in some factor which rapidly increases in value with the concentration of the solution. This result is very different from that which is found in the case of salts of simpler types, so even after making allowance for the fact that the freezing-point result depends upon the activity of the constituents of the salt, and the conductivity upon the number and speed of the ions, it still seems as though a large part of the deviation remains to be explained. It is interesting that this deviation is in the direction which would be predicted from the intermediate ion hypothesis as advanced by Harkins.<sup>1</sup>

#### Conductivity Measurements (by W. A. ROBERTS).

None of the salts whose conductivity was measured showed appreciable decomposition at 0° with the exception of trinitrotri-amine. At 25°

<sup>1</sup> See the fourth paper in this number of THIS JOURNAL.

all with the exception of the hexammine showed some change, but not enough to be considered in the time taken for measurement.

The cells used were the type devised by Kraus and used by Noyes, Melcher, Washburn and others. The cell used for the more concentrated solutions had a constant of 4.745 at  $0^\circ$ , and the one used for the more dilute solutions had a constant of 0.09710 at  $0^\circ$ . The conductivity of  $N/50$  KCl was taken as  $1.521 \times 10^{-3}$ .

For the calculation of the equivalent conductivities the hexammine was considered to have four, the pentammines three, and the tetrammines two ions, as determined by the freezing-point measurements. The value of  $\Lambda_0$  was found by plotting  $1/\Lambda$  against  $(CA)^{n-1}$ . The range of  $(n-1)$  was found to be from 0.4 to 0.8.

Measurements were begun upon sodium cobalt nitrite, but such rapid decomposition took place that the data were not recorded. Trinitro-triammine which is supposed by Werner not to be ionized showed the following molecular conductivities which are only about 1/20,000 that of the di-ionic croceo and flavo salts:

**Summary.**—The freezing-point lowerings of nine cobaltammines of different types have been determined. These salts, with the exception

of sodium cobaltic nitrite, were prepared by methods proposed by Jørgensen. On the whole, the results obtained from the freezing-point measurements, correspond very closely with those given by simple salts of like ionic types. Our results show that the type of each salt is the same as that assumed by Werner and his co-workers, but on the other hand they do not agree well with Werner's own freezing-point measurements. No explanation can be offered for the erroneous results given by Petersen's work, other than that his thermometric measurements must have been approximately 100% in error, except in the work on triamminotritinitro cobalt.

Conductance measurements have also been made on the same series of cobaltamines.

In conclusion, we wish to thank L. H. Adams and John Johnston of the Geophysical Laboratory in Washington, for the loan of the freezing-point apparatus and the interferometer, and to express our indebtedness for a grant of two hundred dollars from the Wolcott Gibbs Fund of the National Academy of Sciences.

CHICAGO, ILL.

[CONTRIBUTIONS FROM THE KENT CHEMICAL LABORATORY OF THE UNIVERSITY OF CHICAGO.]

## THE FREE ENERGY OF DILUTION AND THE FREEZING-POINT LOWERINGS IN SOLUTIONS OF SOME SALTS OF VARIOUS TYPES OF IONIZATION, AND OF SALT MIXTURES.

BY RALPH E. HALL AND WILLIAM D. HARKINS.<sup>1</sup>

Received September 1, 1916.

### I. Experimental.

The experimental work outlined in this paper was begun for the purpose of obtaining accurate freezing-point data from which the free energy of dilutions of dilute salt solutions can be determined. It seemed particularly desirable that accurate measurements should be carried out on higher type salts, in order that the results for salts of different types might be compared. It was found, too, that, while it is well known how mixtures of common ion salts in aqueous solution behave with respect to the conductivity of the separate salts, there are no similar data for the freezing-point lowerings of mixtures. This paper gives data for the freezing-point lowerings of uni-univalent, uni-bivalent, uni-trivalent, and bi-bivalent salts, and for mixtures containing two uni-univalent salts.

<sup>1</sup> This paper forms the basis for a part of a dissertation presented to the University of Chicago by Ralph E. Hall in part fulfilment of the requirements for the degree of Doctor of Philosophy.

The work of Adams<sup>1</sup> on freezing-point lowerings has given a simple method for investigations of this type, even in quite dilute solutions, and one which in general is probably the most accurate. The introduction of vacuum jars for containing the equilibrium mixture and the ice-water reference zero, in place of the beakers or platinum vessels used by previous investigators in this field, the use of a differential temperature measuring device, and the application of the Zeiss interferometer to the analysis of the equilibrium solutions, have made the attainment of accuracy in measurements at comparatively high dilutions a relatively simple matter. Adams' data cover only solutions of the nonelectrolyte mannite, and the salts potassium chloride and potassium nitrate. The present investigation extends the method, with slight changes, to salts of various types of ionization, and to equimolar mixtures of di-ionic salts, in which the known freezing-point data agree closely with those derived from conductivity measurements as regards the apparent degree of ionization.

#### The Apparatus.

**Thermoelement.**—A copper constantan element of fifty junctions was used.<sup>2</sup> In its construction, No. 36 copper wire, and No. 30 constantan wire, both double silk insulated, were used. The constantan wire was tested carefully for inhomogeneities<sup>3</sup> and any parts evidencing them were removed. The soldering of the couples, and the assembling of the element were done as recommended by Adams. The junctions, thoroughly insulated by waterproof varnish, and bound together in a small cone, were encased in glass tubing, and surrounded by naphthalene, the latter extending a little more than half the length of the tube. To insure against short circuits between the couples, and between the halves of the element, the resistance was tested frequently throughout the construction, and always at the beginning and close of a series of determinations. The wire, where exposed, and in the glass tube above the naphthalene, were treated with melted paraffin; a reinforcing brass rod was inserted, and this and the exposed wires were wrapped with silk ribbon. The latter was varnished to prevent as far as possible any chance for moisture to decrease the internal resistance. The thermoelement when not in use should be kept in a closed vessel containing  $P_2O_5$ .

The element was calibrated against a twenty-four junction element made by White, which had been standardized at the Bureau of Standards. Comparisons were made in a thoroughly stirred kerosene bath, and these

<sup>1</sup> THIS JOURNAL, 37, 481 (1915).

<sup>2</sup> This element was made at the Geophysical Laboratory in Washington. We wish to make acknowledgment of the courtesy of Dr. Day in granting permission for this; and of the coöperation of Drs. Adams, White and Johnston in its construction. We are also indebted to them for the loan of their freezing-point apparatus and interferometer.

<sup>3</sup> W. P. White, THIS JOURNAL, 36, 2296 (1914); L. H. Adams, *Loc. cit.*, footnote.

readings used in determining the relation of microvolts to temperature for the element. The solution of the cubic equation  $E = At + Bt^2 + Ct^3$  gave

$$E = 1879.7t + 2.52t^2 - 0.0057t^3.$$

The following data show how closely observed and calculated readings agree:

TABLE I.—DATA TAKEN FOR DETERMINING THE EQUATION OF THE THERMOELEMENT, AND FOR TESTING ITS ACCURACY.

$t^\circ$ determined by standard White couple.	$\mu v$ observed.	$\mu v$ calculated by equation.	Difference.
9.760	18580.8 <sup>1</sup>	.....	...
14.785	28326.8	28323.8	3.0
15.778	30263.0 <sup>1</sup>	.....	...
23.350	45194.0	45192.4	1.6
23.525	45539.7	45539.4	0.3
32.291	63134.8 <sup>1</sup>	.....	...
35.364	69366.0	69370.3	-4.3

It will be noted that the greatest deviation of observed from calculated values is a little less than one part in nine thousand. The differential of the above equation gives the gradient in microvolts per degree. For temperature differences of  $0.1^\circ$  or less, all terms but the first may be neglected, *i. e.*, microvolts may be converted into degrees by multiplying by 0.0005320. The second term, however, must be used for larger differences, but the third was entirely negligible for our freezing-point measurements, in which the greatest lowering was  $2.2^\circ$ .

The above equation for the thermoelement was based entirely on temperatures above  $0^\circ$ . To obtain a calibration below  $0^\circ$ , the freezing-point depressions of the alcohols mannite and erythrite were determined for a number of concentrations, and the deviations of the observed temperature from the theoretical at low concentration, calculated on the basis of  $1.858^\circ$  for the molal lowering of water, were accepted as the corrections necessary to apply. Reference to Table II will show that the above equation gave depressions consistently  $0.0001^\circ$  too small both with mannite and with erythrite, up to concentrations of  $0.0606 N$  for the former and  $0.0230 N$  for the latter. In the solutions of greater concentration than this, there is an increasing divergence between observed and calculated values, and in the other direction, *i. e.*, in the direction which corresponds to hydration. The analysis of the solutions of mannite by the interferometer was accurate to  $0.00001 N$ , and to  $0.00002 N$  for those of erythrite. A correction of  $0.0001^\circ$  has been made, accordingly, on all temperature readings for low concentrations, where this amount would affect the  $\Delta t/N$  values.

**Galvanometer.**—A Weston galvanometer, Model 89, was used. This

<sup>1</sup> Used in calculating the equation.

instrument gave a sensibility of 1 mm. on the scale per microvolt at approximately a meter's distance, so that the estimation of  $0.1 \mu v$  was entirely certain.

**Potentiometer.**—A double combination potentiometer (the first of this type to be constructed), recommended by White,<sup>1</sup> and constructed by the Leeds & Northrup Company, was used. One of the great advantages of this instrument is that by means of compensating coils, the resistance in the galvanometer circuit, and consequently the sensibility of the galvanometer, is maintained constant, whatever the potentiometer reading. A false top of glass, blackened on one side, raised about an inch above the top of the potentiometer has served to protect the hard rubber from the effects of light, and to shield the connections from any sudden changes of temperature. The switches were made from double throw copper knife switches of the pattern suggested by White. They were removed from their fiber bases, and set on a single sheet of hard rubber which was protected from the action of light at all times except when the system was in use. All soldered connections were made thermally neutral according to the method suggested by Wenner. The Weston standard cell was calibrated by the Bureau of Standards, and its factor given as 1.018348. Constancy of temperature was assured by placing it in an asbestos-lined chamber. The whole system, including the freezing-point apparatus, was doubly shielded as recommended by White,<sup>2</sup> and practically no trouble has been experienced from leakage currents at any time. An eliminating switch took care of any chance thermal electromotive forces, or other parasitic effects.

Fig. 1 is a diagram of the potentiometer and switchboard, with the accompanying batteries, standard cell, galvanometer, and rheostats. The dials designated by P correspond to one potentiometer, those marked P' to the other. The switches have the following significance: A is a key in the cadmium cell circuit, and F the same in the galvanometer circuit. BB', CC', DD', connect to various thermoelements; BB', when making the connections of B', has been closed by a resistance of 230 ohms, as this was the resistance of our 50 junction element, and this connection facilitated checking the sensibility of the galvanometer. EE', when in the position E', connects into the system thermoelements BB' and CC', and potentiometer P'; in position E, connects in thermoelements DD' and potentiometer P. GG' is a key which permits very low electromotive forces to be read directly by the deflection of the galvanometer. In position G, the potentiometer is connected in; in position G', the potentiometer is cut out, and an equal resistance substituted for it. HH' and II' regulate the sensibility of the galvanometer; with the switches

<sup>1</sup> THIS JOURNAL, 36, 1874 (1914).

<sup>2</sup> *Loc. cit.*

thermocouples.  $KK'$ , in position  $K$ , connects the cadmium cell with the terminals of the 1018 ohm resistance in the potentiometer, which in conjunction with rheostat  $R$  regulates the current from storage battery  $BL$ ; in position  $K'$ , connects it with the terminals of the 10180 ohm resistance, which with rheostat  $R'$  regulates the current from battery  $B2$ .  $LL'$  is the eliminating switch. In position  $L'$ , the circuits are adjusted for regular determinations; in position  $L$ , the currents from the batteries no longer run through the dial resistances of the potentiometer, but only through the fixed resistances and that of their rheostats. Also, the thermoelement has been cut out, and a resistance equal to it (230 ohms in this case) has been substituted in its place. The galvanometer setting on zero is made with the switch in this position; and as the switch was thoroughly tested for thermoneutrality, this setting will cut out practically all parasitic  $E. M. Fs.$  in the potentiometer, galvanometer, and switch-board from the reading of the thermoelement, when the switch is in position  $L'$ .

#### Freezing-Point Apparatus.—

This was the same apparatus used by Adams,<sup>1</sup> and needs no further description.

#### Experimental Procedure.

The apparatus was set up as shown in Fig. 2, with the exception that ice filled the upper portions of the stirring compartments in the vacuum jars. In the earlier work, the regular artificial ice was used. It was broken on an iron grating with a wooden pestle, and suitable sized pieces were chosen from the top of the grating and washed thoroughly with pure water before being placed in the vacuum jars. This ice when melted and compared with pure water seldom gave a reading of more than 3 divisions on the interferometer, and usually less, although on one occasion a reading of 11 divisions was noted.

The results of this series of

Fig. 2.—Cross-section of freezing-point apparatus.—Courtesy of L. H. Adams.

<sup>1</sup> *Loc. cit.*

freezing-point determinations were discarded, except for the more concentrated solutions, where the error involved became negligible. It was thought best, finally, to make ice from the laboratory distilled water, and thus avoid any chance of error from this source. A covered nickel-plated copper vessel,  $2 \times 20$  inches at the bottom,  $3 \times 20$  inches at the top, and 16 inches high, filled with water and placed in an ice salt mixture, froze solid overnight, and gave ample ice for both freezing-point jars. To the ice and water in pan M, Fig. 2, a little salt was added, and the temperature in the air space above the vacuum jars was noted by means of a single couple introduced at C. The apparatus was allowed to stand for a few hours, during which the vessels were stirred occasionally, and the zero reading of the potentiometer observed. Usually this would change very slowly for the first hour, but would then remain constant for an indefinite period. This reading varied from  $1.0 \mu v$  to  $2.0 \mu v$  during the year it was under observation, and as Adams suggests, probably represented not a difference in temperature ( $0.0005$ – $0.001^\circ$ ) between the two vessels, but a summation of several small electromotive forces in the system apart from those excluded by the eliminating switch. Hausrath<sup>1</sup> and Flügel<sup>2</sup> have noted this same zero reading in their freezing-point work. That it can have no detrimental effects on the differential temperature determinations is evidenced by its constancy, when equilibrium is finally attained, and by the data obtained on the nonelectrolytes erythrite and mannite.

By the time the apparatus was in equilibrium, the air chamber above the freezing-point vessels had assumed a temperature which varied in the different determinations between  $-0.2^\circ$  and  $-0.3^\circ$ , but which was usually more nearly  $0^\circ$  than this. At the close of a series, some 3 or 4 hours later, this temperature had risen to about  $0.5^\circ$  or  $0.6^\circ$ . It is to be noted that this convergence temperature, in view of the large amount of ice in the equilibrium mixture, could have no appreciable effect. The convergence temperatures noted during the work on erythrite and mannite are included in Table II.

The final procedure was as follows: When equilibrium was definitely attained, the zero reading of the potentiometer thermoelement system was taken, and a sample of water (the zero sample for the interferometer) was withdrawn through the pipet, and an equal amount of chilled water containing the desired amount of salt was introduced. The solution was then stirred until equilibrium was reached, when the pipet was rinsed by partially filling it with the freezing mixture, and giving it a rotary motion. When this liquid had flowed back into the freezing-point vessel, stirring was resumed until the temperature had become stationary again.

<sup>1</sup> *Drude's Ann.*, **9**, 522 (1902).

<sup>2</sup> *Z. physik. Chem.*, **79**, 579 (1912).

In order that the heat developed by the stirrers should have no effect, and to make certain that the true equilibrium point had been reached, the apparatus was allowed to stand for a few minutes without stirring, the reading of the potentiometer was noted, and then the solution was again agitated. The apparatus was allowed to stand a second time for several minutes, during which the temperature was noted. If the equilibrium temperature proved to be the same as before, this was taken as the correct value, and a sample of the solution was removed through the pipet; if not, the process was repeated until the second reading was in accord with the one preceding. With the dilute solutions, the equilibrium temperature once attained would show no change for a half hour or more, and in the more concentrated solutions, the change was slight over a like period. After removal of the sample for analysis, a second quantity of salt was introduced as before, and the same procedure followed until the desired number of points had been taken.

**Effect of Air on the Freezing-Point Lowering.**—The determinations were made in such a way as to eliminate the very considerable error which may be caused by the presence of dissolved air on the freezing-point lowering. In both of the Dewar flasks the ice and the water used were from the same samples, and the contents of both were stirred to the same extent for several hours preceding the run, until no change in the reading during an hour or more could be detected. Also, blank runs were made, under the same conditions. It was found, using these precautions, that no difference in temperature ( $\Delta t$ ) between the contents of the two Dewar flasks, could be detected, which in any case resulted from the solutions of unequal amounts of air in the two liquids.

**Analysis of the Equilibrium Solution.**—The concentration of the samples taken from the equilibrium mixture was determined by the Zeiss interferometer,<sup>1</sup> except in the case of the iodates. In the determinations on potassium sulfate, barium chloride and magnesium sulfate, the second method outlined by Adams was followed. The zero point of the interferometer was determined by placing distilled water in both chambers, and noting the scale reading. Then the sample of water from the freezing-point apparatus (the zero sample mentioned above) was substituted in one chamber. Usually a reading of one or two divisions was noted, and this was the real zero for the series of unknown salt solutions to be determined. With ice made from the laboratory distilled water, the zero reading was not more than one-half scale division. Solutions of nearly the same strength as the unknown, one a little more, the other a little less concentrated, were next placed in the chambers of the interferometer and the scale reading noted. From the difference between this and the original zero, and between the solutions, a linear gradient over a small

<sup>1</sup> Discussed by Adams, *THIS JOURNAL*, 37, 1181 (1915).

range of concentration can be obtained. Finally, the unknown was substituted for one of the known solutions, and the scale reading noted, whence the concentration could be determined at once. For the other salts analyzed by the interferometer, a slightly different method was used. One or two determinations of the gradient were made. Then a solution was prepared similar in concentration to the unknown, and a comparison made, from which the concentration of the unknown could be almost exactly calculated. Finally, a solution was made of almost exactly this concentration, and compared with the unknown. At low concentrations, this solution would differ from the unknown by no more than 1-10 divisions of the interferometer, and in the quite concentrated solutions by only 50-100 divisions, thus obviating any possibility of mistaking the band to be read, and any error due to interpolation by the gradient. These methods both presume a knowledge of the approximate concentration of the unknown solutions. Usually this is the case; but if not, a comparison of the most dilute solution with water will give its strength, and from this, an approximation of the other solution strengths can be made.

If we assume an accuracy in setting equal to one scale division, the interferometer will be correct to 0.0002% in the case of most salts.<sup>1</sup> An error of this amount, however, with dilute solutions of cobalt chloride (0.0035 *N*) represents an error of 1% figured on the basis of total salts and similarly with all salts of small equivalent weight. For the determination of the unknown solutions of the iodates, therefore, titrations were made with thiosulfate.

**Calculation of Data.**—All weights taken were corrected to values *in vacuo*, and all solutions were calculated on the basis of weight normality. In calculating the values of *i*, the equation  $iN = \Delta t(1 + 0.0055 \Delta t)/1.858$  was used.<sup>2</sup> For the apparent degree of ionization, the values were obtained by the usual equation  $i = 1 + (n - 1)\gamma$ . *N* refers to the number of mols of solute to 1000 g. of water, *n* to the number of ions into which the salt dissociates, and  $\gamma$  to the apparent degree of ionization.

#### Experimental Data.

**Mannite and Erythrite.**—Kahlbaum's pure materials were used. The mannite was twice recrystallized from pure water. The melting point of the air-dry crystals, as determined by Hedenburg, was 167.3°. It was finally dried at 100° for a few hours, and then at 120° for 4 hours. The erythrite was twice recrystallized from a weak alcohol solution; final drying was at 115° for a few hours.

The freezing-point lowerings of these nonelectrolytes was determined primarily to test the accuracy of the potentiometer system and the thermo-

<sup>1</sup> L. H. Adams, *THIS JOURNAL*, 37, 1187 (1915).

<sup>2</sup> *Ibid.*, 32, 1011 (1910).

element equation. At the low concentrations, the deviation between observed and theoretical values is consistently approximately  $0.0001^\circ$ , the greatest deviation being  $0.00014^\circ$  in erythrite at a concentration  $0.00483$  formal. This correction was consequently applied to all measurements at low concentration. The  $0.0628$  formal solution of erythrite, and the  $0.1197$  formal solution of mannite, however, show considerable deviation from the theoretical values, as calculated by the equation given above, and the magnitude of this increases with increase in concentration. The deviation is in the same direction as with cane sugar,<sup>1</sup> in which Washburn<sup>2</sup> has shown rather definitely that this departure from the theoretical is due to hydration, and also the same as with levulose<sup>3</sup> and dextrose.<sup>4</sup> In Fig. 3 the cube root of the temperature lowering has been plotted against the cube root of the mol fraction. With the exception of the last point on erythrite, no deviation from a straight line can be noted,

although the curve shows an appreciable deviation from the theoretical at the higher concentrations. The values given by Jones<sup>1</sup> and Loomis<sup>1</sup> on mannite in concentrated solutions show a large deviation from the theoretical curve.

Table II contains the complete data on erythrite and mannite, and shows the deviation of the observed temperature depression from the theoretical, assuming the concentration as correct, and the difference in concentration from the theoretical, assuming the temperature measurement as correct.

**Sodium and Potassium Iodates.**—The pure salts were twice recrystallized (the sodium salt but once) from distilled water. The potassium iodate was dried by heating at  $160^\circ$  for several hours, the sodium salt by like heating at  $150^\circ$ . These salts were chosen, as the work of Jahn<sup>1</sup> had shown that their freezing-point lowerings were practically identical at all concentrations he investigated, and the data collected by Noyes and Falk<sup>2</sup> showed that the apparent degree of ionization as determined by the freezing-point method coincided very closely with that obtained by conductivity measurements. They also show that within the limit of experimental error no difference from the temperature depressions given by the pure salts can be detected in the freezing-point lowerings of the equimolar mixture. Fig. 4 shows the values of  $\Delta t/N$  plotted against the cube root of the concentration; Fig. 5 brings together on the same curve the values for the pure salts, and for the equimolar mixture.

Fig. 5.

Table III contains the complete data, and Table IV the  $\Delta t/N$  values at rounded concentrations, the value of  $i$ , and the corresponding degree of dissociation. Jahn's values for  $i$  are included for comparison.

Table III contains the complete data, and Table IV the  $\Delta t/N$  values at rounded concentrations, the value of  $i$ , and the corresponding degree of dissociation. Jahn's values for  $i$  are included for comparison.

**Equimolar Mixture of Potassium Chloride and Potassium Nitrate.**—Pure commercial salts were twice recrystallized from pure water, and dried for several hours at  $160^\circ$ .

Only the equimolar mixture was used, as Adams had determined the values for the pure salts with the same apparatus. Table V contains the

**Potassium Sulfate, Barium and Cobalt Chlorides.**—The potassium sulfate and barium chloride were twice recrystallized from pure water. The cobalt chloride was made by dissolving the carbonate in hydrochloric acid, filtering off the excess carbonate, and crystallizing after the addition of three or four drops of hydrochloric. The crystals obtained were dissolved and recrystallized from the solution to which no acid had been added. The stronger solutions gave a slight acid reaction to litmus.

The determination with cobalt chloride was made to obtain data for comparison with the freezing-point results on the cobaltammines, since no data were available on dilute solutions of this salt. The values of Biltz,<sup>1</sup> and of Jones and Getman,<sup>2</sup> on the more concentrated solutions,

<sup>1</sup> *Z. physik. Chem.*, **40**, 200 (1902).<sup>2</sup> *Am. Chem. J.*, **31**, 322 (1904).

give curves similar in shape to ours, but differently placed, as may be seen by noting the values for  $\Delta t/N$  at rounded concentrations in Table X. The determinations on barium chloride and potassium sulfate were made with the intention to work on mixtures with these types of salts, but this has not been done as yet. The value of  $\Delta t/N$  for the most dilute concentration of barium chloride is higher than that obtained by Bedford<sup>1</sup> at this concentration, but on the whole our values agree very well with his. The  $i$  values for potassium sulfate and barium chloride at rounded concentrations are compared with those of Osaka<sup>2</sup> (with those of Archibald at points not reached by Osaka's data) and Bedford,<sup>3</sup> respectively; the latter were calculated from the rounded concentration  $\Delta t/N$  values summarized by Noyes and Falk.<sup>4</sup>

It is interesting to note the shape of the curves in Fig. 8 in the concentrated solutions. The cobalt chloride curve shows a departure from the ordinary form of curve in dilute solutions, the barium chloride is slower in showing the change, and potassium sulfate has just begun to show this effect in the most concentrated solutions taken. It will be noted, too, that the curve which shows this effect first, is the one which gives the highest values for  $\Delta t/N$  in dilute solutions, so that probably its influence extends even to the dilute solutions. The same thing

Fig. 8.

<sup>4</sup> *THIS JOURNAL*, 32, 1011 (1910).

may be seen in the curve for lanthanum nitrate, and here, too, the break in the curve comes at a comparatively dilute point. It will be observed that this break comes sooner, the less basic the metallic element. Also, as pointed out by Jones, the substance with the largest amount of water of hydration gives the largest freezing-point depression, pointing to hydration in the solution.

Tables IX and X summarizes the data on these three salts, and Fig. 8 represents their curves plotted in the usual manner.

**Lanthanum Nitrate.**—We are indebted for our lanthanum nitrate to Dr. Miner of the Welsbach Co. This was in the form of its double ammonium salt. To obtain the pure substance, the lanthanum was precipitated as the oxalate, washed repeatedly until free from ammonia,

dried, and changed to the oxide by ignition. While the oxide was not pure white in color, spectroscopically it showed no evidence of impurities. We are indebted to Mr. Aronberg for this examination. The oxide was dissolved in strong nitric acid, in such amount that a small excess of oxide remained, and a clear solution was obtained by filtering. According to Noyes and Johnston,<sup>1</sup> this method of preparing lanthanum nitrate gives a neutral solution; but in the concentrated solutions which we made in this way, a slight acid reaction toward litmus was always noticeable. Finally, by evaporation *in vacuo*, the salt was obtained in the hydrated crystalline form.

The work on lanthanum nitrate was undertaken because we wished data on this type of salt for comparison with some of the cobaltammines. Noyes and Johnston determined the freezing-point lowerings in strong solutions, but no data were found for the dilute solutions.

Table XI contains the experimental data on this salt, and Table XII gives the values at rounded concentrations. It also gives for comparison the values of  $\Delta t/N$  obtained by Noyes and Johnston.

**Summary.**—A potentiometer system was installed, and a fifty-junction thermoelement constructed and standardized. The accuracy of temperature measurements of this system was checked by freezing-point determinations on the nonelectrolytes mannite and erythrite. In the dilute solutions, the greatest divergence in temperature from the theoretical was  $0.00014^\circ$ . As this deviation was consistently  $0.0001^\circ$ , it was used as a correction for the freezing-point depressions at low concentrations for all salts investigated. The accuracy of the system for greater differences of temperature was further checked by the readings in microvolts of a single couple, standardized at the Geophysical Laboratory against the vapor of boiling water, naphthalene and benzophenone. Our system was

<sup>1</sup> THIS JOURNAL, 31, 1008 (1909).

repeatedly tested with the water-vapor point, and found to agree in all cases well within the limit of error.

The freezing-point lowerings of various salts at different concentrations have been determined, their  $\Delta t/N$  values plotted against the cube root of the concentration, and their ionization values, as derived by this method, tabulated at rounded concentrations. Comparisons have been made with the values found in the literature; these have been chosen with the view of citing those obtained by the most accurate methods.

The freezing-point lowerings of two equimolar mixtures of di-ionic salts have been determined for concentrations between 0.01 and 0.1 or 0.2 formal; and over the range investigated, the values of  $i$  agree very closely with those obtained by averaging the  $i$  values for the pure salts at like concentrations.

In conclusion, we wish again to make acknowledgment of the courtesy of the staff at the Geophysical Laboratory for their coöperation; to acknowledge the advance of funds from the Wolcott Gibbs Fund of the National Academy for the installation of the potentiometer and galvanometer; and to thank the donors of the Swift Fellowship.

## THE FREEZING-POINT LOWERINGS IN AQUEOUS SOLUTIONS OF SALTS AND MIXTURES OF SALTS AND OF A SALT WITH A NONELECTROLYTE.

BY WILLIAM D. HARKINS AND W. A. ROBERTS.

Received September 1, 1916.

The apparatus and methods of analysis were the same as used by Harkins, Hall and Roberts, in the measurements of the freezing-point lowerings of the cobaltammines.

In the study of the effect of a nonelectrolyte on a salt, a mixture of mannite and KCl was used. The solutions were in the ratio of molar mannite to two molar KCl. The values of  $\Delta t$  for mannite in the table were calculated on the basis that a molar solution of mannite gives a depression of the freezing point of  $1.859^\circ$ . The data for  $\Delta t/N$  for KCl alone were taken from the work of Adams.<sup>1</sup>

TABLE I.—TEMPERATURE LOWERING AND VALUES OF  $\Delta t/N$  FOR THE KCl MANNITE MIXTURE.

Conc. mannite.	Conc. KCl.	Total $\Delta t$ .	$\Delta t$ mannite.	$\Delta t$ KCl alone.	KCl in $\Delta t/N$ for mixture.	$\Delta t/N$ for KCl. Adams.	Temperature deviation in degrees.

<sup>1</sup> THIS JOURNAL, 37, 481 (1915).

Only one set of determinations of the effect of mixtures on the freezing-point lowering could be found in the literature.<sup>1</sup> In each of the four experiments recorded the values given for the mixtures were farther from the experimental value of the salt alone than the deviation here found, but this difference may be due to the choice of mannite and potassium chloride in this particular case.

Unless there are two opposing effects which happen to cancel each other these results seem to indicate that the osmotic pressure of neither the mannite nor the potassium chloride is affected by the presence of the other in the mixture. Therefore the great increase in activity which the nonionized part of a salt exhibits, provided the present methods for the calculation of the ionization of salts is anywhere nearly correct, could not be attributed to the effect of the ions upon the activity of the nonionized part of the salt, if the nonionized part of a salt acts at all in a similar way to mannite. In other words, it seems necessary to conclude that either our present methods for the calculation of ionization are incorrect or else the nonionized part of a salt is very different in its make-up from a substance such as sugar. Assuming our present ionization values as correct there seems to be evidence to show that the un-ionized part of a salt is joined together extremely loosely. However, even on this basis it is very difficult to account for the extremely great increase in activity found for the nonionized part of the salt. Thus the solubility of the ionized part of thallos chloride is decreased from 17.55 to 9.7 millimols by the presence of 0.1 normal potassium nitrate solution, a decrease of 44.7% which represents an enormous increase in the activity of the nonionized salt.

Bates obtains somewhat similar results by calculations of freezing-point and conductivity data, and shows that at 0.1 normal the osmotic pressure of the "undissociated molecules" is 1.35 times greater than corresponds to van't Hoff's law.

<sup>1</sup> Osaka, *Z. physik. Chem.*, 41, 560 (1902).

The freezing-point lowerings of equimolar solutions of sodium and potassium sulfate and of sodium sulfate were measured. The values for potassium sulfate were taken from the work of Hall and Harkins.

The concentration of the mixture was calculated on the basis of the average molecular weight. The curve, Fig. 1, shows  $\Delta t/N$  plotted against the cube root of the concentration.

Fig. 1.—Freezing-point lowerings for two uni-bivalent salts and for their 1:1 mixture.

The results indicate that in the case of these two uni-bivalent salts the lowering of the freezing point caused by the mixture is very nearly the average of the lowering of the two salts taken separately.

The lowering of the freezing points of solution of sodium chloride and of mixtures of sodium and potassium chloride were measured. The results indicated an exceptional lowering in the case of these mixtures. A mixture of 1 NaCl to 1 KCl showed a value of  $\Delta t/N$  below either NaCl or KCl at the more dilute points. A mixture of 2 NaCl to 1 KCl gives values between the 1:1 mixture and the values expected, if there is no effect of the one salt on the other. The numerical results will not be given as it is thought best to redetermine the values for these mixtures.

Table III gives the value for the sodium chloride alone.

### Summary.

This paper gives determinations of the freezing-point lowerings for solutions of sodium sulfate, potassium sulfate, and their equimolar mixture, for sodium chloride, and for a mixture of mannite and potassium chloride. The greatest temperature deviation to be found from the calculated value in the potassium-chloride-mannite mixture, was six one-hundred-thousandths of a degree.

## IONIZATION AND SOLUBILITY RELATIONS OF SALTS OF HIGHER TYPES.<sup>1</sup> IV.

### INTERMEDIATE IONS IN SOLUTIONS OF UNI-BIVALENT SALTS, AND OF LANTHANUM IODATE, A TRI-UNIVALENT SALT.

BY WILLIAM D. HARKINS AND W. TUDOR PEARCE.<sup>2</sup>

Received August 23, 1916.

### Introduction.

A survey of any general treatise on chemistry indicates that lower type salts, that is, those of the uni-univalent type, are few in number in comparison with salts of the higher types, yet the latter class of salts has received little attention from the standpoint of general ionization and solubility relations. So slight indeed is the attention paid

<sup>1</sup> The part of this work which bears directly upon uni-bivalent salts was done by Harkins in the Research Laboratory of Physical Chemistry of the Massachusetts Institute of Technology, and the importance of such an investigation was suggested by Dr. A. A. Noyes, who obtained financial support for the work from the Carnegie Institution of Washington. The first three papers on higher type salts (Papers V, VI and VII, The Effect of Salts upon the Solubility of Other Salts, *THIS JOURNAL* 33, 1807-73 (1911)) were largely experimental and did not give an adequate discussion of the theoretical relations involved in the intermediate ion hypothesis.

<sup>2</sup> This paper, and one published later in this series, have been presented to the University of Chicago by W. Tudor Pearce as a dissertation in part fulfilment of the requirements for the degree of Doctor of Philosophy. In addition to the work here presented, a considerable time was spent upon the separation of the yttrium group elements.

to higher type salts, that although it was shown in 1911 by Harkins<sup>1</sup> that all salts of the uni-bivalent type ionize in two steps, and thus give solutions containing intermediate ions, almost none of the recent texts on general, inorganic, or physical chemistry<sup>2</sup> even mention the possibility of the existence of intermediate ions. This of itself might not be so bad if these texts did not persist in giving the altogether false percentage ionizations which are obtained by calculation when the presence of intermediate ions is neglected. Thus in two well-known college text books published recently the percentage ionization of potassium sulfate in a tenth normal solution is given as 72%, even although the work cited above shows that in all probability more nearly 95% of a salt of this uni-bivalent type is in the ionic form at this concentration. Even if the authors of these texts do not believe that intermediate ions exist in appreciable quantities in solutions of such salts, the better method would be to express their results in terms of the conductance ratio without the application of the hypothetical term "degree of ionization."

Previous to the publication of the first papers of this series it had been suggested by a number of workers that intermediate salt ions were present in certain specific cases, but these suggestions were made to cover only what seemed to be extraordinary cases. Thus Abe $\ddot{g}$ g and Spencer<sup>3</sup> assumed that when thallium oxalate ionizes it forms intermediate ions, but that potassium oxalate does not. Also Jellinek<sup>4</sup> concluded from freezing-point results that intermediate ions are formed by sodium sulfate, but not by potassium sulfate. The new feature of the intermediate ion hypothesis is that it assumes that intermediate ions are present in solutions of all salts of higher types, and that the percentage amount of the intermediate ion increases regularly with the concentration, somewhat as the concentration of the un-ionized part of a lower type salt increases.

The most striking fact found by Harkins was that, while the solubility of a uni-bivalent salt is depressed in a normal way by the addition of a salt with a univalent ion, and while on the whole the action of a salt with a non-common ion is also normal, that when the common bivalent ion is added the effect on the solubility is extremely abnormal for very soluble salts and in concentrated solutions, and is still quite abnormal in dilute solutions, but becomes almost normal in solutions of extreme dilution. The effect found is that the decrease in solubility produced by the addition of a salt with a bivalent common ion is very much less than would be expected in dilute solutions, and in concentrated solutions there is often

<sup>1</sup> THIS JOURNAL, 33, 1807-73 (1911).

<sup>2</sup> Washburn's "Principles of Physical Chemistry" is an exception in this respect.

<sup>3</sup> *Z. anorg. Chem.*, 46, 406 (1905).

<sup>4</sup> *Z. physik. Chem.*, 76, 309 (1911).

even an *increase instead of a decrease* of solubility. Since salts which form complexes were avoided as much as possible in the experimental work, this behavior suggests what may be called a non-common ion effect. Now if strontium bromide and strontium nitrate in concentrated solutions were to ionize only to the extent of one step, the ions formed would be  $\text{SrBr}^+$  and  $\text{SrNO}_3^+$ ,  $\text{Br}^-$ , and  $\text{NO}_3^-$ . None of these is a common ion, and, therefore, from the standpoint of intermediate ions an increase of solubility is easily explainable.

There will now be considered the lowering of the solubility of a salt caused by the presence of (1) a common univalent ion, and of (2) a common bivalent ion. One calculation will be made assuming that intermediate ions are absent, and a second on the basis of the presence of such ions, and then a comparison of the results obtained in the two cases will be possible.

**1. Solubility Effects when Intermediate Ions are Absent.**—Let a salt  $\text{A}_2\text{B}$  ionize directly into  $2\text{A}^+$  ions and one  $\text{B}^-$  ion. Then, when formulated according to the mass law, and when  $\text{S}_0$  represents the solubility in water,  $\text{S}_1$  when the common univalent ion is added, and  $\text{S}_2$  when the common ion is bivalent, the following expressions are obtained:

$$(\text{A}_2\text{B})_0 = (\text{A}_2\text{B})_1 = (\text{A}_2\text{B})_2 \quad (1)$$

$$(\text{A})^2(\text{B})_0 = (\text{A})_1^2(\text{B})_1 = (\text{A})^2(\text{B})_2 \quad (2)$$

$$\text{S}_0 = (\text{A}_2\text{B})_0 + (\text{B})_0 \quad \text{S}_1 = (\text{A}_2\text{B})_1 + (\text{B})_1 \quad (3)$$

$$2\text{S}_0 = 2(\text{A}_2\text{B})_0 + \text{A}_0 \quad (4) \quad 2\text{S}_2 = 2(\text{A}_2\text{B})_2 + (\text{A})_2 \quad (5)$$

By combining these equations results may be obtained which represent the fractional decrease of solubility produced by increasing the concentration of the univalent ion from  $(\text{A})_0$  to  $(\text{A})_1$ , and of the bivalent ion from  $(\text{B})_0$  to  $(\text{B})_2$ :<sup>1</sup>

$$\text{S}_0 - \text{S}_1 = \frac{(\text{A})_1 - (\text{A})_0}{(\text{A})_0} \left[ \frac{\text{A}_0\text{B}_0}{\text{A}_1} \left( 1 + \frac{\text{A}_0}{\text{A}_1} \right) \right] \quad (6a)$$

$$\text{S}_0 - \text{S}_2 = \frac{1}{2} \frac{(\text{B})_2^{1/2}(\text{B})_0^{1/2}}{(\text{B})_0^{1/2}} \left\{ (\text{A})_0 \left[ \frac{(\text{B})_0}{(\text{B})_2} \right]^{1/2} \right\} \quad (7)$$

Equation 6a may be more simply expressed as follows:

$$\text{S}_0 - \text{S}_1 = \frac{(\text{A})_1 - (\text{A})_0}{(\text{A})_1} \left[ (\text{B})_0 \left\{ 1 + \frac{(\text{A})_0}{(\text{A})_1} \right\} \right]$$

<sup>1</sup> These calculations made on the basis of the law of mass action will be somewhat in error, since the principle that the concentration of the un-ionized part remains constant seems to be considerably in error if we judge from the behavior of uni-univalent salts, but the effect of the error on the result in case intermediate ions are present is exceedingly slight, since the concentration of the un-ionized part is very small in proportion to the total concentration. There is also some deviation from the solubility product principle, but this deviation is slight and the resultant error is in the opposite direction from the first one mentioned.

From these equations it would be expected that the addition of the common univalent ion would in all cases effect a considerable lowering in the solubility. The addition of the common bivalent ion would also produce a considerable effect of the same kind, though slightly smaller in magnitude.

**2. Solubility Effects when Intermediate Ions Are Present.**—When intermediate ions are present Equations 6 and 7 take the form

$$S_0 - S_1 = \frac{(A)_1 - (A)_0}{(A)_1} \left[ (B)_0 \left( 1 + \frac{(A)_0}{(A)_1} \right) + (AB)_0 \right] \quad (6b)$$

$$S_0 - S_2 = \frac{1}{2} \frac{(B)_2^{1/2} - (B)_0^{1/2}}{(B)_0^{1/2}} \left[ (A)_0 \left( \frac{(B)_0}{(B)_2} \right)^{1/2} - (AB)_0 \right] - (ADB)_2 \quad (7b)$$

However, in Equations 6b and 7b the values of the concentrations are very different from what they are in Equations 6 and 7

The positive sign of the term  $(AB)_0$  in Equation 6b shows that the effect of the presence of the intermediate ion is to make the *decrease* of solubility larger, and the effect of this term increases with the percentage of the intermediate ion. The experimental results show that curves of this type exhibit this effect, and especially with salts like lead chloride and calcium hydroxide, which contain in solution an exceptionally large percentage of the intermediate ions. The curves for these salts, and also for lead iodate fall below the theoretical limiting curve for this type in the more dilute solutions. \* (Fig. 1.) The theoretical limiting curve is calculated for a salt of 100% ionization, which means that the presence of intermediate ions is not considered.

The negative signs on the terms  $(AB)_0$  and  $(ADB)_2$  indicate that when intermediate ions are present the decrease in solubility would be much less than that calculated on the basis that they are not present, which is exactly in accord with the experimental results. However, with a slightly soluble salt to which the bivalent common ion is added, the effect of the presence of the intermediate ion will not be specially noticeable, so long as the concentration of the added bivalent ion  $(B)_2$  is not greatly increased, since in this case the ratio of  $(AB)_0$  to  $A_0 B^{1/2} / B_2^{1/2}$  is small.

The decrease in solubility with this type of curve will change over into an increase when with a moderately soluble salt the concentration of the added salt is moderately increased for in this case the ratio  $(AB)_0 / A$  is fairly large and the negative term  $(AB)_0$  will soon compensate the steadily decreasing positive term containing  $(A)_0$  to so great an extent that the whole latter term of Equation 7b becomes negative, and this occurs all the sooner since the negative term  $(ADB)_2$  is constantly increasing.

When either the saturating salt is very soluble, or contains a specially large percentage of intermediate ion, even the first addition of a salt with a common bivalent ion may cause an increase in solubility, for where

$(AB)_0/(A)_0$  is sufficiently large the two negative terms may exceed the positive one, even when the factor of the latter  $B_0^{1/2}/B_2^{1/2}$  is equal to unity. The general agreement of these equations, derived on the supposition that intermediate ions are present, with the experimental facts, is a strong argument in favor of the existence of intermediate ions.

**3. Evidence against the Intermediate Ion Hypothesis.**—The purpose of the present paper is to add experimental evidence which bears on the ionization of tri-univalent salts to that which has already been obtained in the case of salts of the uni-bivalent type. In studying such a problem it may be well to outline the evidence which has in the past seemed to indicate that intermediate ions do not exist in solutions of the latter type, and for this purpose there is cited a quotation from a paper by Noyes and Bray<sup>1</sup> as follows: "In the case of salts of the uni-bivalent type, there is furthermore the uncertainty as to whether intermediate ions (such as  $KSO_4^-$  or  $\cdot NO_3Ba^+$ ) are present in considerable proportions. Certain remarkably simple principles have, however, been established, which have been thought to indicate that the complications which would arise from ionization in two successive stages do not exist, namely: 1. The conductance ratio of such salts changes with the concentration according to the same exponential law  $(C\gamma)^n/C(1-\gamma) = K$  that holds in the case of uni-univalent salts. 2. The conductance of mixtures of such salts can be approximately calculated from the conductance of the constituents by the same principle expressed by the equation 
$$\left[ \frac{C_{B^+} \times C_{A^-}}{C_{BA}} = K(C\gamma)^{2-n} \right]$$

that holds for univalent salts. 3. The transference numbers of uni-bivalent salts (except those of the bivalent metal halides) change only slightly with increasing concentration. 4. Simple mixed salts (such as  $BaClNO_3$ ) scarcely ever separate in the solid state when solutions of the constituent salts are evaporated." In order that this quotation may not be misunderstood it may be said that in spite of the above evidence, the paper from which it is taken seems to favor rather than oppose the idea that intermediate ions exist.

**4. Conditions under Which the Objections Become Invalid.**—The very fact that the same equation

$$C_B \times C_{A^-}/C_{BA} = K(C)^{2-n} = K(\Sigma i)^q \quad (1)$$

which is found valid for the conductance ratios of single uni-univalent salts and which may also be used to calculate the conductance of mixtures of such salts, may be applied to salts of higher types without any essential change, should at once suggest that this equation, and other modified equations of this general type, are after all nothing more than they pretend to be, that is, entirely empirical equations which are valuable in

<sup>1</sup> THIS JOURNAL, 33, 1645 (1911).

connection with calculations of conductance and of conductance ratios, but which, at least in the case of salts of higher types, are not directly related to the ionization. Thus, if the above equation is valid for the ionization of the simple type salts, for those of the uni-bivalent type the equation should be of the form

$$\frac{C_B^2 \times C_{A^+}}{C_{B_2A}} = K (\Sigma i)^q \quad (2)$$

in case intermediates do not exist, and this latter equation would not change at all into the form of Equation 1 if intermediate ions are present.

Perhaps the most serious objection to the intermediate ion hypothesis is that given above under number (3), that the transference numbers of the uni-bivalent salts, except those of the bivalent metal halides, change only slightly with the concentration, even although the concentration of the intermediate ion if it is present, should increase rather rapidly with the concentration, at least in all cases where complex ions are not present. The fact is, from the experimental standpoint, that extensive researches on the transference numbers of potassium sulfate, barium nitrate,<sup>1</sup> and upon thallous sulfate and lead nitrate,<sup>2</sup> show that the change of the transference number with the concentration is very small, at least between 0.03 and 0.10 normal; in fact, there was no detectable change greater than might result from experimental errors. As a result of this work Falk comes to the following conclusion: "Some degree of probability therefore attaches to the hypothesis that such tri-ionic salts do not as a rule give rise to intermediate ions, at any rate in quantity exceeding a few per cent. at 0.1-0.2 normal; but that they dissociate directly into three ions. At any rate the statement can be made with positiveness that the transference relations of the tri-ionic salts afford no indication of the presence of intermediate ions, but whether this is due to the nonexistence of such ions or to the fact that they have a conductance of such magnitude as not to influence the transference, cannot be definitely stated."

In this connection it should be noticed that the transference method is by no means sufficiently accurate so that conclusions based upon transference results could be looked upon as at all conclusive, especially where the ions investigated have not very different speeds. In sulfuric acid, where the ions  $H^+$ ,  $HSO_4^-$  and  $SO_4^{2-}$  have greatly different velocities, the intermediate ion has been detected by transference measurements.

**5. Transference Number of Intermediate Ion.**—The necessary relation between the migration values of the different ions in order that the existence of the intermediate ion may escape detection, may easily be calculated. Thus for potassium sulfate the existence of the intermediate

<sup>1</sup> A. A. Noyes, *THIS JOURNAL*, 23, 37 (1901).

<sup>2</sup> Falk, *Ibid.*, 32, 1555 (1910).

ion must not very greatly alter the transference number of the potassium ion as it is calculated on the supposition that no intermediate ion is present. In a general form the equations are given below, where  $T_o$  represents the transference number when no intermediate ion is present, and  $T_i$  gives its value if the intermediate ion is present, and when the ionization occurs only for the first step. Now for a salt  $A_2B$

$$T_{oA+} = \frac{\Lambda_{A+}}{\Lambda_{A+} + \Lambda_{B-}} \quad (3)$$

$$T_{iA+} = \frac{\Lambda_{A+} - \Lambda_{AB-}}{\Lambda_{A+} + \Lambda_{AB-}} \quad (4)$$

Now if  $T_{oA+} = T_{iA+}$

$$\frac{\Lambda_{A+}}{\Lambda_{A+} + \Lambda_{B-}} = \frac{\Lambda_{A+} - \Lambda_{AB-}}{\Lambda_{A+} + \Lambda_{AB-}} \quad (5)$$

or  $\Lambda_{AB-} = \Lambda_{A+} \times \Lambda_{B-} / 2\Lambda_{A+} + \Lambda_{B-}$ . (6)

Equation 6 expresses the exact relationship which would absolutely prevent the detection of the intermediate ion, but since the transference method is not a very sensitive indicator in the case of salts, the conductance of the intermediate ion might vary considerably from this value without causing any very noticeable change in the transference number ( $T_A$ ) with the concentration.

If it is assumed that when the ions  $A^+$  and  $B^-$  unite to form the intermediate ion  $AB^-$ , the resistance to the motion of the intermediate ion is equal to that of its constituent ions, or  $R_{AB-} = R_{A+} + R_{B-}$ , then the equation for its conductance would be

$$\Lambda_{AB-} = \frac{I}{R_{AB-}} = \frac{I}{R_{A+} + R_{B-}} = \frac{I}{I/\Lambda_{A+} + I/\Lambda_{B-}} = \frac{\Lambda_{A+} \times \Lambda_{B-}}{2\Lambda_{A+} + \Lambda_{B-}}, \quad (7)$$

which is the same as Equation 6. So the condition necessary in order that the intermediate ion may have no influence upon the transference number is that the resistance to motion of the intermediate ion shall be equal to the sum of the resistance of its component ions.

**6. The Union of the Ions in Intermediate Ions and Probably in Molecules of Salts in Aqueous Solutions is a Loose One.**—It has been pointed out by G. N. Lewis that in the case of intermediate salt ions this condition should be very nearly fulfilled, since the properties of salts in solution are additive properties of the constituent ions, and the heat of ionization is small, so that the union of the ions is a loose one. On the other hand, the heat of ionization of the dibasic acids is considerable, and therefore in the case of such intermediate ions as  $HSO_4^-$  the above relationship would not hold, and such ions should be detected by transference measurements, as is the case. Not only is this true but the great differences in the

migration values of the constituent ions of such intermediate ions make the experimental detection of these ions by transference measurements much more feasible.

In spite of the failure of previous attempts to prove the presence of intermediate salt ions by transference measurements, it is not improbable that some evidence of their existence might be obtained by using salts of higher types in which one ion has a far greater migration value than the other, which might be done by loading up one of the ions with heavy organic radicals. However, the fact that such a method at the best would not prove a very sensitive one, makes it advisable to turn to other experimental methods.

A consideration of the migration values of some of the ions of salts of higher types will give some specific idea of the reasonableness of such an hypothesis in regard to the migration values of the ions. In the special case where these values are the same for both of the simple salt ions, Equations 5 and 6 give the result that the migration number of the intermediate should be one-third that of the constituent ions; or

$$\Lambda_{AB^-} = \frac{1}{3}\Lambda_{B^-} = \frac{1}{3}\Lambda_{A^+}. \quad (19)$$

In the case of potassium sulfate at 25°,

$$\Lambda_{SO_4^{2-}}/2 = 80.0, \Lambda_{K^+} = 74.8 \text{ and } \Lambda_{KSO_4^-} = 26.$$

Since the  $SO_4^{2-}$  ion if it had one charge could be pulled only one-half as fast, the migration value would be 40. The potassium would still further load up the  $KSO_4^-$  ion, and thus increase its resistance. So that the decrease of the migration value from 40 to anywhere near 26 must be due to the resultant increase in size of the ion.

**7. The Intermediate Ion Hypothesis.**—The intermediate ion hypothesis, as proposed by Harkins in 1911, but not that time emphasized, may be stated as follows: (1) All salts, acids and bases which dissociate electrolytically into more than two ions, dissociate in steps, and thus form in solution intermediate ions. (2) These intermediate ions are present in dilute as well as in concentrated solutions, but the percentage of the salt present as intermediate ion decreases as the solution becomes more dilute.

When the intermediate salt ions, such as  $KSO_4^-$ , are compared with the corresponding intermediate acid ions, such as  $HSO_4^-$ , it is found that the intermediate salt ion has in general the higher ionization constant. It is well known that the intermediate ion of a strong acid ( $HSO_4^-$ ) has a moderately high ionization constant, but that this constant is extremely small in the case of the weak acids ( $HCO_3^-$ ). Undoubtedly the same relations are true for the intermediate ions of bases. The ionization of intermediate salt ions differs from that of the similar ions in acids and bases, somewhat as the ionization of uni-univalent salts differs from that of acids and bases;

that is, the ionization constants are in all cases relatively high in the case of salts (with of course such exceptions as occur in cadmium and mercury salts, which have a high tendency toward complex formation). However, the ionization constants of intermediate salt ions are not so high as to make these ions negligible in solutions of ordinary concentration.

**8. Calculation of the Percentage of Intermediate Ions and Other Constituents in Solutions of Higher Type Salts.**—The greatest difficulty which we encounter when an endeavor is made to calculate the percentage of intermediate ion present in the solution of a higher type salt, is that we do not as yet know how to calculate the percentage ionization of a salt of the simplest type. If we assume that the value of the conductance ratio, or of the conductance ratio modified by some function of the viscosity, gives the correct values for the ionization of simple type salts, then it is possible without the introduction of assumptions which are any more doubtful than those used in this simple case, to calculate the ionization of salts of the uni-bivalent type.

In order that comparisons may be made between the ordinary system of calculating the ionization of tri-ionic salts, and that which takes account of the existence of intermediate ions, and also so that the similar relations for uni-trivalent salts may be understood, the results of calculations of this kind will be given.

There are two assumptions which seem to afford the best basis for estimating the proportions of the constituents in solutions of uni-bivalent salts. The first of these is the assumption that the principle that different salts of the same valence type have approximately the same ionization values, or more properly the same ionization constants,<sup>1</sup> applies to the first stage of the ionization of uni-bivalent salts. Thus if a salt  $A_2B$  (such as  $Ag_2SO_4$ ) ionizes at first into  $A^+ + AB^-$ , it ionizes as a uni-univalent salt, and should therefore be about 83% ionized in this way in 0.1 normal solution.

The second assumption is based on the fact that the transference numbers of uni-bivalent salts (excluding the halides of bivalent metals) vary scarcely at all with the concentration. As has been shown, it is a necessary consequence of this fact that the intermediate ion, if it be present in considerable quantity, has an equivalent conductance equal to  $\Lambda_A \Lambda_B / (2\Lambda_A + \Lambda_B)$  where  $\Lambda_A$  and  $\Lambda_B$  are the equivalent conductances of the simple univalent and bivalent ions of a salt,  $A_2B$ . The method used was to calculate by a method of approximations the concentrations of the constituents which under the assumptions just stated cause the calculated specific conductance of the solution in each case to be the same as that experimentally determined. The results are given in Table I.

<sup>1</sup> Noyes, *THIS JOURNAL*, 30, 351 (1908).

<sup>1</sup> Calculated for us by Dr. S. D. Wilson.

It will be seen from this table that the proportion of intermediate ion increases rapidly with increasing concentration. The most striking result, however, is that  $K_2$ , the ionization function for the second stage of ionization, increases with increasing ion concentration, and is nearly proportional to  $K_1$ .

The assumption used in the calculation of the first step of the ionization of a tri-ionic salt was that usually adopted for salts of the simplest type, that is, that the conductivity ratio, or the conductivity ratio modified by a function of the viscosity, gives the ionization. When such an assumption is made, it is found empirically that the Storch<sup>1</sup> equation

$$\frac{\Lambda_0 - \Lambda}{\gamma \Lambda_0} = k \left( \frac{\Lambda}{\Lambda_0} \right)^x$$

or in its modified form as given by Bancroft<sup>2</sup>

$$C_2^n / C_3 = K$$

expresses the relations which are found, where  $N = 2 - f(K)$ , where  $f(K)$  varies approximately between 0 and  $1/2$ . The latter equation is now often used in the following forms:

$$\frac{(C\gamma)^2}{C(1-\gamma)} = K_1(C\gamma)^{2-n}, \quad \frac{(C\gamma)^2}{C(1-\gamma)} = k_1(\Sigma i)^{2-n} \quad \text{or} \quad \frac{C_{B^+} \times C_{A^-}}{C_{BA}} = k_1(\Sigma i)^{2-n}.$$

Since the value of  $k(\Sigma i)$  becomes 0 at zero concentration, it has been proposed by Kraus,<sup>3</sup> and by Kraus and Bray that an additional constant be inserted, which gives the equation the following form when the viscosity correction is included:

$$(C\gamma/\eta\eta_0)^2 / C(1-\gamma/\eta\eta_0) = k + k_1(C\gamma/\eta\eta_0)^h$$

which is perhaps better expressed:

$$\frac{(\Lambda\eta/\Lambda_0\eta_0)^2 C}{(1-\Lambda\eta/\Lambda_0\eta_0)} = k + k_1 \left( C \frac{\Lambda\eta}{\Lambda_0\eta_0} \right)$$

However the simpler form of the equation gives sufficiently accurate results for highly ionized substances in aqueous solution at the concentrations given in Table I, so this simpler form has been used in the calculation, which would otherwise be extremely involved. The results of these calculations show that when it is assumed that the first step in the ionization follows the usual rule of the uni-univalent salts, the second step follows a similar rule, but with a much smaller value of  $K(\Sigma i)^{2-n} = K_2$ .

**9. Values of the Exponent  $n$  for the Steps in the Ionization of the Tri-ionic Salt Silver Sulfate.**—It is interesting in this connection to calculate the values of  $n$  in the equations which fit the different steps in the ionization.

<sup>1</sup> Storch, *Z. physik. Chem.*, **19**, 13-19 (1894).

<sup>2</sup> *Ibid.*, **31**, 189 (1899).

<sup>3</sup> *THIS JOURNAL*, **35**, 1412 (1913).

Normal concn.	First step. $\text{Ag}_2\text{SO}_4 = \text{Ag AgSO}_4^{-n_1}$	Second step. $\text{AgSO}_4 = \text{Ag SO}_4^{n-n_1}$
0.01 to 0.05	1.52	1.57
0.05 to 0.10	1.49	1.56

This shows that an equation of the Storch form also fits the second step in the ionization of salts of the tri-ionic type.

The equations for these two steps may be given as follows:

$$\frac{C_{B^+} \times C_{AB^-}}{C_{B_2A}} = K' (\Sigma i)^{2-n_1} \quad (1)$$

$$\frac{C_{B^+} \times C_{A^-}}{C_{BA^-}} = K'' (\Sigma i)^{2-n_2} \quad (2)$$

or combined in one equation:

$$\frac{C_{B^+}^2 \times C_{A^-}}{C_{B_2A}} = K'K'' (\Sigma i)^{4-n_1-n_2} \quad (3)^1$$

For silver sulfate:

$$\frac{C_{B^+}^2 \times C_{A^-}}{C_{B_2A}} = K'K'' (\Sigma i)^{0.94} = K (\Sigma i)^{0.94}$$

So approximately  $\frac{C_{B^+} \times C_{A^-}}{C_{B_2A}} = K_i$ , for this salt, where  $K_i$  is a real constant.

The results given in Table I are compared with those obtained by Noyes and Eastman<sup>2</sup> in Table II.

TABLE II.—COMPARISON OF THE IONIZATIONS OF SULFURIC ACID AND OF POTASSIUM SULFATE, CALCULATED FROM THE STANDPOINT OF THE EXISTENCE OF INTERMEDIATE IONS.

	Salt.	Acid.	Salt	Acid.
Equiv. concn.....	0.01	0.01	0.1	0.1
Formal concn.....	0.005	0.005	0.05	0.05
$K^+$ or $H^+ = \Sigma i$ .....	0.0090	0.0081	0.0774	0.0625
$\text{KSO}_4^-$ or $\text{HSO}_4^-$ .....	0.0009	0.0017	0.0176	0.0315
$\text{SO}_4^{2-}$ .....	0.00405	0.0032	0.0299	0.0155
$\text{K}_2\text{SO}_4$ or $\text{H}_2\text{SO}_4$ .....	0.00005	0.00010	0.0025	0.0030
$K_1 = A^+ \times AB^-/AB_2$ .....	0.150	0.138	0.553	0.626
$K_2 = A^+ \times B^-/AB^-$ .....	0.040	0.0152	0.132	0.0307

It will be seen that the first ionization constant obtained ( $K_1$ ) is nearly the same for the salt or the acid at the same concentration, but that the ionization constant of the intermediate ion ( $K_2$ ) is much smaller for the acid ion than for the salt ion, which is in accord with the idea presented earlier in this paper. In all cases the second ionization constant ( $K_2$ ) is much smaller than the first (about  $1/4$  as much in the case of the salts),

<sup>1</sup> It must be remembered in applying this equation that the concentrations are not those usually used and are *not* equal to the conductance ratios, but are the concentrations given in Table I.

<sup>2</sup> Noyes and Eastman, *THIS JOURNAL*, 32, 1148 (1910).

as might be expected, since in the intermediate ion the univalent ion must separate from a doubly charged ion.

**10. The Ionization of a Tri-univalent Salt.**—The calculation of the concentration of the constituents in a solution of a tri-univalent salt, such as lanthanum nitrate or iodate has not been attempted, though it would be possible to make such a calculation. However, some additional assumptions would be introduced, and without making the calculations all of the general conclusions of value can be obtained by considering the results given in Table I. As compared with the uni-bivalent salt which on ionization forms only one intermediate ion, we would expect that in the uni-trivalent salt the percentage of univalent ion would be increased, the percentage of the ion of highest valence would be decreased, that of the molecules would be decreased, and the percentage of intermediate ion would be increased, since now there would be two intermediate ions instead of one. Thus lanthanum nitrate would ionize as follows:

**11. Discussion of the Valence-Product Rule.**—From the standpoint of the above paragraph it may be said that for uni-univalent, uni-bivalent, and uni-trivalent salts, *the total percentage amount of salt in the ionic form increases with the valence product*, which is just the opposite of the rule which has been considered valid in the past.<sup>1</sup> Also when these salts are taken in the same order, the percentage of un-ionized salt decreases, which is again the opposite of the usual rule.

An inspection of Table I will show that the total number of particles (mols) present is not very greatly different when allowance is made for the presence of intermediate ions from that usually calculated when they are supposed to be absent. Thus in *N*/10 potassium sulfate the total number of mols is 0.1274 on the intermediate ion basis, and 0.1210 from the ordinary standpoint, so that the former method gives only a slightly larger number than the latter. When the number of ions is calculated for the same solution, the values are 0.1249 and 0.1065, respectively, so that many more ions are present from the intermediate ion standpoint. If 0.1 normal (0.05 molar) potassium sulfate were to completely dissociate it would give 0.15 mol of ions, so that with the intermediate ions present we have 83.3% of the possible number of ions instead of 71% as usually calculated. However, only 5% of the salt remains in the un-ionized form, so 95% is in the form of ions. There is no real contradiction in these values, but only an apparent one, due to the fact that the intermediate ions are intermediate in composition between the un-ionized molecules and the ions which result from complete ionization.

<sup>1</sup> Noyes and Johnston, *THIS JOURNAL*, 31, 1002 (1909).

Since a salt of the uni-univalent type gives at tenth normal concentration only 85% of the total possible number of ions, and as seen above, a uni-bivalent salt gives about 83% of the possible number at the same normal concentration, there is not much difference between the ionization of the two types of salts when they are looked at from just this standpoint.

When the ionization of a higher type salt is calculated without reference to the presence of intermediate ions, the relations are found to be expressed by the valence-product rule, that the ionization decreases rapidly when the product of the valences of the constituent ions increases. This relation is shown in Table III.

TABLE III.—VALUES OF THE CONDUCTANCE RATIO (OR IONIZATION IF THE PRESENCE OF INTERMEDIATE IONS IS NOT TAKEN INTO ACCOUNT) IN RELATION TO VALENCE TYPE.

Noyes and Johnston find that these results can be expressed in another form, in which they show that there is an approximate proportionality between the un-ionized *fraction* of a salt and the valence product, when no allowance is made for the existence of intermediate ions in the solution. It seems that the idea which led to the expression of the results in the latter form was undoubtedly that as the valence product increases the electrical forces tending to hold the ions together increase, and therefore, from a theoretical standpoint the un-ionized fraction should increase. From the intermediate ion standpoint, however, while the above rules still apply to the conductance ratio, they no longer apply to the ionization, since, as has been stated above, the ionized fraction seems to increase and the un-ionized fraction to decrease as the valence product increases if the salts are of the 1,1; 1,2; or 1,3 types. However, that the idea from which the valence-product rule was derived is itself correct is indicated by the ionization functions, often called ionization constants, for the two steps in the ionization of a uni-bivalent salt, as given by Table I. These show that the ionization is much greater for the first step where the two univalent ions separate according to the reaction  $B_2A = B^+ + BA^-$ ,

than when the univalent ion separates from the bivalent one,  $BA^- = B^+ + A^-$ , in fact the ionization function is only about one-fourth as large for the second reaction as it is for the first.

### Experimental Part.

**1. Introduction.**—In the first three papers dealing with intermediate ions, the solubility and conductivity results on a large number of uni-bivalent salts were presented. Perhaps the most striking experimental result obtained was that while the salts of this type behave quite normally as to the variation of their solubility when either (1) a salt with a common univalent ion, or (2) a salt with *no common ion* is added to the solution, the same is not true when (3) a salt with a common bivalent ion is added. In the latter case the effect is on the whole a normal one, with one exception which will be pointed out later, when the saturating salt is of extremely slight solubility, as was the case with lead iodate, solubility 0.00011-equivalent per liter at 25°. However, as the solubility of the saturating salt increases, the effect becomes more and more abnormal, until for very soluble salts the solubility curve for the common bivalent ion takes on the form of a curve representing the addition of a salt with no common ion. The generality of the result at once suggests that the effect is not due to complex salt formation, which is more specific in its action.

The experimental work in this paper will deal with the solubility effects in the case of a tri-univalent salt. In solutions of salts of this type it would be expected that any abnormalities found in the relations of the uni-bivalent salts would become more pronounced, that is, when the two types of salts are compared at the same concentration. In the work on uni-bivalent salts all practical ranges of solubility have been studied from 0.0001 to 8.6 equivalents per 1000 grams of water, a range expressed by a factor nearly equal to 10,000. It was desired that the tri-univalent salt chosen should be as little inclined toward complex formation as possible, and in order that the principal part of the data might be obtained in very dilute solutions, a very slightly soluble salt was desired. There are as a matter of fact very few salts which meet these specifications, and of these lanthanum iodate seemed to be the best adapted for the purpose. Other suitable salts were certain cobaltammines, but lanthanum iodate has the advantage that it is a more stable salt, and that its solution can be analyzed with extreme accuracy.

**2. Preparation of Salts and Solutions. Lanthanum Iodate.**—Hot dilute solutions containing lanthanum nitrate and potassium iodate were brought together, the former being in excess. The solution was stirred, and then quickly cooled by pouring into a vessel surrounded with ice. The precipitated salt was filtered, washed and *recrystallized* (a very tedious process in the case of such a slightly soluble salt) from conductivity water, with a maximum specific conductance of  $0.6 \times 10^{-6}$ . The slightly soluble salt was recrystallized in large evaporating dishes heated on steam baths. The

white salt on analysis gave the value of  $\text{La}_2\text{O}_3$  and iodine value as calculated from the formula  $\text{La}(\text{IO}_3)_3$ . Spectrographs made on a 6-in. Rowland concave grating showed the presence of no other rare earth.

**Lanthanum Nitrate.**—Crystals of the double nitrate of lanthanum and ammonium were obtained from the Welsbach Burner and Light Co., through the courtesy of Dr. H. S. Miner. These were recrystallized. A solution of the salt was made and the lanthanum precipitated as the oxalate, thoroughly washed and ignited in platinum dishes to the oxide. The lanthanum nitrate was then made by adding an excess of the oxide to nitric acid and crystallizing the salt from the clear solution. The salt was recrystallized from conductivity water.

All of the other salts used were chemically pure salts recrystallized from conductivity water. In making solutions and in diluting, conductivity water of the quality mentioned above was used.

The solubility was determined by the method formerly employed by Harkins in this kind of work.<sup>1</sup> At least four separate solubility determinations, two from undersaturation and two from supersaturation, were made for each.

**3. Methods of Analysis. Iodate.**—About fifty cc. of the saturated solution were quickly transferred from its container in the thermostat to a small weighed glass-stoppered Erlenmeyer flask. Two samples were taken from each bottle, making eight analyses for each determination of the solubility. The weighings were made at once, the solution transferred to a 700 cc. beaker and the flask rinsed until a volume of 400 cc. was obtained. Three cc. of concentrated hydrochloric acid were added, 5 grams of potassium iodide put in, and sodium thiosulfate was run in from a weight buret until the color of iodine had about disappeared. Then two cc. of a freshly made starch solution were added and the titration completed. The time for the titration was in each case three minutes.

The thiosulfate solution was made up with conductivity water and kept in a black bottle with a siphon attached. It was carefully standardized against resublimed iodine, pure recrystallized potassium iodate, and against a standard solution of potassium permanganate. For use as a reagent the stock solution, which was one-tenth normal, was transferred to another black bottle and diluted to ten times its volume.

**Lanthanum.**—(1) A weighed quantity of the solution was evaporated in a small weighed platinum dish or crucible in an air bath and ignited to the oxide. (2) The solution was diluted and the lanthanum precipitated as the oxalate. The oxalic acid was liberated and titrated in the usual way.

Table I gives the solubility of lanthanum iodate in water as 0.6842 gram per 1000 grams of water at 25°.

Fig. 2.—The solubility of lanthanum iodate in solutions of other salts. (For the dilute solutions see Fig. 1.)

tions are given in Table II. The mean values for the solubilities, with the solubility of the saturating salt expressed in millimols, are found in Table III together with the fractional concentrations of the added salt and the fractional solubility of lanthanum iodate. The "fractional conc. of added salt" is the ratio

$$\frac{\text{Equivalent conc. of added salt}}{\text{Equivalent solubility of the saturating salt}}$$

while the fractional solubility is the ratio

$$\frac{\text{Solubility of salt in salt solution}}{\text{Solubility of salt in water}}$$

These ratios are used for plotting the curves in Fig. 5. The solubility data presented in Table II are given in a graphic form in Figs. 1 and 2, where the ordinates represent the equivalent solubility of lanthanum iodate and the abscissae, the equivalent concentration of the added salts.

### 5. Theoretical Limiting Solubility Curves for Various Type Salts.—

An examination of Figs. 1 and 2 shows that in the case of the tri-univalent salt, the addition of the common univalent ion gives the same form of curve as would be expected; that when a common trivalent ion is added the solubility decreases slightly, passes quickly through a minimum, and then

rapidly increases to a solubility greater than in water, with increasing concentration of the added salt. The rise of the curve in the latter case is far greater than would be the rise of a salt of the bi-univalent type of the same order of solubility. Fig. 2 shows the striking change of the curve from the type of the common ion to the one of the non-common ion.

We will now turn to a study of Fig. 5. The ordinates represent the fractional solubility of the dissolved salt, and the abscissas the fractional

concentration of the added salt. The heavy lines both solid and dotted represent the "theoretical limiting" curves for several types of salts. The coördinates for these curves were calculated by the following equations:

For a  $1,1 + 1$  or a  $2,2 + 2$  univalent salt with a univalent common ion added, or a bi-bivalent salt with a bivalent common ion added:

$$S(S + C) = 1.$$

For a  $1,2 + 1$  uni-bivalent salt with a univalent common ion added:

$$S(S + C)^2 = 1.$$

For a  $1,2 + 2$  uni-bivalent salt with a bivalent common ion added:

$$S^2(S + C) = 1.$$

For a  $1,3 + 1$  tri-univalent salt with a univalent common ion added:

$$S(S + C)^3 = 1.$$

For a  $1,3 + 3$  tri-univalent salt with a trivalent common ion added:

$$S^3(S + C) = 1.$$

For a  $1,4 + 1$  uni-tetravalent salt with a univalent common ion:

$$S(S + C)^4 = 1.$$

For a  $1,4 + 4$  uni-tetravalent salt with a tetravalent common ion:

$$S^4(S + C) = 1.$$

For a  $2,3 + 2$  bi-trivalent salt with a bivalent common ion:

$$S^2(S + C)^3 = 1.$$

For a  $2,3 + 3$  bi-trivalent salt with a trivalent common ion:

$$S^3(S + C)^2 = 1.$$

It was noted by Harkins, in the paper last referred to, that the curves of the salts of the  $1,1 + 1$  and the  $1,2 + 1$  types lie very close to the theoretical limiting curves, while the curves of the salts of the  $1,2 + 2$  type deviate from it very widely. Two experimental curves of salts of the

Fig. 3.—Theoretical limiting curves which express the fractional solubilities of various types of salts.

1,3 + 1, and the 1,3 + 3 types are interesting. In the first case the curve goes far below the theoretical limiting curve, then crosses and finally rises considerably above it, and in the second case we note a similar behavior, but the curve rises higher above the theoretical limiting curve. The latter part of this curve resembles the curves of the 1,2 + 3 type, and is similar to the curve showing the effect of the addition of a non-common ion. Harkins<sup>1</sup> found that several of the salts of the 2,1 + 1 type which he studied fell below the theoretical limiting curve. To see if a very insoluble salt of the 1,2 + 1 type would show this phenomenon to a greater degree, the curve for lead iodate in potassium iodate was plotted, and it may be seen that it falls about as far below as the curve for lanthanum iodate in potassium iodate and in general is similar in form. Of the two salts, lead iodate is much the more insoluble in water.

**6. Calculation of the Specific Conductance of Mixtures of Salts of the Tri-univalent Type.**—So far as is known to the writers no calculations have previously been made of the specific conductance of mixtures of salts of the tri-univalent type, at least not in cases where the salts in the mixture contain no common ion. For the calculations in this section the method employed is that previously used in the case of tri-ionic salts.<sup>2</sup> This method was first used to calculate the concentration of the constituents in mixtures of salts of the uni-univalent type, and has since been applied in a similar way for uni-bivalent salts. While from the standpoint of this paper, that is, that intermediate ions are present in solutions of salts of higher types, the calculated concentrations are only hypothetical, to those who still hold to the opposite theory they may appear to be real. In any event the results of such calculations will be of value for use in comparison of the uni-trivalent salts with those of lower types.

The values for the conductance and the conductance ratios of lanthanum nitrate and iodate, potassium and sodium iodates, and sodium nitrate, are given in Table IV, while Table V gives the apparent concentration of the constituents of mixtures in which lanthanum iodate is the saturating salt, and the added salts are lanthanum nitrate, potassium iodate and sodium nitrate. The logarithm of the apparent concentration of the un-ionized part of the saturating salt, lanthanum iodate (Table VI), is plotted against the logarithm of the apparent total ion concentration in Fig. 4, and Fig. 5 gives the similar values for the apparent solubility product, as calculated in Table VII. Tables VIII, IX and X give the similar values for a uni-bivalent salt, lead iodate.

When allowance is made for the fact that the concentration of a saturated lanthanum iodate solution is only about 0.001 molar, so that small errors in the conductance measurements produce a considerable per-

centage effect, it will be seen that the calculated specific conductances of the mixtures are very closely in accord with the determined values, when either the common univalent ion is added, or when the added salt is sodium nitrate, which has no common ion. It is remarkable that an empirical equation of the general form of the Storch equation, derived entirely from the behavior of uni-univalent or the simplest type salts, can be used to calculate with as good an accuracy as this, the conductance of mixtures of salts of such a high type as the uni-trivalent. However,

when the common ion is trivalent the agreement is not nearly so good, and the calculated values becomes several per cent. higher than that determined by experiment. This is in the direction of the change of conductivity which occurs when there is a small amount of complex formation.

Fig. 4 shows the variation in the apparent total ion concentration

Fig. 4.—The solubility of the un-ionized part of the salts calculated on the assumption that intermediate ions are not present.

for three uni-bivalent salts, lead iodate, barium iodate and barium bromate, and for one uni-trivalent salt, lanthanum iodate. Raising and shifting the curve for barium iodate toward one side will show how closely parallel are the similar curves for barium bromate and iodate, even although the former salt is 25 times as soluble as the latter. Lead chloride is about seven hundred times as soluble as lead iodate, yet a

comparison of the sets of curves for the two salts shows that the similar curves still remain very nearly parallel. It is remarkable that when a uni-univalent salt with a *non-common ion* is added, the curve for the apparent concentration of the un-ionized part of the saturating salt has practically the same slope whether the saturating salt is uni-, bi-, or tri-univalent.

In the case of the uni-univalent salt the apparent solubility of the un-ionized part always falls, at practically the same rate with the total ion concentration, no matter what the type of the added salt may be. However, in the case of the uni-bivalent salts the solubility of the apparent un-ionized part decreases much more rapidly when the common univalent ion is added, and what is much more remarkable, increases when the common ion is bivalent. We now find exactly the same result for the uni-trivalent salt, but in this case the apparent solubility of the un-ionized part increases much more rapidly at the same total ion concentration, than it does in the case of the uni-bivalent salts barium iodate and barium bromate, which are the most nearly similar in solubility. It may thus be said that these effects which are abnormal in the case of the uni-bivalent salts, become even more abnormal with this tri-univalent salt.

It is thus seen that when the concentration of the constituents of a mixture is calculated by the ordinary method, that in the case of higher type salts, the non-common ion salts have a seemingly normal effect upon the solubility of the non-ionized part of the salt, but that when a common univalent ion is added the effect is abnormal in giving an extraordinary depression in solubility, while with the common bivalent ion there is the much more abnormal and even absurd result that the solubility of the un-ionized part of the salt seems to rise rapidly. It has been shown by Harkins<sup>1</sup> that when calculations are made upon the basis of the non-existence of intermediate ions, just such abnormal results should be obtained in case intermediate ions are present, and that, if allowance is made for the presence of intermediate ions, according to the calculations presented in Table I of the present paper, these irregularities disappear, as well as the irregularities found in the behavior of the solubility product, as shown in Fig. 5. Thus assuming that Table I gives the proper percentage ionization of salts of the uni-bivalent type, it is found that upon calculation that the true solubility of the un-ionized part decreases at nearly the same rate, with the total ion concentration, no matter whether the salt added contains no common ion, a common univalent, or a common bivalent ion. That the somewhat greater abnormalities in the case of the tri-univalent salt could be as readily smoothed away seems certain

<sup>1</sup> *Loc. cit.*

when it is remembered that in the solution of such a salt there would be two intermediate ions instead of one.

Fig. 5.—The solubility product calculated on the assumption that intermediate ions are not present.

**7. Summary of Experimental Part.**—1. Equations are given for the calculation of the constituents of mixtures of salt solutions both on the basis of the non-existence and existence of intermediate ions. A comparison of the degrees of ionization of several substances calculated on both assumptions is also made.

2. Pure lanthanum iodate was made and its solubility at  $25^\circ$  was determined in solutions of salts containing common univalent ions, common trivalent ions, and non-common ions. It was found that: (a) the solubility decreases rapidly as the concentration of the salt having a common univalent ion increases; (b) the solubility decreases slightly at first and then increases as a salt with a common trivalent ion is added, the curve approaching the curve for the non-common ion effect.

3. Conductance measurements were made on the dilute solutions.

4. Calculations of the constituents of the mixtures of the solutions were made and curves were drawn to show the changes in the solubility products and concentrations of the un-ionized part with changes in the total ion concentration. In these calculations, intermediate ions are

assumed to not exist. It was found that the apparent concentration of the *un-ionized part* is affected normally by the addition of non-common ion salts; is affected abnormally by the presence of salts having a common univalent ion in that it gives an extraordinary depression; is affected even more abnormally by the addition of salts having a common trivalent ion, giving a rapid rise in the apparent solubility. These abnormalities disappear if intermediate ions are assumed to be present.

5. The theoretical discussion has not been summarized, since it has been given in a condensed form in the body of the paper.

## THE EFFECT OF SALTS UPON THE SOLUBILITY OF OTHER SALTS. VIIIa. THE SOLUBILITY RELATIONS OF A VERY SOLUBLE BI-UNIVALENT SALT.

BY WILLIAM D. HARKINS AND HARRY M. PAINE.

Received August 14, 1916.

### Introduction.

Since, as has been shown in previous papers of this series,<sup>1</sup> the moderately soluble uni-bivalent salts show such a wide variation from the solubility product principle, an investigation of the effect of the addition of salts to a bi-univalent salt of extremely high solubility was considered advisable. Strontium chloride with a solubility at 25° of 7.034 equivalents per 1000 grams of water, seemed to be the salt best suited for this purpose. Its solubility at 25° was determined in water and in various concentrations of strontium nitrate, sodium nitrate, nitric acid, hydrochloric acid, hydrobromic acid, hydriodic acid, potassium iodide, potassium chloride, cupric chloride, and potassium nitrate. The densities of all solutions and mixtures were measured. In calculations the atomic weights for 1911 were used and all weighings reduced to vacuum.

### Preparation of Salts.

**Strontium Chloride.**—A special grade of strontium chloride was recrystallized from conductivity water and the salt preserved in a moist condition in closely stoppered bottles.

**Sodium Nitrate.**—Sodium nitrate was recrystallized twice from conductivity water.

**Hydrochloric and Nitric Acids.**—"C. P." acids were used after careful testing.

**Hydriodic Acid.**—This acid was prepared by careful hydrolysis of phosphorus triiodide, with exclusion of air. The product obtained was carefully redistilled and showed no test for free iodine.

**Hydrobromic Acid.**—The acid was prepared in a manner analogous to that used for hydriodic acid.

<sup>1</sup> THIS JOURNAL, 33, 1808 (1911).

**Potassium Chloride.**—Potassium chloride "Zur analyse" was recrystallized twice from conductivity water.

**Potassium Iodide.**—The best potassium iodide obtainable was recrystallized from conductivity water.

**Cupric Chloride.**—This salt was recrystallized twice from conductivity water.

**Potassium Nitrate.**—Potassium nitrate was recrystallized three times from conductivity water.

### Methods of Analysis.

**Chloride, Bromide or Iodide.**—The halogens were determined by adding to the solutions, containing these radicals, a little less than an equivalent amount of dilute silver nitrate solution, allowing to stand overnight, and adding a slight excess of silver nitrate the next day.<sup>1</sup> The precipitates were transferred to platinum Gooch crucibles and washed with very dilute silver nitrate solution and then with water containing a little nitric acid. The weight of the precipitate weighed was about 2 g.

**Acids.**—These were determined by titration with 0.1 *N* sodium hydroxide which had been previously standardized against hydrochloric acid, the strength of which was determined gravimetrically.

**Nitrates.**—Several methods were thoroughly tried out and in every case where the nitrogen was finally obtained as ammonia, from strongly alkaline solution, it was found that the gelatinous strontium hydroxide precipitate adsorbed the nitrate sufficiently to destroy the accuracy of the result. The Pelouze-Fresenius method which depends on the oxidation of ferrous iron in a solution strongly acidified with hydrochloric acid was used. This was done in an atmosphere of carbon dioxide, carefully freed from oxygen, obtained from a Kipp generator charged with marble previously boiled in conductivity water, and hydrochloric acid boiled for fifteen minutes just previous to use. Cuprous chloride was added to absorb any remaining oxygen and a layer of oil poured over the acid on the surface exposed to air.

The carbon dioxide produced was further purified by passing through a tower of chromous acetate and then through conductivity water. A weighed amount of pure iron was dissolved in hydrochloric acid and the nitrate solution run in through a dropping funnel, care being taken to prevent the entrance of air. After standing for fifteen minutes at 100° the compound resulting from the addition of nitric oxide to the ferrous chloride was broken up by boiling, the solutions cooled, and in duplicate experiments titrations were made with both potassium permanganate and potassium dichromate. Carefully carried out this method gave, with solutions of known concentration, results always within 0.1% of the amount taken.

**Strontium.**—When required the strontium was determined by precipitation as carbonate and weighing both as carbonate and sulfate.

**Copper.**—This was determined by the iodide method using the modification suggested by Lowe.<sup>2</sup> In this as in all other volumetric methods employed, weight burets were used, and weighed amounts of solutions were taken.

**Iodides.**—In the determination of strontium chloride in potassium iodide a total halogen analysis was made and the iodine determined in a fresh portion of solution by the method of Bray and MacKay.<sup>3</sup>

### Solubility Measurements.

The results of the solubility determinations are given in Table I. In the majority of cases each point was checked by four duplicates.

The principal object of this investigation was to show that the predictions based upon the earlier investigations on the less soluble salts of the uni-bivalent type is true, namely, that the form of the solubility curve for the addition of a salt with a common bivalent ion is, on the whole, the same as that for the addition of a salt with no common ion when the

saturating salt is a very soluble one.<sup>1</sup> The first step in the ionization of strontium chloride is

and in a very concentrated solution this should be almost the only form of ionization. However, the second step in the ionization

must take place to a slight extent, and for this reason in solutions of strontium chloride and nitrate there should be a small percentage of the common  $\text{Sr}^{++}$  ion. Since the ions present to the greatest extent are the non-common  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SrCl}^+$ , and  $\text{SrNO}_3^+$  ions, the curve should have the same form as for the addition of a salt with no common ion, but might fall slightly below the non-common ion curve on account of the presence of the small percentage of the common  $\text{Sr}^{++}$  ion.

That this is true is shown by the data in Table I. Thus the solubility of strontium chloride in solutions of strontium nitrate is practically the same as in water itself, and this is true also for nitric acid. Here the curves representing the effect of the common bivalent ion, and of no common ion, are the same. If, however, sodium nitrate is added the solubility of the strontium chloride increases slightly up to a concentration of 3.5 equivalents of sodium nitrate, but this increase amounts to only 5%. When the non-common ion salt potassium iodide is added, the solubility of the strontium chloride remains constant, just as when nitric acid or strontium nitrate is added. It is therefore found that in saturated solutions the solubility relationships seem, in so far as they bear upon the question at all, to accord with the hypothesis of intermediate ion formation, though the specific solubility effects are so great in these extremely concentrated solutions that this fact cannot be considered as bearing very strongly upon this question.

The principal work upon the effects of salts on the solubility of extremely soluble salts was done by Engel,<sup>2</sup> who developed the empirical rule that the addition of an acid to the saturated solution of an extremely soluble salt precipitates an equivalent quantity of the salt, and Armstrong<sup>3</sup> and others suppose that the reduction of solubility caused by an acid, or by a salt, is caused by the appropriation of solvent molecules by the substance which is introduced. According to the idea of Armstrong, strontium nitrate, potassium iodide and nitric acid do not appropriate any of the solvent.

The data given in Table I show that the solubility of strontium chloride

<sup>1</sup> However it was realized that in the case of so soluble a salt as strontium chloride, what may be called specific solubility, might largely, but probably not entirely, mask this result.

<sup>2</sup> *Compt. rend.*, 102, 619 (1886); 104, 433 (1887); *Ann. chim. phys.*, [6] 13, 376 (1888).

<sup>3</sup> *Proc. Roy. Soc.*, (A) 79, 564; 84, 123.

is greatly decreased by the addition of any halogen acid, whether or not the acid contains a common ion, but the solubility is not very greatly depressed by the addition of any of the alkali salts of the halogens which were used. While the salting out effect of the common chlorine ion is marked, it is plain that what may be called specific effects have become very prominent in these extremely concentrated solutions. This may be considered as probably due to a real solubility effect, and it seems that solutions of the halogen acids are poor solvents for salts, at least for the salts of the alkalis and alkaline earths.

Fig. 1.—Solubility of strontium chloride in equivalents per 1000 g. water at 25° C.

Fig. 1 shows that of the non-common ion acids, hydrobromic and hydriodic very greatly depress the solubility of strontium chloride, while in nitric acid the solubility per 1000 g. of water is the same as in the water alone. Since the curve for hydrobromic lies above that for hydriodic acid, it may be assumed that the hydrochloric acid curve would lie higher still were it not for its common ion effect. Just as hydrochloric acid depresses the solubility more than hydrobromic acid, so potassium chloride gives this effect more strongly than potassium iodide. The curves for sodium nitrate and nitric acid have, on the whole, the same relative positions as those for potassium iodide and hydriodic acid, and for potassium chloride and hydrochloric acid. In all of these cases the strontium chloride is much less soluble in the acid than in the corresponding salt solution. From the literature of the subject we would judge

that the salts of the alkalis are less soluble in solutions of bases, than in the corresponding salt solutions. Cupric chloride depresses the solubility much more than potassium chloride. The curve for the non-common ion effect of potassium nitrate is not plotted in the figure, but it lies close to the sodium nitrate curve, and only slightly above it. It was shown in an earlier paper that solubility effects, in general, can be divided into four classes. The specifically great depressing action of the acids upon very soluble salts gives a fifth class which is important.

Other specific effects have been noticed in work upon very soluble salts. For example, other salts seem in general to show a specially high solubility when the added salt is a nitrate. Thus a chloride depresses the solubility of a nitrate much more than the nitrate depresses the solubility of the chloride.

The fact that solutions of the halogen acids are much poorer solvents for salts of the alkalis and alkaline earths is important in connection with the determination of the relative degrees of ionization of these acids and salts. From conductivity measurements alone it was at one time supposed that hydrogen chloride is more highly ionized in aqueous solution than is potassium chloride. However, a study of the change of the migration values of the ions with the concentration has led to the idea that it is quite probable that the acid is not more highly ionized. The evidence obtained from solubility measurements has been opposed to the idea that both have the same ionization, since in dilute saturated solutions the solubility of a chloride is more depressed by hydrochloric acid than by an equivalent amount of potassium chloride. Now that it has been shown that hydrochloric acid is a poorer solvent for salts than a solution of potassium chloride, it destroys the supposed value of the evidence obtained by solubility measurements; or, since in dilute solutions the difference between the salting out effects of the acid and the salt is very small, it may be considered that if anything the solubility results tend to help prove that potassium chloride and hydrochloric acid are dissociated to practically the same extent.

## THE EFFECT OF SALTS UPON THE SOLUBILITY OF OTHER SALTS. VIII<sup>b</sup>. THE SOLUBILITY RELATIONS OF SOME EXTREMELY SOLUBLE SALTS.

By WILLIAM D. HARKINS AND W. TUDOR PEARCE.

Received August 18, 1916.

### Introduction.

In the preceding paper the solubility relations of the very soluble uni-bivalent salt, strontium chloride, have been discussed, and the present

paper will extend the work to three other salts, strontium bromide, which is extremely soluble (8.6 equivalents to 1000 g. of water), and to two pentaionic salts, potassium and sodium ferrocyanides. Extremely variable results have heretofore been obtained upon the solubility of potassium ferrocyanide in water. Thus the results vary from 28 to 48 g. per 100 g. of water at 25°. The data obtained by us give this value as 24.796 g. per 100 g. of water.

The principal object of this paper was to see if with these extremely soluble salts the effect of the presence of intermediate ions upon the solubility relations could be found, after allowances are made for the specific effects which are extremely large in solutions of such high concentration. The effect to be expected, if intermediate ions are present, is that the solubility should not be depressed by the addition of a salt with a common ion of a valence of more than one, and that the increase of solubility should increase with the valence of the common ion. That this is just what is found experimentally may be seen, but it is difficult to determine how much of the effect is due to the presence of intermediate ions, since there is no exact method for determining the magnitude of what have been called the specific solubility effects. However, the results of the work presented in these two papers, when compared with the data collected in the literature on lower type salts, seem to indicate that a part of this effect must be due to intermediate ions.

### Experimental.

**Preparation of Solutions.**—Salts of the highest purity obtainable commercially were crystallized from conductivity water in all cases and the method of procedure was the same as the one referred to in the preceding paper.

**The Solubility of Strontium Bromide in Strontium Nitrate.**—The bromine was determined by weighing as silver bromide. The precipitant, 0.01 *N* silver nitrate, was added in very slight excess. The precipitate was washed with 0.01 *N* nitric acid and finally with water very slightly acid. It was weighed in a Gooch crucible.

The nitrogen was determined by the Kjeldahl-Gunning-Jodwohl method with the usual precautions, *viz.*, letting the digestion mixture stand overnight and when distilling to continue the process until the flask is nearly dry. The results in grams per 1000 g. of water are given in Table I and shown graphically in Fig. 1.

**The Solubility of Potassium Ferrocyanide and Sodium Ferrocyanide in Each Other.**—The determination of hydroferrocyanic acid was made by a modification of de Haen's method. It was found necessary to use a very dilute solution and titrate in a definite time. To about 1 g. of ferrocyanide 100 cc. solution and 10 cc. of 0.5 *N* sulfuric acid were added and three minutes' time was taken for the titration.

The determination of potassium and sodium<sup>1</sup> were made by modification of the method given in Lunge's "Technical Analysis."<sup>2</sup> In order to get a satisfactory decomposition when the concentration of the added salt was high the following procedure was necessary: About 1 g. was taken for analysis. This was transferred to a beaker and diluted with 50 cc. of water; then 5 drops of sulfuric acid (1 : 10) were added, and

<sup>1</sup> Cf. Treadwell-Hall, Vol. II, p. 497.

<sup>2</sup> *Ibid.*, p. 729, Part 1; and *Ber.*, 36, 1930 (1903).

30 cc. of a filtered 0.1 *N* solution of ammonium persulfate. The solution was then warmed on water bath until colorless. If it was as still blue after forty minutes, another 30 cc. of ammonium persulfate were added. From this point on the method referred to gave satisfactory results.

To prevent oxidation, pure hydrogen was used to saturate all solutions before rotation and the air in the bottles was replaced by it. In spite of this precaution, decomposition certainly took place in some cases, as was made evident by the formation of a blue precipitate. In no case, except when the two solid phases were present, was a solution that gave a blue color to the asbestos mat through which it was filtered, used for analysis. In the exception mentioned, the solution analyzed showed only a faint coloration. All titrations were made and the samples for the potassium and sodium determinations taken, as quickly as was possible. However, it was noted that in all the solutions a blue precipitate was formed on standing, the amount of which increased with the time and with the concentration of the hydroferrocyanic acid. Although the change was very slight, and the agreement of duplicate analyses was good, so that the results when plotted give a fairly smooth curve, the degree of accuracy is not so great as was obtained in the work on the other salts.

### Solubility Measurements.

The results of the solubility measurements are given in Tables II and III and are shown graphically in Fig. 1.

Fig. 1 shows the interesting result, which is very similar to that obtained for strontium chloride,

that, up to 2.8 equivalent weight concentration (per 1000 g. of water) of added salt, the addition of strontium nitrate has no effect upon the solubility, that is, the solubility is expressed by a straight horizontal line. This is remarkable when it is considered that the most concentrated solution is 11.4 *N* with respect to total salt concentration. The data indicate that the solubility does not remain exactly constant, but the variation is extremely slight, only 0.78% for this wide range of concentrations.

The solubility results for potassium and sodium ferrocyanides are of even more interest, since they indicate that in the case of these salts of high type each salt increases the solubility of the other.

## Summary of Papers on Extremely Soluble Salts.

1. This paper and the one which precedes it give data for the solubility of the higher type salts, strontium chloride, strontium bromide, potassium ferrocyanide and sodium ferrocyanide, in solutions of different salts and acids. In these extremely concentrated solutions what may be called specific effects have become very prominent, so that the behavior of these salts does not give very definite evidence for or against the hypothesis of intermediate ion formation, but, nevertheless, the general solubility relations seem to be what would be expected if intermediate ions are present.

## THE MOLECULAR REARRANGEMENT OF TRIARYLMETHYL-AZIDES.<sup>1</sup>

By JAMES KUHN SENIOR.<sup>2</sup>

Received September 21, 1916.

Molecular rearrangements have been observed by Stieglitz and his collaborators in the triphenylmethane series when triphenylmethyl hydroxylamines<sup>3</sup>  $\text{Ar}_3\text{C.NHOH}$  are subjected to the action of phosphorus pentachloride, and when triphenylmethylhalogenamines<sup>4</sup>  $\text{Ar}_3\text{C.NH(Hal)}$  are treated with alkaline reagents. These rearrangements are entirely analogous,<sup>5</sup> respectively, to the Lossen-Beckmann rearrangements of acyl hydroxylamines and ketoximes and the Hofmann rearrangement of acyl halogenamines  $\text{RCO.NH(Hal)}$ —in fact the rearrangements in the triphenylmethane series were anticipated and explored as the result<sup>6</sup> of the investigations of Stieglitz on the nature of the Lossen-Beckmann-Hofmann rearrangements. There is a third group of acyl derivatives, the azides  $\text{RCO.N}_3$ , which, as Curtius found, undergo exactly the same kind of rearrangement as do the acyl hydroxylamines and halogenamines. This parallelism, together with Stieglitz's theory that the rearrangement in all of these cases is due to the primary formation of univalent nitrogen<sup>7</sup> derivatives,  $\text{RCO.N}$ ,  $\text{R}_3\text{C.N}$ , etc., made it appear certain that triphenylmethylazides  $(\text{C}_6\text{H}_5)_3\text{C.N}_3$ , would be found, on investigation, to undergo a rearrangement analogous to that of triphenylmethyl hydroxylamines and halogenamines. Further, it was anticipated that for the rearrangement of the azides heat<sup>8</sup> alone would be required

With the object of determining these relations, I undertook, at the

<sup>1</sup> A brief preliminary report by Stieglitz and Senior appeared in the *Proc. Nat. Acad. of Sciences*, **1**, 207 (1915).

<sup>2</sup> The work presented in this paper forms, in part, the basis of a dissertation presented to the University of Chicago in partial fulfilment of the requirements for the Ph.D. degree.

<sup>8</sup> Stieglitz, *Am. Chem. J.*, **18**, 751 (1896); **29**, 49 (1903).

suggestion of Professor Stieglitz, the investigation of triphenylmethyl azide. This seemed particularly desirable because, for the azides, the alternative theory of a direct exchange<sup>1</sup> of radicals in these rearrangements seems quite inapplicable. Cumulative evidence that in every instance the azides behave exactly as do the hydroxylamines and the halogenamines was anticipated.

A rearrangement somewhat analogous to the one I proposed to investigate had already been observed by Curtius<sup>2</sup> in the case of benzyl azide, and Curtius also interprets the formation of the main products of the rearrangement by assuming the formation of a univalent nitrogen derivative:

The reagent used was not heat alone, but a strong acid and heat, and the reactions were complicated by subsequent changes of the main products.

On the other hand, triphenylmethylazide itself had been prepared by Wieland<sup>3</sup> in 1909 and found to be remarkably stable for an azide, differing markedly in this respect from the well-known acyl azides. Nevertheless, it was noted that Wieland had observed that triphenylmethylazide turns yellow with decomposition at its melting point. This is the color of phenylimido-benzophenone, the product of rearrangement anticipated by us. Experiment showed, without difficulty, that triphenylmethylazide does indeed form this product in good quantity when it is heated, the rearrangement proceeding as indicated in Equation 1. The phenylimido-benzophenone was identified by its products of hydrolysis, aniline and benzophenone formed under the influence of acids.

As a further main object of the present investigation, it was proposed to examine substitution derivatives of this azide, such as  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C}.\text{N}_3$  and  $(\text{XC}_6\text{H}_4)(\text{YC}_6\text{H}_4)(\text{C}_6\text{H}_5)\text{C}.\text{N}_3$ . In the rearrangement of the intermediate univalent nitrogen derivatives, in some of the molecules the phenyl radical would presumably migrate from the carbon to the nitrogen. In other molecules the derived radical  $(\text{XC}_6\text{H}_4)$  or  $(\text{YC}_6\text{H}_4)$ , would be the migrating group. For a mono substitution product we should have the simultaneous rearrangements

<sup>1</sup> Beckmann, *Ber.*, 19, 988 (1886); 27, 300 (1894); Hoogewerff and van Dorp, *Rec. trav. chim.*, 8, 173 (1889); Hantzsch, *Ber.*, 24, 3516 (1891); Kuhara, *Mem. Coll. Sci. <sup>3</sup> *Ber.*, 42, 3020 (1909). Wieland did not look for any molecular rearrangement.

and

A determination of the ratio in which the groups migrate in a given case seemed of particular importance for the purpose of comparing such a ratio with the results obtained from similar studies of the rearrangement of the corresponding compounds in the triphenylmethyl hydroxylamine and halogenamine series. All these series should give, according to Stieglitz's theory, the same intermediate product  $(\text{XC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.N}$  and might well show the same ratio of migrating radicals in spite of the difference in environment (temperature, reagents, etc.), since the rearrangement of the univalent nitrogen derivative is an intramolecular reaction. The time at my disposal has permitted the exhaustive investigation of only one instance of this kind, namely the rearrangement of *p*-chlorophenyldiphenylmethylazide. I found that in 68.1% of the rearranging molecules the phenyl radical migrates to the nitrogen, in 31.9% the chlorophenyl group is the migrating one. For the corresponding *p*-chlorophenyldiphenylmethylhydroxylamine, Leech<sup>1</sup> obtained the ratio 70.8/29.2. These results compare very favorably with mine. A broader basis of comparison between the series will ultimately be necessary, if coincidences are to be excluded.

It is evident that, thus far, the triarylmethylazides behave qualitatively and quantitatively like the corresponding triarylmethylhydroxylamines—a result, which is decidedly in favor of the Stieglitz theory of these molecular rearrangements, and against the Beckmann theory of a direct exchange of the migrating groups.

#### Experimental Part.

**Triphenylmethylhydrazine Hydrochloride**,  $(\text{C}_6\text{H}_5)_3\text{CNH.NH}_2.\text{HCl}$  and **Symmetrical Bis-Triphenylmethylhydrazine**,  $(\text{C}_6\text{H}_5)_3\text{CNH.NHC}(\text{C}_6\text{H}_5)_3$ .—Some attempts to prepare the first of these substances by the method described by Wieland<sup>2</sup> were unsuccessful. The source of this unexpected failure was not sought, instead the following alternative procedure which gave satisfactory results was developed. Triphenylmethylchloride was prepared according to the method of Gomberg.<sup>3</sup> Hydrazine hydrate (8 g.) and triphenylmethylchloride (21 g., 95% pure) were boiled in the presence of 60 cc. of absolute ether in a flask fitted with a reflux condenser. After a few hours, a precipitate appeared, and in ten hours the reaction was complete. The contents of the flask were then filtered and the precipitate, chiefly *bis*-triphenylmethylhydrazine, washed with ether and with water. The ethereal filtrate was shaken twice with water to remove

<sup>1</sup> THIS JOURNAL, 36, 272 (1914).

<sup>2</sup> Ber., 42, 3021, 3025 (1909).

<sup>3</sup> Ibid., 33, 3147 (1900).

traces of hydrazine hydrochloride, and the ether layer then dried over calcium chloride. To the dried ethereal solution a strong solution of dry hydrogen chloride in anhydrous ether was added. The triphenylmethylhydrazine hydrochloride was precipitated as a gummy mass, which, on being scratched, quickly turned granular. The flask was cooled in ice for half an hour and the precipitate then collected in a filter and dried. The yield was 11.5 g. of substance, melting at 108–113°.

The compound was analyzed by titration according to the Volhard method.

0.2469 g. subs. required 7.89 cc. of 0.1 *N* AgNO<sub>3</sub>.

Calc. for C<sub>18</sub>H<sub>15</sub>N<sub>2</sub>HCl: HCl, 11.74. Found: 11.65.

Analyses of many samples prepared by this method always showed that the substance was nearly pure. It was, therefore, used without further refinement. Attempts to purify it by recrystallization from absolute alcohol and ether, according to the method of Wieland, failed in every case. The substance was always rapidly "alcoholized" by the solvent.

The precipitate formed in the flask when the hydrazine hydrate and triphenylmethylchloride were boiled together was symmetrical *bis*-triphenylmethylhydrazine. After it had been washed with ether and water on the filter, it was removed and boiled with alcohol, collected again on a filter and dried. The yield was 4 g. of material melting at 205°. The substance was further purified by the method of Wieland.<sup>1</sup> When pure, it melted at 210°.

**Triphenylmethylazide, (C<sub>6</sub>H<sub>5</sub>)<sub>3</sub>CN<sub>3</sub>.**—This compound was prepared from triphenylmethylhydrazine hydrochloride according to the method of Wieland.<sup>2</sup> The crude reaction product melting at 57° was used for the rearrangements. A small portion, recrystallized from alcohol, melted at 61°.

**Rearrangement of Triphenylmethylazide.**—Two portions of triphenylmethylazide of 0.5 g. each were heated in sealed tubes at 225° for one hour. The tarry product of the reaction was examined for the expected rearrangement product, phenylimido-benzophenone, as follows: it was extracted with about 20 cc. of benzene and the extract evaporated to dryness in a flask on the steam bath. No attempt was made to first to isolate the pure phenylimido-benzophenone from the residue thus obtained; instead, it was hydrolyzed and identified by its decomposition products, aniline and benzophenone. For this purpose this residue was dissolved in alcohol, a little hydrochloric acid was added to the solution, and the mixture boiled for half an hour in a flask fitted with a reflux condenser. Excess of sodium hydroxide was then added to the solution, and the liquid distilled with steam to isolate the aniline and benzophenone

<sup>1</sup> *Loc. cit.*

<sup>2</sup> *Ber.*, 42, 3027 (1909).

formed. The milky distillate gave a strong purple color with hypochlorite. It was acidified, the solution washed with ether to remove benzophenone, and the aqueous solution evaporated. It yielded 0.276 g. of substance, equivalent to 60% of the aniline hydrochloride, which could, theoretically, be obtained from the rearrangement of the amount of azide used. From the hydrochloride, the chloroplatinate of aniline was obtained and analyzed.

(I) 0.3772 and 0.1278 g. subs. gave 0.1258 and 0.0413 g. Pt.

Calc. for  $C_{12}H_{16}N_2PtCl_6$ : Pt, 32.75%. Found: (I) 33.35; (II) 32.32.

The ether extract of the acidified steam distillate on evaporation to dryness gave an oily residue. When this was seeded with a tiny crystal of benzophenone it quickly crystallized. The solid, after recrystallization from alcohol and water, melted at 47–47.5°. A mixture of this substance with benzophenone (melting point 47–47.5°) also melted at 47–47.5°.

These results identify the products of hydrolysis of the chief end product of the action of heat on triphenylmethylazide as aniline and benzophenone. These are the products of hydrolysis of phenylimido-benzophenone. Triphenylmethylazide undergoes rearrangement therefore under the influence of heat, as expressed in the equation

The phenylimido-benzophenone produced is then hydrolyzed by the dilute acid:

Attempts to isolate the intermediate phenylimido-benzophenone were given up on account of the large proportion of tarry products present.

***p*-Chlorophenyl-diphenylmethylhydrazine Hydrochloride**,  $(C_6H_4Cl)-(C_6H_5)_2C.NH.NH_2.HCl$ .—Dichlorodiphenylmethane,  $(C_6H_5)_2C.Cl_2$ , was prepared according to Mackenzie,<sup>1</sup> and from it *p*-chlorophenyl-diphenylmethylchloride was obtained by the method of Gomberg.<sup>2</sup> The substance used in the preparations to be described melted at 86°. It was analyzed by hydrolysis with standard alkali.

Calc. for  $C_{19}H_{14}Cl_2$ : hydrolyzable Cl, 11.33%. Found: 11.27.

In the preparation of *p*-chlorophenyl-diphenylmethylhydrazine hydrochloride and symmetrical *bis-p*-chlorophenyl-diphenylmethylhydrazine, the proportions of *p*-chlorophenyl-diphenylmethylchloride and hydrazine hydrate used must be varied according to which of these two products is desired. The method used to obtain the mono derivative is given here.<sup>3</sup> *p*-Chlorophenyl-diphenylmethylchloride (5.75 g.) and hydrazine hydrate (4 g.) were boiled with a small amount of absolute ether in a flask fitted

<sup>1</sup> *J. Chem. Soc.*, 69, 987 (1896).

<sup>2</sup> *Ber.*, 37, 1633 (1904).

<sup>3</sup> The preparation of the *bis*-derivative is described in the following paper.

with a reflux condenser. The hydrazine hydrate did not dissolve in the ether, and the two layers of liquid persisted till the end of the reaction. After a few hours a precipitate appeared, and at the end of eight hours the reaction was finished. The flask was stoppered and allowed to stand overnight. The reaction mixture was then poured through a filter moistened with absolute ether on a Hirsch funnel. The filtrate consisted of two layers. The upper layer was an ethereal solution of *p*-chlorophenyl-diphenylmethylhydrazine and the lower was a mixture of hydrazine hydrate and hydrazine hydrochloride. The ethereal layer was dried over calcium chloride and then an excess of dry hydrogen chloride in absolute ether was added to the solution. After a few minutes, a heavy precipitate of *p*-chlorophenyl-diphenylmethylhydrazine hydrochloride appeared. The flask was cooled in ice for about 15 minutes and the solid then collected on a filter and dried on a clay plate. It melted at 122°. The yield was 4 g.

The compound is not very stable. It is slowly decomposed by the moisture of the air, and all attempts to purify it by recrystallization failed. Consequently the crude substance was used to prepare the azide. It was analyzed by titration by the Volhard method.

0.1524 g. subs. required 4.91 cc. of 0.1 *N* AgNO<sub>3</sub>.

Calc. for C<sub>15</sub>H<sub>17</sub>ClN<sub>2</sub>HCl: HCl, 10.57. Found: 11.75.

A small amount of symmetrical *bis-p*-chlorophenyl-diphenylmethylhydrazine was always formed during the boiling of the *p*-chlorophenyl-diphenylmethylchloride with hydrazine hydrate. It crystallized out of the reaction mixture and was removed by the filtration on the Hirsch funnel. It was washed with alcohol and water to remove adhering traces of hydrazine, etc., and then dried. The yields were always small. The compound melted at 201°.

***p*-Chlorophenyl-diphenylmethylazide**, (C<sub>6</sub>H<sub>4</sub>Cl)(C<sub>6</sub>H<sub>5</sub>)<sub>2</sub>CN<sub>3</sub>.—For the preparation of this azide 4.8 g. of the corresponding hydrazine hydrochloride were dissolved in 60 cc. of absolute alcohol, and to this solution were added 30 cc. of hydrochloric acid, containing 7 g. of hydrogen chloride per 100 cc. of the acid. The flask was immersed in ice and 20 cc. of sodium nitrite solution, containing 1.6 g. of sodium nitrite, were run slowly into the solution while the flask was constantly shaken. The original solution in alcohol and acid was clear, but as the sodium nitrite was run in, the solution became cloudy and, on standing a few hours in the cold, the milky emulsion settled out at the bottom of the vessel as a yellowish gum. After the aqueous liquid had been decanted, the gum was dissolved in ether and the solution dried over calcium chloride. When the ether was boiled off, the yield of gum was 3.75 g.

All attempts to crystallize the material were unsuccessful. A variety of solvents and extreme cold were tried without avail. No analyses

were therefore attempted, and the crude substance was used directly for rearrangement.

**Rearrangement of *p*-Chlorophenyl-diphenylmethylazide.**—A solution of 3.75 g. of *p*-chlorophenyl-diphenylmethylazide in ether was placed in a hard glass test-tube, the ether was boiled out, and the tube containing the gum heated in a metal bath. At about 185° a fairly active evolution of gas began. The temperature was slowly raised until 215° was reached at the end of about ten minutes. The tube was then cooled, and the tarry mass examined for the products of rearrangement, phenylimido-chlorobenzophenone and chlorophenylimido-benzophenone, by the isolation of the products of hydrolysis of these two imides. The mass was extracted with ether, the ether extract transferred to a flask and the ether boiled off on the steam bath. About 30 cc. of alcohol and a little hydrochloric acid were added to the residue and the mixture boiled for half an hour with a reflux condenser. The liquid was then made alkaline with sodium hydroxide and distilled with steam. The distillate was a milky liquid containing oily drops which crystallized in standing. With hypochlorite it gave a strong purple color. It was acidified with hydrochloric acid, to convert the anilines into their salts, the ketones were removed by extraction with ether, and the ether extract (A) separated from the aqueous solution (B). The rearrangement was found to be far from quantitative<sup>1</sup> and on account of the small yields some difficulty was experienced in identifying the products. \*

(A) **Identification of Benzophenone and *p*-Chlorobenzophenone.**—The ether extracts (A) of the acidified steam distillates of several reactions like the one described above were combined. The ether was dried over calcium chloride and evaporated in an open dish. A crystalline residue was left. About three-fourths of this residue was dissolved by alcohol. The remainder, when dried on a clay plate, melted at 71–72°. When this substance was mixed with *p*-chlorobenzophenone (melting point 74.5–75.5°), the mixture melted at 72.5–73.5°. These results established the identity of this fraction of the unknown substance with *p*-chlorobenzophenone.

Attempts to isolate pure benzophenone from the alcoholic solution were unsuccessful. Efforts were made to use the fact that benzophenone is much more soluble than *p*-chlorobenzophenone in cold ligroin (boiling point 30–50°). The alcoholic solution was evaporated to dryness, extracted with ligroin, and the extract evaporated to dryness. The crystalline residue was again extracted with ligroin and the ligroin evaporated. The process was repeated once more. On evaporation, the final ligroin solution left behind the roset-shaped aggregates characteristic of *p*-chloro-

<sup>1</sup> Attempts to improve the yield by the use of acids and other reagents will be made in this laboratory.

benzophenone, and a few drops of oily liquid. When these drops were seeded with a tiny crystal of benzophenone, they crystallized. This action, often observed in this laboratory to be characteristic of benzophenone, was taken as an indication that the oily droplets consisted of benzophenone, but there was not enough pure material to confirm the conclusion.

(B) **Identification of Aniline and *p*-Chloroaniline.**—After the steam distillates of several reactions like the one described above had been acidified and extracted with ether, the aqueous solutions (B) were combined, made alkaline with excess sodium hydroxide and again extracted with ether. The ether extract was acidified with a little aqueous hydrochloric acid and evaporated to dryness. A white crystalline residue of hydrochlorides of aniline bases was left. This was divided into several portions and treated as follows:

(1) One portion was dissolved in water, made alkaline with sodium hydroxide and extracted with ether. The ether extract was dried over anhydrous potassium carbonate. To it was then added a solution of anhydrous oxalic acid in absolute ether. The white crystalline precipitate which immediately formed was filtered out, dried, and dissolved in a small amount of hot water containing a little oxalic acid. When the liquid was cooled, a precipitate appeared. This oxalate was brought on a filter and dried. The mother liquor gave with hypochlorite a strong purple color, showing definitely the presence of aniline in the original mixture. The oxalate just described was dissolved in a very little water, and to the solution a few drops of ammonia were added. An oil immediately separated, which, on standing a few minutes, solidified. The solid was brought on a filter and dried on a clay plate. It melted at  $67.5^{\circ}$ . When this substance was mixed with *p*-chloroaniline (melting point  $70.5^{\circ}$ ) the mixture melted at  $69.5^{\circ}$ . These results showed that this fraction of the unknown substance was *p*-chloroaniline. When burned on a clean copper wire, it gave a green flame, confirming the presence of halogen (chlorine).

(2) Another portion of the dry hydrochlorides described under (B) was dissolved in absolute alcohol and, after filtration of the solution, the hydrochlorides were reprecipitated by the addition of absolute ether containing a small amount of dry hydrogen chloride. The precipitate was collected and dried on a clay plate. From it were taken Samples I and II for the analyses given below under C. The alcohol-ether mother-liquor was evaporated to dryness, the residue taken up with absolute alcohol and the hydrochlorides again precipitated by means of absolute ethereal hydrochloric acid. This second precipitate was collected and dried as before. From it, analysis Sample III was taken.

(3) A third portion of the dry hydrochlorides described under (B) was treated like the portion (2), except that the precipitation process was carried out a third time. All three yields of precipitate in this case were combined, and from the mixture, analysis Sample IV was taken.

The qualitative results thus far obtained have shown that products of the action of heat on *p*-chlorophenyl-diphenylmethylazide yield on hydrolysis chlorobenzophenone and benzophenone besides aniline and chloroaniline. These are the products to be expected from the hydrolysis of phenylimido-chlorobenzophenone

and chlorophenylimido-benzophenone

the two imido ketones which are the anticipated products of the rearrangement of the azide (see Equations 3 and 4).

(C) **The Determination of the Ratio of the Rearrangement Products.**—A determination of the ratio in which the two imidoketones are formed was a matter of considerable theoretical interest (see the theoretical part of this paper). For this reason the molecular proportions of the hydrochlorides of the two bases were next determined, the samples enumerated under (B) being analyzed volumetrically by the bromination method of Curme.<sup>1</sup>

	Mixed hydrochloride.	0.1N KBrO <sub>3</sub> required.	Molecular % aniline.	Molecular % <i>p</i> -chloroaniline.
(I)	0.0384 g.	14.75 cc.	69.2	30.8
(II)	0.0415	15.68	66.5	33.5
(III)	0.0221	8.14	62.4	37.6
(IV)	0.0418	16.15	74.1	25.9
			Average, 68.1	31.9

The proportions in which the pair of rearrangement products of *p*-chlorophenyl-diphenylmethylazide are formed are very close to those found by Leech for *p*-chlorophenyl-diphenylmethylhydroxylamine (70.8/29.2).

In conclusion I wish to express my gratitude to Professor Stieglitz under whose direction this work was done, and to whom I am much indebted for the kind assistance and advice which enabled me to carry it out.

# THE MOLECULAR REARRANGEMENT OF *sym.-bis*-TRIARYLMETHYLHYDRAZINES.<sup>1</sup> PRELIMINARY REPORT.

BY JULIUS STIEGLITZ AND JAMES KUHN SENIOR.<sup>2</sup>

Received September 21, 1916.

The fundamental analogy between hydroxylamine and hydrazine is a well-established fact,<sup>3</sup> equally evident from the reactions of the substances and from the parallelism existing between their organic derivatives, a parallelism which extends even to the formation of stereoisomeric oximes and hydrazones.<sup>4</sup> It seems to have escaped comment, however, that in one important respect there exists a gap between the chemistry of hydroxylamine derivatives and that of the corresponding derivatives of hydrazine. Hydroxamic acids<sup>5</sup>  $\text{RCO.NHOH}$ , dihydroxamic acids  $\text{RCO.NHO.COR}$ , ketoximes<sup>7</sup>  $\text{R}_2\text{C} : \text{NOH}$ , and triphenylmethylhydroxylamines<sup>8</sup>  $\text{R}_3\text{C.NHOH}$ , under the influence of appropriate reagents, readily undergo molecular rearrangements in which a radical R migrates from the carbon atom originally holding it to the neighboring nitrogen atom. Similar rearrangements<sup>9</sup> of hydrazine derivatives have never been observed or even attempted, as far as we can find. It is worthy of note, too, that even derivatives of hydrogen peroxide, the third member<sup>10</sup> of the hydrazine-hydroxylamine family,<sup>11</sup> undergo rearrangements analogous to those of the hydroxylamine derivatives; this fact has been observed, for instance,

<sup>1</sup> A brief statement was published in *Proc. Nat. Acad. Sciences*, **1**, 207 (1915).

<sup>2</sup> The work in this paper forms the basis, in part, of a dissertation presented to the University of Chicago in fulfillment of the requirement for the Ph.D. degree.

Chem.*, **25**, 443 (1912); Stieglitz and Leech, *Ber.*, **46**, 2147 (1913); *THIS JOURNAL*, **36**, 272 (1914); Stieglitz and Stagner, *Ibid.*, **38**, 2046 (1916); Stagner, *Ibid.*, **38**, 2069 (1916), and Vosburgh, *Ibid.*, **38**, 2081 (1916).

<sup>9</sup> The benzidine and related rearrangements are of a different type, although arising no doubt from the same source of instability in the molecules involved (see Stieglitz and Stagner, *THIS JOURNAL*, **38**, 2051 (1916).

<sup>10</sup> Cf. Angeli, *Loc. cit.*; Stieglitz and Curme, *Loc. cit.*; Stieglitz and Leech, *Loc. cit.*

<sup>11</sup> The list might well be extended to include hypochlorous, hypobromous and hypoiodous acids and their derivatives. The members have as a common characteristic an atom with an unstable positive charge and a tendency to convert this atom into the common, stable negative variety.

in the cases of ketone peroxides<sup>1</sup> and triphenylmethyl peroxide.<sup>2</sup> The fundamental analogy between hydrazines, hydroxylamines and peroxides suggested the desirability of investigating hydrazine derivatives from this point of view, and of attempting to close the gap which at present exists between these groups in this one respect. The theory of one of us as to the mechanism and cause of the molecular rearrangements of this type made it appear altogether likely that similar rearrangements might be brought about without great difficulty in hydrazine derivatives. As is known, according to this theory,<sup>3</sup> the rearrangement of a triarylmethylhydroxylamine, for instance, is considered to be due to the formation of a univalent nitrogen derivative by the loss of water, or its equivalent, under the influence of a dehydrating agent like phosphorus pentachloride.

To effect the rearrangement of the corresponding hydrazines, it seemed only necessary to use a suitable reagent to induce the loss of ammonia.

From the point of view of the electronic theory of valence, we consider<sup>4</sup> that the primary force leading to the rearrangement of hydroxylamine derivatives<sup>5</sup> resides in the *unstable positive charge* on the oxygen atom.<sup>6</sup> There must be a great tendency of the positive hydroxyl group to go over into its common, stable negative form, as it does, if water or its equivalent is taken from the hydroxylamine derivative by dehydrating agents. We have

<sup>1</sup> Baeyer, *Ber.*, 32, 3627 (1900). The relation of the peroxide rearrangement to the rearrangements of hydroxylamine derivatives was first recognized by Baeyer, but both were given a wrong interpretation (see Stieglitz, *Am. Chem. J.*, 29, 49 (1903); and Stieglitz and Stagner, *Loc. cit.*). Especially the results in this laboratory on the rearrangements of triphenylmethane derivatives make Baeyer's assumptions quite untenable. The peroxides have now been included in our studies of the theory from the point of view of the one of us.

<sup>2</sup> Wieland, *Ber.*, 44, 2350 (1911).

<sup>3</sup> The literature references are given by Stieglitz and Leech, *Loc. cit.*, and Stieglitz and Stagner, *Loc. cit.*

<sup>4</sup> The electronic version of the univalent nitrogen theory of one of us for this and analogous rearrangements is found in detail in *THIS JOURNAL*, 36, 272 (1914). While the article was in press an article by L. W. Jones appeared (*Am. Chem. J.*, 50, 440 (1913)), giving an interpretation of this theory, differing from the Stieglitz views in some important details, but agreeing with them in the fundamental considerations. See footnote, *THIS JOURNAL*, *Loc. cit.*, p. 287.

<sup>5</sup> Stieglitz and Leech, *Loc. cit.*

<sup>6</sup> For the rearrangement of the closely related chloroamines similar relations hold, as expressed by Stieglitz and Leech, *Ber.*, 46, 2147 (1913).

The shifting of electrons is indicated by heavy type for the charges which are about to undergo change.

In hydrazines,  $\text{H}_2\text{N}^+ \text{---} \text{NH}_2$ , there is likewise an unstable positive group,<sup>1</sup> which should have a decided tendency to go over into the stable negative radical  $\text{N} \equiv$  as it exists in ammonia  $\text{N} \equiv (\text{H}^+)_3$ . If this tendency showed itself in the loss of ammonia by certain hydrazine derivatives, it might lead to a series of reactions similar to those just described and ending in the postulated molecular rearrangement.

From this point of view the reagents that suggest themselves for effecting such rearrangements are strong acids and zinc chloride. To our disappointment, not a single rearrangement of this character was observed in studying the effect of concentrated sulfuric acid on a great variety of hydrazine derivatives.<sup>2</sup> Simple hydrolysis or sulfonation was the only reaction detected. The heating of dry hydrochlorides of hydrazine derivatives was no more effective in producing rearrangements.

Although these experiments were preliminary ones, they were sufficiently extensive and thorough to make us pause and consider the theoretical relations in greater detail. In the case of the hydroxylamine derivatives which undergo rearrangement, there can be no question as to the distribution of the original charges—the hydroxyl in hydroxylamine  $\text{H}_2\text{N} \text{---} \overset{+}{\text{OH}}$  is originally positive and ultimately forms water (or its equivalent) with a negative hydroxyl group.<sup>3</sup> For the substituted hydrazines, however, we have as yet no trustworthy basis for determining the exact electronic structure.<sup>4</sup> A single illustration will make the point clear: triphenylmethylhydrazine may have either of two electronic structures:

Either one, according to the mechanism of the possible loss of ammonia, might account for the failure of acids to induce the loss of ammonia and subsequent rearrangement. In B, for instance, the  $\text{NH}_2$  group is already negative and in its most stable electronic structure, and so the funda-

<sup>1</sup> Stieglitz and Curme, *Ber.*, **46**, 911 (1913).

<sup>2</sup> Some of these experiments and their results will be described later by Mr. Senior.

<sup>3</sup> See the evidence given by Stieglitz, *THIS JOURNAL*, **36**, 288 (1914), and by Jones, *Ibid.*, **36**, 1268 (1914).

<sup>4</sup> In the salts the wholly negative nitrogen atom is probably the one that is combined with the acid, but this does not help us toward a solution of the problem before us.

mental force leading to its elimination from the molecule as ammonia with the subsequent rearrangement of the organic radical might well be altogether lacking.<sup>1</sup> These considerations made it appear desirable to attempt the rearrangement of a *symmetrical molecule*, bis-triphenylmethylhydrazine, about whose electronic structure there can be no doubt:  $(\text{C}_6\text{H}_5)_3\text{C.NH}^+ \text{---} \text{NH.C}(\text{C}_6\text{H}_5)_3$ . A loss of triphenylmethylamine from *either side* would yield a univalent nitrogen derivative  $(\text{C}_6\text{H}_5)_3\text{C.N}$  and rearrangement should inevitably follow. Whether this argument is ultimately found to be right or wrong, it certainly is of peculiar interest that in this instance we were at last successful in effecting a rearrangement. Zinc chloride was the agent used. The occurrence of a rearrangement was proved by the isolation and identification of aniline as a product of the action: aniline could be formed only by a migration of a phenyl radical from carbon to nitrogen—the typical migration of this class of molecular rearrangements. As far as we can discover, this is the first time any hydrazine derivative has been observed to rearrange in this fashion. *sym.-bis-p*-Chlorophenyl-diphenylmethylhydrazine,  $(\text{ClC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.NH.NHC}(\text{C}_6\text{H}_5)_2(\text{C}_6\text{H}_4\text{Cl})$ , has been found by us to suffer the same rearrangement, producing aniline and, probably, *p*-chloroaniline as well. This agrees with the results obtained in the molecular rearrangements of *p*-chlorophenyl-diphenylmethylhydroxylamine  $(\text{ClC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.NHOH}$  and the corresponding chloroamine  $(\text{ClC}_6\text{H}_4)(\text{C}_6\text{H}_5)_2\text{C.NHCl}$ .

As to the mechanism of the rearrangement of the hydrazine we can state nothing positive, since the action is not a smooth one and the products, other than aniline and triphenylmethane, a product of a parallel reaction, have not, as yet, been identified. It is altogether likely, however, that the rearrangement is the result either of a primary dissociation into a univalent nitrogen derivative, along the lines indicated above, or of a dissociation into bivalent nitrogen radicals, according to

$$\begin{array}{c}
 (\text{C}_6\text{H}_5)_3\text{CNH.NHC}(\text{C}_6\text{H}_5)_3 \longrightarrow 2(\text{C}_6\text{H}_5)_3\text{C.NH} \longrightarrow 2(\text{C}_6\text{H}_5)_2\text{C.NHC}_6\text{H}_5 \\
 \begin{array}{c} | \\ (\text{C}_6\text{H}_5)_2\text{C.NHC}_6\text{H}_5 \end{array} \qquad \qquad \qquad \begin{array}{c} | \\ (\text{C}_6\text{H}_5)_2\text{C.NHC}_6\text{H}_5 \end{array} \\
 \begin{array}{c} | \\ (\text{C}_6\text{H}_5)_2\text{C.NHC}_6\text{H}_5 \end{array}
 \end{array}
 \tag{4}$$

The latter reaction would correspond to the molecular rearrangement of triphenylmethylperoxide under the influence of heat, as observed and interpreted by Wieland.<sup>2</sup> It may be remarked in this connection that, in the case of the rearrangement of  $\beta$ -triphenylmethyl- $\beta$ -methylhydroxylamine, where the same alternative was presented, exhaustive examina-

<sup>1</sup> A decomposition  $(\text{C}_6\text{H}_5)_3\text{C.NH} \text{---} \text{NH}_2 \longrightarrow (\text{C}_6\text{H}_5)_3\text{C.NH}_2 + (\text{NH})$  would not lead to a rearrangement. This would hold either for A or B.

<sup>2</sup> *Loc. cit.*

tion of the secondary products finally decided against this type of rearrangement for the hydroxylamine compound in question.<sup>1</sup>

The formation of triphenylmethane is probably the result of a parallel decomposition of the symmetrical hydrazide, as expressed in the equation

The reaction is of some interest from the electronic point of view. We have:<sup>2</sup>

According to this equation, the instability of the radical  $\equiv\text{N}^+$  leads to a breakdown of the molecule, in which the extraordinarily stable nitrogen is formed by a transfer of electrons to (*i. e.*, reduction of) the methyl carbon atoms.<sup>4</sup>

### Experimental Part.<sup>5</sup>

*sym.-bis-Triphenylmethylhydrazine*,  $(\text{C}_6\text{H}_5)_3\text{CNH.NHC}(\text{C}_6\text{H}_5)_3$ .—The compound was prepared according to the method described by one of us,<sup>6</sup> and purified by the method of Wieland.<sup>7</sup> The substance used for rearrangement melted at 210°.

**Rearrangement of *sym.-bis-Triphenylmethylhydrazine*.**—One gram of the substance was triturated with 6 g. of anhydrous zinc chloride in a warm mortar. The mixture turned bright yellow. It was transferred to a hard glass test-tube and heated in a metal bath at 300° for ten minutes. After the tube had been cooled, the dark-colored melt was dissolved out with ether and water. Sufficient sodium hydroxide was added to get all the zinc into alkaline solution and the liquid was then shaken twice

<sup>1</sup> Stieglitz and Stagner, *THIS JOURNAL*, 38, 2046 (1916).

<sup>2</sup> The electronic structure given to free nitrogen is simply illustrative. The formula used agrees with the formation of nitrogen from ammonia and nitrous acid, but the reversed action, the saponification of nitrogen (nitrous acid nitril) does not seem to have been accomplished as yet. Free energy calculations, made at the suggestion of Professor G. N. Lewis, indicate, as anticipated, that the hydrolysis would involve the absorption of a great deal of energy. The combination of nitrogen, as a substituted amine, has also not yet been accomplished, although preliminary experiments to combine it with hydrogen chloride were made by one of us some years ago. An investigation of these problems and of the electronic structure of nitrogen is being undertaken.—J. S.

<sup>3</sup> The electronic changes are indicated by heavy type.

<sup>4</sup> The decomposition of the hydrazide in this direction is being further investigated by Mr. R. L. Brown.

<sup>5</sup> I am glad to take this opportunity to thank my young collaborator for his painstaking experimental work and tenacious energy in an investigation that at first brought only disappointing results.—J. S.

<sup>6</sup> See the preceding article.

<sup>7</sup> *Ber.*, 42, 3022 (1909).

in a separatory funnel with ether. The ether layers were combined, transferred to a flask, and the ether boiled off on the steam bath. A tarry residue remained behind. With the object of having any aniline derivative present hydrolyzed, this residue was dissolved in alcohol and some hydrochloric acid added to the solution, which was then boiled for half an hour under a reflux condenser. Excess of sodium hydroxide was next added, and the mixture steam distilled. The cloudy distillate was collected in two portions. The first portion gave a strong purple color with hypochlorite, thus showing the presence of aniline. When the droppings ceased to give this test, the receiver was changed. Throughout the distillation a white solid (later identified as triphenylmethane) was deposited in the condenser. When this substance ceased to come over, distillation was stopped. The first portion of the distillate was acidified with hydrochloric acid and extracted with ether, the acid solution (A) being preserved for further investigation. The second portion of the distillate was also extracted with ether, and the water layer discarded. The two ether extracts were combined and to them was added the ethereal solution of the solid which collected in the condenser.

The acid solution (A) of the first distillate, on evaporation, yielded a small amount of white crystalline residue. From the qualitative tests, the substance was presumed to be aniline hydrochloride. For the quantitative study, the process described had to be repeated several times to obtain sufficient material for analysis. When this material was treated with chloroplatinic acid, the precipitate was found to be pure aniline chloroplatinate.

0.1375 g. subs. gave 0.0451 g. Pt. Calc. for  $C_{12}H_{18}N_2PtCl_6$ : Pt, 32.75. Found: 32.80.

The combined ether extracts of the distillate were dried over calcium chloride and the ether then evaporated. There was left a gummy residue which, on being scratched, quickly crystallized. The crystals, when dried on a clay plate, melted at  $79-81^\circ$ . When the yields of several experiments such as the one described above had been collected, the substance was crystallized from alcohol. After two recrystallizations, the compound apparently had a constant melting point of  $81.5-82^\circ$ .

(I) 0.1496 and 0.1620 g. subs. gave 0.0834 and 0.0903 g.  $H_2O$  and 0.5062 and 0.5476 g.  $CO_2$ . Calc. for  $C_{18}H_{18}$ : C, 93.40; H, 6.60. Found: (I) C, 92.28 and 92.19; H, 6.24 and 6.24.

Qualitative and quantitative (combustion) tests showed the absence of nitrogen, and a qualitative test for halogen also proved negative. The melting points of mixtures showed that the material was neither triphenylcarbinol nor triphenylmethylether, which might have been formed by hydrolysis or alcoholysis of the hydrazine or of one of its decomposition products. A mixture of equal quantities of triphenylmethane (m. p.  $89-90^\circ$ ) and the substance, melted at  $85-89^\circ$ , and a mixture of four parts of the substance with one part of triphenylmethane showed no depression

of the melting point of the substance. The compound gave the (spectroscopic) *p*-rosaniline test for triphenylmethane. The substance seems therefore to be somewhat impure triphenylmethane.<sup>1</sup>

In an effort to obtain a smoother rearrangement and reaction, attempts were made to rearrange *sym.-bis-triarylmethylhydrazine* by heat (in a sealed tube) and also by the action of dry hydrogen chloride at 300°. In both cases the substance was decomposed, but no trace of aniline could be found in the hydrolyzed reaction products. The reactions were not further investigated.<sup>2</sup>

*sym.-p-Chlorophenyl-diphenylmethylhydrazine*,  $(C_6H_4Cl)(C_6H_5)_2CNH.NHC(C_6H_5)_2(C_6H_4Cl)$ .—Dichlorodiphenylmethane,  $(C_6H_5)_2CCl_2$ , was prepared according to Mackenzie,<sup>3</sup> and from it *p*-chlorophenyl-diphenylmethylchloride by the method of Gomberg.<sup>4</sup> The action of this chloride on hydrazine gives fair yields either of the mono-substituted hydrazine or of the *bis*-derivative, according to the conditions used. The preparation of the mono-derivative is described in the preceding article. For the preparation of the *bis*-derivative, *p*-chlorophenyl-diphenylmethylchloride (5.75 g.) and hydrazine hydrate (2 g.) were boiled for seven hours in the presence of a small amount of absolute ether in a flask fitted with a reflux condenser. A considerable amount of precipitate was formed. The mixture was filtered on a Hirsch funnel, the filter being wet with ether, and the precipitate washed with ether, water and alcohol to remove adhering impurities. When dried on a clay plate, it melted at 201°. Attempts were made to recrystallize this material by the same method as that used in the case of *sym.-bis-triphenylmethylhydrazine*. The substance was dissolved in hot benzene. On addition of warm alcohol it crystallized out. There was no apparent decomposition, but that some change had occurred was shown by the fact that the melting point of the substance was much lower than that of the original substance. Several repetitions of the process yielded a product melting at 171°. This substance was analyzed.

0.2903 g. subs. gave 0.1377 g. Ag Cl (Carius' method).

(I) 0.3610 g. subs. gave 5.12 cc. of  $N_2$  at 28.0° and 729.9 mm.; (II) 0.3727 g. gave 5.31 cc. at 28.8° and 729.1 mm.

Calc. for  $C_{28}H_{20}N_2Cl_2$ : Cl, 12.12; N, 4.79. Found: Cl, 11.73; N, (I) 1.54, (II) 1.54.

On account of the obvious decomposition encountered in the attempt to recrystallize it, the crude substance melting at 201° was next analyzed.

<sup>1</sup> To confirm this conclusion and especially to secure sufficient material for a molecular-weight determination, the preparation will be repeated as soon as occasion offers. (Since this was written, Mr. R. L. Brown has obtained the product as pure triphenylmethane, melting at 92°.—J. S.)

<sup>2</sup> They are now being investigated by Mr. R. L. Brown.

<sup>3</sup> *J. Chem. Soc.*, 69, 987 (1896).

<sup>4</sup> *Ber.*, 37, 1633 (1904).

0.3600 g. subs. gave 21.21 cc. of  $N_2$  at  $22.4^\circ$  and 740.1 mm.

Calc. for  $C_{18}H_{10}N_2Cl_4$ : N, 4.79. Found: 6.63.

The high nitrogen content of this crude substance melting at  $201^\circ$  was supposed to be due to an impurity of hydrazine. The substance was assumed for the present to be *sym.-bis-p-chlorophenyl-diphenylmethylhydrazine* and was used in a preliminary way as material for rearrangements. This compound and its decomposition product, melting at  $171^\circ$ , will be investigated further in this laboratory.

**Rearrangement of *sym.-bis-p-Chlorophenyl-diphenylmethylhydrazine*.**

—The rearrangement was carried out with the aid of zinc chloride in exactly the same way as described above for the corresponding chlorine-free compound. A considerable portion of the original melt was found to be insoluble in both ether and water. Steam distillation, after the hydrolysis of the product (see above), yielded a slightly cloudy distillate which gave a purple color with hypochlorite. No substance solidified in the condenser as in the case of the triphenylmethyl compound. The distillate was acidified with hydrochloric acid and shaken with ether. After the ether layer had been dried over calcium chloride, it was evaporated to dryness. The gummy residue left behind was so trifling in amount that it was not further investigated. The acidified water layer was evaporated to dryness. A small white crystalline residue was left behind. This was presumably a mixture of the hydrochlorides of aniline and *p*-chloroaniline.

When the yields of several reactions like the one described above had been collected and combined, the substance was dissolved in water, and a little sodium hydroxide added to the solution. The solution was shaken twice with ether, and the ether layer separated and dried over anhydrous potassium carbonate. To it was added an absolute ethereal solution of anhydrous oxalic acid. The precipitate formed was filtered out and dried on a clay plate. A small portion of it, when heated on a clean copper wire, gave a green flame, indicating that probably some *p*-chloroaniline was present. The main part of the precipitate was dissolved in a small amount of hot water containing a little oxalic acid. When the solution was cooled, a crystalline precipitate separated out. This was filtered off and dried. The mother liquor gave a strong purple color with hypochlorite, thus confirming the presence of aniline. The precipitate was dissolved in a little water and a few drops of ammonia added. The solution became cloudy, but the expected separation of solid *p*-chloroaniline did not occur. The solution was shaken with ether and the ether layer separated and evaporated to dryness. When the small gummy residue was scratched with a tiny crystal of *p*-chloroaniline, it crystallized. This indicated that the gum was probably impure *p*-chloroaniline, but the amount of material was too small to permit of further identification.

**Attempts to Rearrange Unsymmetrical Hydrazines and Hydrazones.**

A number of attempts were made to rearrange unsymmetrical hydrazines and hydrazones. These attempts were in all cases unsuccessful. A short account of them is appended.

**Triphenylmethylhydrazine Hydrochloride**,  $(\text{C}_6\text{H}_5)_3\text{C}-\text{NH}-\text{NH}_2\text{HCl}$ .—The preparation of this compound has already been described.<sup>1</sup> Some of the substance (0.5 g.) was triturated with anhydrous zinc chloride (3 g.) and the mixture heated in a test tube to  $300^\circ$ . No trace of aniline could be detected in the hydrolyzed reaction product.

**Benzophenonehydrazone**,  $(\text{C}_6\text{H}_5)_2\text{C}=\text{NNH}_2$ .—The substance was prepared according to Curtius.<sup>2</sup> The sample used melted at  $96.5^\circ$ . A small portion was heated for half an hour at  $100^\circ$  with an excess of concentrated sulfuric acid. No aniline or aniline sulfonate could be detected in the reaction product.

**Benzophenonehydrazone Hydrochloride**,  $(\text{C}_6\text{H}_5)_2\text{C}=\text{NNH}_2\text{HCl}$ .—The substance was prepared according to Curtius.<sup>3</sup> The sample used melted at  $182.5^\circ$ . One gram of substance was heated to  $275^\circ$  for ten minutes in a stream of dry hydrogen chloride. No aniline could be detected in the reaction product.

**Benzophenonephenylhydrazone**,  $(\text{C}_6\text{H}_5)_2\text{C}=\text{NNH}(\text{C}_6\text{H}_5)$ .—The substance was prepared according to Pickel.<sup>4</sup> The sample used melted at  $136.5^\circ$ . Some of the substance (2 g.) was heated for one hour at  $100^\circ$  with 20 cc. of concentrated sulfuric acid. No trace of aniline could be found in the reaction product. When the substance was treated at room temperature with dry hydrochloric acid gas, it was observed to turn red and absorb two molecules of hydrochloric acid which were given off again when the addition product was heated in the air. No formation of aniline could be detected.

One phenyl hydrazine derivative, after treatment with zinc chloride, gave a test for aniline. But as this might have been formed from the original substance by some process other than intramolecular rearrangement, its presence was not considered significant.

**$\alpha$ -Triphenylmethyl- $\beta$ -phenylhydrazine**,  $(\text{C}_6\text{H}_5)_3\text{C}-\text{NHNH}(\text{C}_6\text{H}_5)$ .—The substance was prepared according to the method of Gomberg.<sup>5</sup> The sample used melted at  $130^\circ$ . Some of the compound (0.5 g.) was triturated with 3 grams of anhydrous zinc chloride and the mixture heated at  $300^\circ$ . The steam distillate of the hydrolyzed reaction product gave a purple color with hypochlorite. It is not known whether the aniline, the presence

<sup>1</sup> See the preceding article.

# HALOGENATION. XIII. METHODS OF ESTIMATION OF SEMI-CARBAZIDE, SEMIOXAMAZIDE AND OXALYLHYDRAZIDE BY THEIR INTERACTIONS WITH HALOGENS AND HALOGEN OXYACIDS.

BY RASIK LAL DATTA AND JOGENDRA KUMAR CHOUDHURY.

Received February 28, 1916.

In a previous paper<sup>1</sup> one of us has given reactions for the volumetric estimation of semicarbazide, using potassium chlorate, bromate and iodate in the presence of strong hydrochloric acid as oxidizing agents. Since hydrochloric acid decomposes chlorate, bromate and iodate with the evolution of halogens, the reactions described are evidently due to free halogens only. Hence a systematic study of the reactions of semicarbazide with the potassium salt of halogen oxyacids with dilute sulfuric acid was undertaken. Furthermore, it was found that substances which are similar in constitution, as those containing a hydrazine group— $\text{NHNH}_2$ , also undergo decomposition when subjected to the action of the halogens and halogen oxyacids with the liberation of a constant volume of nitrogen.

When semicarbazide is treated with potassium bromate, iodate or periodate in conjunction with sulfuric acid, a quantity of nitrogen which is always three-fourths of the theoretical is liberated. Bromine water also gives the same amount of nitrogen. Chlorine, which cannot be obtained in suitable concentration, is not suitable for such reactions. Potassium chlorate and sulfuric acid do not cause evolution of nitrogen since semicarbazide hydrochloride is stable in the presence of chloric acid and is not decomposed by it. Hypobromite solutions decompose semicarbazide with quantitative evolution of nitrogen. These reactions could be used for the volumetric estimation of the compound, since a constant quantity of nitrogen is always evolved under different conditions of dilution. Semioxamazide is also decomposed by the halogen oxyacids with the liberation of three-fourths of its nitrogen. With bromine, as also with hypobromite, quantitative liberation of nitrogen is the result. Oxalylhydrazide is decomposed by potassium bromate, iodate or periodate in conjunction with sulfuric acid as also by bromine water and hypobromite with the evolution of nitrogen, carbon dioxide and carbon monoxide. The evolu-

<sup>1</sup> Datta, *THIS JOURNAL*, 36, 1014 (1914).

tion of nitrogen is quite quantitative under varying conditions. Thiosemicarbazide is decomposed by the above reagents with the evolution of nitrogen, but the results obtained are quite anomalous and could not be used for the volumetric estimation of this substance. Aminoguanidine is decomposed by the reagents with the evolution of nitrogen, but the results obtained are quite varying. In the case of semicarbazide and semioxamazide the portion of nitrogen not evolved remains behind as ammonia, as has been noticed in a previous communication.<sup>1</sup> It was further confirmed as follows: Semicarbazide hydrochloride was treated with silver chlorate to form semicarbazide chlorate in solution. This decomposes with evolution of nitrogen on heating or evaporating, leaving behind pure ammonium chloride. A similar result was also obtained by evaporating a little semicarbazide hydrochloride with excess of bromine water, when ammonium bromide is left behind.

**Formation of Semicarbazide Chlorate.**—An interesting fact has been found in this connection. If the solution of semicarbazide chlorate prepared by double decomposition, instead of heating on the water bath, be allowed to evaporate in a vacuum desiccator, the chlorate is formed, which as soon as it assumes a solid state, decomposes with explosive violence. Quantities of less than a gram have been found to smash large vacuum desiccators to small pieces. As its isolation in a sufficiently cold atmosphere would entail much danger, it was not attempted.

**Formation of Urea from Semicarbazide.**—In this connection the isolation of semicarbazide nitrite was attempted by the double decomposition between semicarbazide hydrochloride and silver nitrite. The interaction is attended with effervescence, evidently due to the decomposition of the nitrite. On evaporating the filtrate, a solid was obtained which has been found to be pure urea melting at 132°. The yield of urea is quantitative, as the reaction is not accompanied by any secondary action.

**Estimation of Semicarbazide.**—Semicarbazide interacts with potassium bromate, iodate or periodate in the presence of sulfuric acid with evolution of three-fourths of the total nitrogen. With bromine water the same decomposition takes place. With chlorine water, however, the proper concentration could not be secured and hence this could not be used as a reagent for effecting the volumetric estimation of semicarbazide. Potassium chlorate and perchlorate do not decompose semicarbazide and hence they could not be used for the estimation of this compound.

The details for carrying out the experiments are as follows: A known weight of semicarbazide hydrochloride is dissolved in a known volume of water in a graduated test tube. One or two cc. of this solution is taken out in a pipet and poured down a Crum's nitrometer filled with mercury and then washed down with a little dilute sulfuric acid. Next, the finely

<sup>1</sup> *Loc. cit.*

powdered oxidizing agent, in excess to what is required for complete decomposition, is washed down with dilute sulfuric acid. As soon as the oxidizing agent is introduced there is a brisk evolution of gas which collects in the nitrometer. After a while the nitrometer is thoroughly shaken to ensure that the reaction is complete, when the solution becomes clear and does not effervesce. The gas which collects consists of a mixture of nitrogen and carbon dioxide. To remove the latter gas, the resulting mixture is washed thoroughly with water and then with caustic alkali when all the carbon dioxide is absorbed. The apparatus containing the gas is then removed to a cylinder full of water where the volume of the gas is read.

The results of the experiments with different reagents at varied concentrations are given below.

I.—WITH POTASSIUM IODATE AND SULFURIC ACID.

	Strength of the acid.	Strength of sol.	Vol. of sol. taken.	Vol. of N <sub>2</sub> .	Mean vol. of N <sub>2</sub> per cc.	Percentage of N <sub>2</sub> (theory for $\frac{1}{4}$ = 28.26%).
1.....	10%	0.2039 g. in 15 cc.	1 cc.	3.55		
			2 cc.	7.0	3.55	27.88
			1 cc.	3.6

5.....	20%	0.1114 g. in 30 cc.	2 cc.	2.05		
			2 cc.	2.0	1.007	28.55
			2 cc.	2.0		

II.—WITH BROMINE WATER.

Found: 27.89; 27.99; 28.19; 28.21

III.—WITH POTASSIUM BROMATE AND SULFURIC ACID.

Found: 28.1; 28.34; 28.47; 28.5; 27.95

IV.—WITH PERIODATE AND SULFURIC ACID.

Found: 28.04; 28.57; 28.35

**Semioxamazide.**—Semioxamazide has a hydrazine group linked to a carbonyl group, as in the case of semicarbazide. It was therefore expected that it would decompose like semicarbazide and this has been found to be the case.

Semioxamazide is decomposed by potassium bromate, iodate or periodate in conjunction with sulfuric acid with evolution of three-fourths of the total nitrogen. With bromine water, however, quantitative liberation of nitrogen is the result. With hypobromite, the whole amount of ni-

trogen is evolved. Potassium chlorate and dilute sulfuric acid do not decompose this substance.

The experimental procedure is practically the same as in the case of semicarbazide. Semioxamazide, however, is but sparingly soluble in water, hence a solution of it is prepared in dilute sulfuric acid which has no action on it. As the gas obtained contains carbon dioxide, it is always washed with a solution of caustic potash. The conditions of experiments are varied a good deal as with semicarbazide, *viz.*, using sulfuric acid of different dilution, as also varying strength of semicarbazide solution or using varying excesses of the oxidizing agent. But in all cases the evolution of gas is quite constant. With bromine water the gas does not evolve as soon as it comes in contact with the solution. On shaking, however, nitrogen begins to collect rapidly. The results of experiments are given below.

I.—WITH POTASSIUM PERIODATE AND SULFURIC ACID.

Found: 30.51; 30.25; 30.45; 30.65. Theory ( $\frac{3}{4}$ ) 30.6

II.—WITH POTASSIUM IODATE AND SULFURIC ACID.

Found: 30.57; 30.37; 30.67; 30.47

III.—WITH POTASSIUM BROMATE AND SULFURIC ACID.

**Oxalylhydrazide.**—Oxalylhydrazide decomposes in the presence of oxidizing agents giving one molecule of carbon dioxide, one molecule of carbon monoxide and two of nitrogen according to the equation

After the absorption of carbon dioxide by alkali and carbon monoxide by ammoniacal cuprous chloride, it has been found that the volume of nitrogen is quite constant and hence the reactions can be used as a method for the volumetric estimation of the compound. As the substance is not soluble in the ordinary solvents, use was made of the slight solubility of the substance in water acidulated with a little sulfuric.

The results of experiments are given below.

## STUDIES ON DERIVATIVES OF TRIHALOGENTERTIARY-BUTYL-ALCOHOLS.

## I. THE ACETIC ESTER OF TRIBROMOTERTIARY-BUTYL-ALCOHOL OR BROMETONE ACETIC ESTER.

BY T. B. ALDRICH AND C. P. BECKWITH.

Received September 27, 1916.

The trichloro- and tribromotertiary-butyl-alcohols are most interesting compounds, both chemically and pharmacologically. The trichloro-compound, "Chloretone,"<sup>1</sup> has pronounced hypnotic, sedative and anesthetic properties, both local and general, and the same may be said of the tribromo-compound, "Brometone,"<sup>2</sup> which is considered to have more marked sedative, but less pronounced hypnotic and anesthetic properties. Both compounds are sparingly soluble in water (chloretone 0.8% and brometone still less), but readily soluble in the organic solvents; both have a camphor-like odor and taste, are readily volatile in the air or with steam, and may be crystallized from dilute alcohol and obtained in the form of beautiful white crystals. Both compounds combine with water more or less firmly and in this respect resemble chloral, although the water is not chemically bound as in the latter substance to form a stable hydrate.

The three halogens attached to one carbon atom impart to these bodies properties different from those of the unsubstituted tertiary alcohols; indeed, as pointed out by Willgerodt,<sup>3</sup> they may be regarded as trihalides of  $\alpha$ -hydroxyisobutyric acid, for they yield  $\alpha$ -hydroxyisobutyric acid upon treatment with alkalis under suitable conditions, probably thus:

The trichlorotertiary-butyl-alcohol may be crystallized from warm moderately concentrated nitric acid without material decomposition. With care the tribromo-alcohol may be similarly crystallized, though with considerable decomposition. They are broken down by concentrated sulfuric acid and by moderately dilute caustic alkali solutions(5%). In general, they are chemically rather inert bodies, fairly resistant to anything

<sup>1</sup> Chloretone and <sup>2</sup>brometone are the commercial names given the trichloro- and tribromotertiary-butyl-alcohols, respectively.

<sup>3</sup> Ber., 15, 2305 (1882).

short of destructive treatment. Willgerodt was unable to replace the chlorine of chloretone by alkyls.<sup>1</sup> It is interesting to note, however, that they form readily a series of esters of remarkable properties, and it is principally with these esters and related compounds that we are concerned in these articles.

It may be well to say in anticipation that one of the most striking properties of this series of esters is their relatively great stability—a fact that was noted by one of us (C. P. B.) in 1903. At that time the salicyclic ester of trichlorotertiary-butyl-alcohol was prepared and studied chemically and pharmacologically in the hope that it might be found to possess therapeutic value comparable with that of salol. The substance proved to be quite resistant to more or less heroic chemical treatment and to pass through the alimentary tract unchanged. Pharmacologically and clinically it appeared to be almost, if not quite, inert. These findings were not published at the time and later the compound was produced in Germany and patented.<sup>2</sup>

An observation very useful in the purification of these esters is that all of them, so far prepared by us, seem to be quite unaffected by gentle warming with caustic alkali solutions of 5–10%, while the uncombined alcohols themselves are broken down and readily removed by this treatment.

In a former article one of us<sup>3</sup> obtained by acetylating trichlorotertiary-butyl-alcohol with acetic anhydride and anhydrous sodium acetate in the usual manner, an ester to which the name acetyl chloretone was given. It has since been noted that this ester had already been prepared and briefly described by Willgerodt<sup>4</sup> under the unusual name, however, of acetyl-oxy-isobutyric-acid-trichloride.

The present article is concerned chiefly with the preparation and properties of a like compound of tribromotertiary-butyl-alcohol, the brometone acetic ester being formed similarly to the chloretone ester according to the following equation:

**Preparation.**—(a) One part of brometone is boiled with two parts of acetic anhydride and one part of anhydrous sodium acetate for two hours, using a reflux condenser. During the heating, the mixture becomes slightly colored, due, no doubt, to the splitting off of bromine or bromine

<sup>1</sup> *J. prakt. Chem.*, **39**, 283–289 (1889).

<sup>2</sup> R. Wolfenstein, D. R. P. No. 267,381.

<sup>3</sup> T. B. A., *THIS JOURNAL*, **37**, 2720 (1915).

<sup>4</sup> *J. prakt. Chem.*, **39**, 283–289 (1889).

compounds. On cooling, the mixture solidifies and on adding water and allowing to stand for some time two layers form, the upper being water, acid, sodium acetate, etc., the lower containing the product desired.

The upper layer is decanted as closely as possible, the residue warmed gently with an excess of caustic soda solution, and after standing some time extracted with ether. The ethereal extract is washed thoroughly, then filtered and the ether allowed to evaporate. The residue left is distilled with steam. A colorless oil passes over, having an odor very similar to, but not so pronounced as that of chloretone acetic ester. It is collected with ether, filtered, and the ether allowed to evaporate. Yield of nearly 50%. It colored slightly yellow on standing, and solidified. When purified by recrystallizing from alcohol it is white and melts at 43-44° (uncorr.).

(b) The following method of preparation is simpler and gives nearly a quantitative yield:

Dissolve two parts of brometone in four parts of glacial acetic acid and to this solution add one and a half parts of acetyl bromide or one part of the chloride. The mixture becomes warm and fumes of the halogen acid are given off. After the reaction has proceeded at room temperature for some time, the flask is heated on the steam bath for two hours and then allowed to stand overnight. Dilute caustic alkali is then added and the mixture warmed to decompose any excess of acetyl haloid or brometone. The ester settles then to the bottom of the vessel as an oil. The water etc., above the oil is decanted and the latter washed several times with water. This oil on cooling strongly, and especially when inoculated with a crystal of the ester, solidifies at once in crystalline form. It may be recrystallized from alcohol. The yield is nearly quantitative.

The preparation may also be carried out without the use of glacial acetic acid as a diluent. In this case the acetyl haloid is poured directly on the brometone, but considerable heat is evolved and it is advisable to provide for adequate cooling. After the reaction is ended, the vessel is heated on the steam bath until very little acid is given off. The compound is then treated as in the other cases.

Whichever method is used, economy of acetylating reagents is served, no doubt, by preliminary drying of the brometone as far as practicable. On the other hand, attempts to dry brometone thoroughly by most of the usual methods entail loss of this substance through volatilization, decomposition, or otherwise. For use in the reaction under discussion, a few days' standing in a desiccator over calcium chloride will suffice. (Sulfuric acid should not be used as a drying agent, since it absorbs and decomposes brometone vapor.) In fact, save that a larger proportion of the acetylating reagent is required, there is no objection to using ordinary crystallized brometone without preliminary drying.

Bromine determinations (Carius) carried out with a product recrystallized several times from moderately strong alcohol and melting at 43–44°, gave the following results:

0.4672, 0.2869, 0.2697, and 0.2584 g. gave 0.3161, 0.1985, 0.1841, and 0.1775 g. Br. Calc. for  $C_6H_5O_2Br_3$ : 67.99% Br. Found: 67.66, 69.20, 68.26, and 68.69%.

Leaving out the second value the results are sufficiently near, especially when the method of preparation is considered, to characterize the compound, without the necessity of making a combustion analysis, as the brometone acetic ester.

**Properties.**—The compound is extremely soluble in strong alcohol, acetone, chloroform, ether, glacial acetic acid, benzene, etc., insoluble in water. The alcoholic solution is precipitated by water.

When boiled with water for some time (29 hrs.), using a reflux condenser, a portion of the substance in the form of an oil, estimated at 0.5 of that taken originally, is found undecomposed. This oil on cooling has a tendency to crystallize. The supernatant liquid is strongly acid toward litmus and gives a heavy yellowish precipitate with  $AgNO_3$ , soluble, though not quickly in an excess of strong ammonia. There is no evidence of the alcohol in the condenser, as was the case when the chloretone ester was treated similarly. No brometone or other body is thrown out by diluting the supernatant liquid with water. Further boiling for 21 hours completely decomposes the remainder of the oil. Probably the brometone ester is saponified and then the brometone decomposed. When brometone acetic ester is boiled with water, to which  $H_2SO_4$  has been added, decomposition takes place in about the same time as when water alone is used.

Three grams of the substance were placed in a pressure tube with 10 cc. of  $H_2O$  and heated for three hours at 160°. There was a slight pressure on opening the tube, a combustible gas was given off, and an oil insoluble in  $H_2O$  had formed which did not solidify on cooling in ice water. On reheating the resealed tube for several hours at 170° complete decomposition of the oil-like substance had taken place, the homogeneous liquid had become yellowish, had a strong acid reaction toward litmus and showed the presence of large quantities of hydrobromic acid and of traces of acetic acid. By diluting with water, brometone was not thrown out. Partial carbonization had occurred.

Although saponification takes place slowly by boiling with water or water and dilute sulfuric acid, it takes place very rapidly when the ester is heated with an excess (three or four times its volume) of concentrated nitric acid. In fact, the brometone ester conducts itself in general toward hot nitric acid the same as the chloretone ester, except that the brometone which is produced at first readily undergoes further decomposition if heat is applied too long. In saponifying the brometone ester the procedure is as follows: Heat with the acid over a free flame until the ester

dissolves. Then cool under running water. If a cloudiness appears, the saponification is not far enough advanced. Heat gently until on cooling the solution remains clear, then dilute with an excess of water. The brometone is precipitated and may be recrystallized from dilute alcohol.

Here again, as with chloretone acetic ester, it is to be noted that saponification may occur with reproduction of the original acid and alcohol, while the usual rule with tertiary alcohols is that an unsaturated hydrocarbon appears instead of the alcohol, thus:

Brometone acetic ester volatilizes slowly, much more slowly than brometone. Placed on a watch glass under a funnel at summer temperature for 12 days, it lost 23% of its weight. In the incubator for 7 days a sample lost 12.5%. Under like conditions the loss of brometone is much greater.

The following preliminary data relative to the pharmacological action of brometone acetic ester as compared with chloretone were kindly furnished by our associate, Mr. L. W. Rowe:

"The toxicity of this preparation was determined by intraperitoneal injection into guinea pigs of an olive oil solution and the minimum fatal dose was found to be 0.5 g. per kg. body weight, that of chloretone being 0.15 g. per kg. body weight.

Because of the practically complete insolubility of the product in water, it was impossible to determine the irritation, if any, which was produced by hypodermic injection. When an olive oil solution was used, some irritation was produced after some hours due to the very slow absorption. When a strongly alcoholic solution was used, irritation was produced immediately by the alcohol. The product itself probably does not possess very irritating properties.

Concerning the anesthetic and sedative action of this drug we can say that as the dose approaches very near the toxic dose, an anesthetic action is observed several hours after administration. The slow action is no doubt due to the very slow absorption of the drug. The anesthetic action, which may be partially due to the toxicity of the drug, is certainly not as strong or as rapidly evidenced as that produced by chloretone.

The action of brometone acetic ester upon the laid-bare frog's heart is not as strong as is that of chloretone.

The blood pressure of an anesthetized dog was somewhat lowered after the intravenous injection of rather large amounts of this drug (4 cc. of a 2% solution in 50% alcohol). A control injection of the same amount of alcohol alone failed to produce as marked a reaction.

In summarizing these data it seems that brometone acetic ester is somewhat similar to chloretone in its pharmacological action but that the action of the former is not nearly as strong or as quickly evidenced. The latter fact can partially be accounted for by the extreme insolubility in water of the brometone acetic ester."

Further pharmacological studies are being made with these esters in comparison with chloretone and brometone.

Owing to delay and confusion in the mails from Germany, there has just reached us an article by R. Wolffenstein, A. Loewy and M. Bachstez on "Esters of Trichlorotertiary-butyl-alcohol and Their Pharmacology."<sup>1</sup> The details of their pharmacological findings are published in a separate article in a number of Schmiedeberg's Archiv. that has not yet come to hand. For the present, it will suffice to say that the results obtained by these gentlemen with the chloretone esters are, in most points, quite in accord with ours with the brometone esters in so far as we have followed parallel lines.

According to these authors the preparation of the esters is ordinarily easily carried out through the action of the acid chloride with or without the aid of tertiary bases, in fact from the acid and the alcohol in the presence of a condensing agent.

The following facts were observed by Wolffenstein relative to the esters of trichlorotertiary-butyl-alcohol: They are not as a rule split up in the body; they exhibit an unexpected action quite different from that of the alcohol from which they are prepared; and they exhibit poisonous properties, causing cramps. These cramps or convulsions begin to manifest themselves in chloretone acetic ester, increasing in the higher homologues and reaching the maximum as far as investigated in the ester of isovaleric acid.

It is further stated that the chloretone acetic ester, the one most thoroughly studied, shows less narcotic action but greater poisonous properties than chloretone.<sup>2</sup> The decrease in narcotic property and increase in poisonous property is shown much more plainly in the propionic ester and still more in the isovaleric ester. The isovaleric ester has no hypnotic action, but has, at least on rabbits, a toxic action causing convulsions.

The authors furthermore state that the only<sup>3</sup> known ester of trichlorotertiary-butyl-alcohol, up until the appearance of their article, is the

<sup>1</sup> *Ber.*, 48, 2035-43 (1916).

<sup>2</sup> According to the results of Aldrich relative to the toxicity of acetyl-chloretone (trichlorotertiary-butyl acetic ester) it was found (*THIS JOURNAL*, 37, 2722 (1915)) that "The toxicity of this acetyl-ester, when introduced subcutaneously into guinea pigs, is slightly less than that of Chloretone." Possibly Wolffenstein and his collaborators employed another method of administration, which would account for the different findings.

<sup>3</sup> Willgerodt prepared also the benzoic ester, *J. prakt. Chem.*, *loc. cit.*

acetic acid ester prepared first by Willgerodt under the name acetyl-oxy-isobuttersäure-trichloride. [Later by Aldrich under the name mono-acetyl trichlorotertiary-butyl-alcohol (chloretone acetic ester).]

The following esters of chloretone were prepared by Wolfenstein: Propionic ester (yellow oil); isovaleric ester (oil); bromoisovaleric ester (oil); monochloroacetic ester (cryst.); trichloroacetic ester (cryst.); diethyl glycine ester (oil); dimethyl glycine ester (oil); piperidine acetyl ester (cryst.); allophanic ester (cryst.); acid malonic ester (cryst.); dibromocinnamic ester (cryst.); neutral malonic ester (cryst.).

### Summary.

The acetic ester of tribromotertiary-butyl-alcohol is most conveniently prepared through the interaction of acetyl chloride or bromide and the alcohol, or by means of acetic anhydride and anhydrous sodium acetate, in the usual way.

Prepared by either of these processes and recrystallized from alcohol, the purified substance melts at 43-44° (uncorr.).

Bromine determinations (Carius) gave results sufficiently near to characterize the compound as brometone acetic ester with the formula

The compound is extremely soluble in the organic solvents, practically insoluble in water. It is not readily saponified by boiling with water or acidulated water and when saponified the alcohol is decomposed still further. Although saponification takes place slowly by boiling with water or water and acid, it takes place very quickly when heated with an excess of moderately concentrated nitric acid. Like chloretone and brometone, though not quite so readily, the ester is volatile in the air and especially with steam. The pharmacological action is similar to that of chloretone and brometone although, presumably on account of its greater insolubility in water, its effects are less rapid and marked.

DETROIT, MICH.

### STUDIES IN ESTERIFICATION. VII.

#### THE ESTERIFICATION OF *o*-, *m*- AND *p*-TOLUIC ACIDS BY ETHYL MERCAPTAN.

By J. H. SACHS AND E. EMMET REID.

Received September 27, 1916.

#### Historical.

As early as 1862 Berthelot and Pean de St. Gilles<sup>1</sup> began the investigation of the general problem of esterification. They studied the limit of

<sup>1</sup> *Ann. chim. phys.*, [3] 65, 385 (1862); 66, 5 (1862); 68, 225 (1863).

esterification for different temperatures. In 1878 Menshutkin<sup>1</sup> took up the problem and by using different alcohols with acetic acid first showed the effect of composition and isomerism on the rate and limit of esterification. Goldschmidt<sup>2</sup>, in 1895, first studied the effect of differences of constitution in isomeric acids upon ester formation. He studied the esterification of *o*-, *m*- and *p*-substituted benzoic acids with ethyl alcohol, using hydrochloric acid as catalyzer. By using a large excess of alcohol in which the hydrochloric acid was dissolved, he was able to use for the calculation of his results the equation for a monomolecular reaction:

$$K = (1/t) \log a/a - x$$

For the toluic acids he got the following constants:

<i>o</i> -Toluic.....	0.011
<i>m</i> -Toluic.....	0.0470
<i>p</i> -Toluic.....	0.0241

The same general relation was noted for other substituted benzoic acids.

About the same time Petersen<sup>3</sup> observed that *p*-toluic acid forms ester much more readily than does the ortho acid.

From 1894 to 1897 Victor Meyer<sup>4</sup> and his co-workers, investigating the problem of steric hindrance, threw much light on the effect of isomerism upon esterification. Working with ethyl and methyl alcohols with ortho, meta and para substituted benzoic acids, they showed that the toluic acids were esterified in the following order: Meta, para and ortho. The same held good for other monosubstituted benzoic acids.

Kellas<sup>5</sup> extended the work of Victor Meyer and found practically the same results. He also studied the rate of saponification of esters of the substituted benzoic acids by caustic potash. In the case of the esters of the toluic acids the results are so close together that no general relation can be gotten from them.

Recently McCombie and Scarborough<sup>6</sup> in studying the rate of saponification of esters of substituted benzoic acids by hydrochloric acid, found the following constants:

	<i>o</i> .	<i>m</i> .	<i>p</i> .
Toluic.....	0.00134	0.00405	0.00275
Chlorobenzoic.....	0.0158	0.0485	0.0298
Bromobenzoic.....	0.0118	0.0445	0.0234

Thus we see that the saponification relation is the same as that of esterification.

<sup>1</sup> *Ann.*, **195**, 334 (1878).

<sup>2</sup> *Ber.*, **18**, 3218 (1895).

<sup>3</sup> *Z. physik. Chem.*, **16**, 403 (1895).

<sup>4</sup> *Ber.*, **27**, 510, 3146 (1894); **28**, 1254, 2773, 3197 (1895); *Z. physik. Chem.*, **24**, 219 (1897).

<sup>5</sup> *Z. physik. Chem.*, **24**, 221 (1897).

<sup>6</sup> *J. Chem. Soc.*, **107**, 156 (1915).

Reid<sup>1</sup> in studying the mechanism of the reaction in esterification showed that mercaptans esterify acids just as do alcohols. However, instead of getting esters of the general formula  $\text{RCOOR}'$ , he got the thiol esters of the general formula  $\text{RCOSR}'$ . This shows that esterification probably takes place as follows:

The present work was taken up therefore with the idea of finding whether or not the above relations hold when the toluic acids are esterified with ethyl mercaptan.

### Materials.

**Acids.**—The *o*- and *m*-toluic acids were a well-known firm's best grade. The *p*-toluic acid was made from *p*-tolyl nitrile which, in turn, was made from *p*-toluidine by the Sandmeyer reaction. This acid was purified by boiling with animal charcoal and then twice recrystallizing from boiling water, m. p. 177°.

**Mercaptan.**—The ethyl mercaptan was made by Reid for use in the above-mentioned work. It had been freed from sulfide, dried, and twice distilled, only the best fraction being used for the work.

The thiol esters were made by alkylating the thiol toluic acids which were prepared according to the directions of Kym<sup>2</sup> for thiolbenzoic acid.

***o*-Thiol Toluic Acid.**—To 80 g. of 85% caustic potash dissolved in 600 cc. of 95% alcohol and saturated with hydrogen sulfide, there was added, with cooling, 70 g. of *o*-toluyl chloride. The potassium salt of the *o*-thiol acid separated at once as a pasty brown mass. This was dried on the water bath, taken up with water and the solution shaken with ether in order to remove any ethyl toluate that might have been present. On acidifying the water solution of the potassium salt with hydrochloric acid, the acid separated as a red oil. This was taken up with ether, the ethereal solution dried over calcium chloride and, after distilling off the ether, the ester was twice distilled *in vacuo*. The yield was 26 g.; b. p. 133°<sup>35</sup>; d. 1.145<sub>125</sub><sup>25</sup>. Weighed portions of the acid were dissolved in alcohol and titrated with 0.0905 *N* barium hydroxide.

I. 0.1559 g. acid required 11.32 cc. alkali; corresponding to M. W. 152.18.

II. 0.1418 g. acid required 10.62 cc. alkali; corresponding to M. W. 152.71.

Calculated, M. W. 152.12.

***p*-Thiol Toluic Acid.**—This was made in exactly the same way as the preceding. The acid separated as a red oil which on cooling, solidified. The yield was 48 g. from 70 g. of *p*-toluyl chloride. B. p. 131°<sup>15</sup>. M. p. after recrystallizing from alcohol 43.5–44°. This was also titrated with the standard alkali.

<sup>1</sup> *Am. Chem. J.*, 43, 489 (1910).

<sup>2</sup> *Ber.*, 32, 3533 (1899).

I. 0.1409 g. acid required 10.30 cc. alkali; corresponding to M. W. 152.64.

II. 0.1981 g. acid required 14.44 cc. alkali; corresponding to M. W. 152.38.

The *m*-thiol toluic acid and its ethyl ester could not be made on account of the scarcity of *m*-xylene and *m*-toluidine.

**Ethyl *o*-Thiol Toluatoe.**—This was made by Wheeler's method for ethyl thiol benzoate, from potassium *o*-thiol toluate and ethyl bromide. The yield was 25 g. from 30 g. of the acid and 35 g. of ethyl bromide. B. p. 133<sup>015</sup>. D. 1.0513<sup>25</sup><sub>25</sub>. The ester has a clear yellow color which has remained unchanged after standing five months.

**Ethyl *p*-Thiol Toluatoe.**—This was made exactly as was the ortho ester. From 25 g. of the acid and 30 g. of ethyl bromide 23 g. of the ester were obtained. B. p. 150<sup>018</sup>. D. 1.0708<sup>25</sup><sub>25</sub>. This ester has also remained unchanged on five months' standing.

All of these acids and esters are insoluble in water, but dissolve readily in alcohol and ether. They are very resistant to oxidation by nitric acid, for after heating them five hours in a Carius tube with fuming nitric acid at 250°, they were not burned up.

The authors have been working for some time upon a new method for the determination of sulfur in organic compounds. The analysis of these acids and esters will appear in a later paper upon this method.

**Water.**—Conductivity water was used.

#### Heating.

The furnace used was that described by Pratt and Reid;<sup>2</sup> electrically controlled and heated, it maintained the desired temperature for weeks with a variation of  $\pm 2^\circ$ .

#### Standard Solution.

The standard hydrochloric acid and barium hydroxide were kept in large stock bottles from which they were run through siphons fitted with stopcocks into their respective burets. The tops of the acid bottle and buret were protected from the air by tubes containing acid of the same strength as the standard solution. The barium hydroxide system was protected by soda lime tubes. Both solutions were approximately 0.1 *N* and were frequently standardized.

#### Procedure.

Hard glass tubes about 6 by 70 mm. outside, closed at one end, were cleaned by boiling one day in dilute hydrochloric acid, 4 hours in distilled water and then thoroughly dried in an air bath at 150°.

**Acid Series.**—Each tube was weighed, partly filled with the acid, drawn out to a narrow neck and weighed again. The mercaptan was then added and after cooling in ice and salt, the tubes were sealed. The tube and tip were then weighed.

<sup>1</sup> *Am. Chem. J.*, 24, 69 (1900).

<sup>2</sup> *THIS JOURNAL*, 37, 1934 (1915).

**Ester Series.**—The procedure was the same as for the acid series, using ester instead of acid, and water instead of mercaptan.

These tubes were then placed in the furnace and heated to 198–202° for different periods of time. On taking the tubes from the furnace they were allowed to cool, scored with a file and broken over a short necked funnel into 120 cc. Erlenmeyer flasks. The funnel was rinsed with 25 cc. of ethyl alcohol, which had been distilled from caustic potash, which dissolved the reaction mixture. The mercaptan which had not reacted, was blown off by bubbling for 15 minutes through the solution, kept at 50°, a current of carbon dioxide-free air. The amount of toluic acid present was then determined by titration with the standard baryta water, using phenolphthalein as indicator. Uniformity of results was gotten by standardizing the baryta with alcoholic solutions of the toluic acids used.

### Experimental.

The chief object of the work was to measure the limits of esterification, but the rates also are of interest. The velocities of esterification are calculated by the formula for bimolecular reactions:<sup>1</sup>

$$(1) \quad K = \frac{2.3025}{(A - B)T} \log \frac{(A - x)B}{(B - x)A}$$

in which A and B are the active masses of the two substances that react, x the amount of each transformed and T the time. As this equation holds even approximately, for balanced reactions, only when the reaction is proceeding with an appreciable velocity, that is, before the limit is nearly reached, it was applied to only the one-, two- and four-day series.

The limits of esterification are gotten by the usual reasoning in consideration of reversible reactions.<sup>2</sup> In this case the amount of ester formed in unit time being equal to (Acid  $\times$  Mercaptan) K and the amount of ester decomposed at the same time being equal to (Ester  $\times$  Water) K', at equilibrium these velocities being equal, we have

$$(2) \quad \frac{(\text{Acid} \times \text{Mercaptan})}{(\text{Ester} \times \text{Water})} = \frac{K'}{K} = r.$$

For equal concentrations of acid and mercaptan at equilibrium,

$$\frac{\text{Amount of mixture unesterified}}{\text{Amount of mixture esterified}} = \frac{\sqrt{K'}}{\sqrt{K}} = \frac{\sqrt{r}}{1}$$

or, the percentage of a mixture of equivalent amounts, esterified at limit =  $100/\sqrt{r} + 1$ .

In the following tables are given the results of the *o*-, *m*-, and *p*-toluic acids with ethyl mercaptan and the results of the *o*-, and *p*-ethyl ester with water.

<sup>1</sup> Reid, *Am. Chem. J.*, **24**, 398 (1900).

<sup>2</sup> Reid, *Ibid.*, **43**, 499 (1910); Bonz, *Zeit. physik. Chem.*, **2**, 865 (1888).

In tabulating the results, the data are thus arranged.

- a*, Acid or ester in grams.
- b*, Millimols of acid or ester.
- c*, Mercaptan or water in grams.
- d*, Millimols of mercaptan or water.
- e*, Cubic centimeters of standard alkali required for titration.
- f*, Millimols of acid present, calculated from *e*.
- g*, Millimols of mercaptan remaining (acid series).
- h*, Millimols of ester remaining (ester series).
- k*, Millimols of water remaining (ester series).
- m*, Millimols of ester, equals water (acid series).
- %, Percentage of esterification, calculated by the above formula.
- x*, The same as *m* in acid series and *f* in ester series.
- K*, The velocity constant of the reaction.

In the acid series the amount of ester = water, (*m*) is found by subtracting the acid remaining (*f*) from the original amount (*b*). The concentration of ester (*m*) equals the concentration of water. The millimols of mercaptan remaining, as given in (*g*), are obtained by subtracting the amount of ester (*m*) from (*d*), the amount of mercaptan originally present.

In the ester series, the amount of ester remaining (*h*) is found by subtracting the acid present from (*b*), the original amount of ester. The water remaining (*h*) is obtained by subtracting the acid present (*f*) from (*d*), the original amount of water.

The percentage esterification (%) and the velocity constant of the reaction (*K*) are obtained by calculation from the equations above discussed. In Series I all the data are tabulated, but in the tables that follow only the most essential are given. Some of the results which are out of harmony with others of same series are bracketed and are not included in the averages.

The work was undertaken as a study of the limits rather than the reaction velocities. Hence close temperature regulation and other precautions required for obtaining concordant values of *K* were not regarded. The values of *K* are only approximate and little stress is put on them.

## Discussion of Results.

On examination of the foregoing results, it is seen that very concordant results are obtained in the acid series, while those from the ester series show large variations. Then, too, the same limit is not reached in the ester series that is reached in the acid series. The cause of these discrepancies lies, no doubt, in the fact that in the acid-mercaptan series the reaction mixture forms a homogeneous liquid at  $200^\circ$ ; in the ester-water series, at that temperature, the oily ester and the water remain separated in two layers, thus leaving a comparative small surface of contact at which the reaction takes place.

On the whole, the results for the one and two days' series are rather unsatisfactory, looking at the curves plotted for the progress of the reaction, one sees at once that the reaction seems to lag at two days. As this lag is observed in all five cases it seems probable that the temperature, at which the two days' series was run, was low, due, doubtless, to faulty

regulation of the furnace. A few degrees, at the temperature at which these experiments were carried out, would make quite a large difference in the short periods of time.

The results for the four, eight and sixteen days' series are very good in the acid series. Another series was run for the eight-day period using larger tubes and smaller amounts of water; furnace trouble developed here and the results proved so unsatisfactory that they are not included. In the ester series there seems to be some relation between the amount of water used and the amount of ester remaining. As a rule, the smaller the amount of water used the more ester, relatively, was decomposed. This is opposite to what one would naturally expect.

A study of the results of the rates and limits of the esterification of the three acids is very interesting; one is struck at once by the very large velocity in the case of the meta acid and the small velocity in the case of the ortho acid. The meta acid proceeds over half way to its limit in the first day while the para goes to about one-fourth and the ortho, to about one-seventh their respective limits in the same time. Thus these results agree very well with those obtained by the workers cited in the first part of this paper. It seems that the limits in all their cases are about the same (14%), for there is a very small increase in the results of the sixteen days' series over those gotten at eight days. In the acid-mercaptan series, especially for the longer times, the relative amounts of acid and mercaptan used have no appreciable influence on the limit of the reaction.

In all the experiments run over two days there was a slight amount of

decomposition. This was shown by the presence of hydrogen sulfide which was detected by the lead acetate paper test.

### Conclusion.

- I. Mercaptans esterify acids just as do alcohols.
- II. Mercaptans show the same relations between velocities and limits of esterification of the toluic acids as do alcohols.
- III. The limits in the case of ethyl mercaptan are much lower than in the case of ethyl alcohol.
- IV. The limit in the acid-mercaptan series is independent of the proportions of the reacting substances.
- V. *o*-, *m*- and *p*-Toluic acids reach nearly the same limits of esterification when esterified with ethyl mercaptan.

## STUDIES IN ESTERIFICATION. VIII.

### THE ESTERIFICATION OF BENZOIC ACID BY ISOMERIC BUTYL MERCAPTANS.

BY J. W. KIMBALL AND E. EMMET REID.

Received September 27, 1916.

### Historical.

The influence of isomerism on the rates and limits of esterification of alcohols has been carefully studied by Menshutkin,<sup>1</sup> who found that the limits for primary alcohols, whether normal or iso-, are practically the same, while those for secondary alcohols are much lower. The limits for tertiary alcohols, he found to be still lower, but the results in this case are not the real limits since a part of the alcohol reacted in another way, decomposing into the unsaturated hydrocarbon and water.

With acetic acid Menshutkin found the following limits for the isomeric butyl alcohols: Normal 67.30%, iso- 67.38%, secondary 59.28%, tertiary 7.10%. The limits are reached in 120 hours at 154°.

Reid,<sup>2</sup> studying the mechanism of the reaction of esterification, employed mercaptans instead of alcohols and showed that the reaction

reaches a well-defined limit as in the case of the oxygen alcohols.

Pratt and Reid<sup>3</sup> then took up this work, using benzoic acid with methyl, ethyl and propyl mercaptans, and accurately determined the limits of these systems. These limits with mercaptans were found to be much lower

<sup>1</sup> *Ber.*, 11, 1507, 2117, 2148 (1878); Liebig's *Ann.*, 195, 334 (1879); 197, 193 (1879); *Ann. chim. phys.*, [5] 20, 289 (1880).

<sup>3</sup> *THIS JOURNAL*, 37, 1934 (1915).

than those found by Berthelot and St. Gilles<sup>1</sup> and by Menschutkin<sup>2</sup> with alcohols, but the relations between the limits in the two series are much the same.

As pointed out by Pratt and Reid, it is much more difficult to get concordant results with mercaptans than with alcohols, since the mercaptans must be eliminated before titration of the unesterified acid. The use, in individual experiments, of varying amounts of mercaptan and acid, instead of the identical and equivalent amounts of alcohol and acid such as have commonly been used, also increases the difficulty.

#### Materials.

**Benzoic Acid.**—The benzoic acid used was a well-known firm's best grade.

**Mercaptans.**—The normal mercaptan<sup>3</sup> was prepared from normal butyl bromide and potassium hydrosulfide. The mercaptan obtained was dried over calcium chloride, fractionated several times and the fraction boiling 97–98° used in the work.

The isobutyl mercaptan used was a standard commercial product.

The secondary butyl mercaptan<sup>4</sup> was prepared from secondary butyl bromide and potassium hydrosulfide. The mercaptan was dried over calcium chloride, fractionated several times, and the fraction boiling 83–84° used.

An effort was made to prepare the tertiary mercaptan according to the method of Dobbin,<sup>5</sup> except that tertiary butyl bromide was used instead of the iodide, but only traces of the desired mercaptan were obtained. On account of the difficulties involved, this preparation was abandoned.

**Normal, Iso-, Secondary and Tertiary Butyl Thiolbenzoates.**—The thiol esters were made by alkylating thiolbenzoic acid, prepared according to Kym's<sup>6</sup> directions. The acid was, however, purified by dissolving the potassium salt in water, filtering and liberating the acid with hydrochloric acid. After settling, the oily acid was separated and the aqueous solution extracted with ether. On evaporation of the ether the acid was ready for use. The potassium salt of the purified thiolbenzoic acid was treated, according to the general directions of Wheeler,<sup>7</sup> for the ethyl ester, with the butyl bromide of which the ester was desired. The esters so obtained were carefully fractionated in a partial vacuum. The boiling points and densities of these butyl thiolbenzoates are given in the following table:

<sup>7</sup> *Am. Chem. J.*, 24, 69 (1900).

Normal.....	160° at 23 mm.	1.0514 25/25
Iso.....	150° at 20 mm.	1.0457 25/25
Secondary.....	151° at 23 mm.	1.0488 25/25
Tertiary.....	110° at 28 mm.	1.0468 25/25

The normal and iso- esters were reddish in color when first prepared but, on standing for several months, the color faded to a light pink. The secondary ester faded from yellow to nearly colorless while the tertiary faded from a very light yellow to colorless. It seems probable that the color is due to some slight impurity.

**Water.**—Conductivity water was used.

#### Apparatus and Procedure.

The same furnace and the same standard solutions were used as in the work of Sachs and Reid in the preceding article. The preparation, filling, heating, and opening of the tubes and the analysis of the reaction products were also the same, except that a longer time was allowed for blowing off the mercaptan remaining. Preliminary experiments with known amounts of benzoic acid and mercaptan showed that it is necessary to pass air through the solutions 25 minutes to remove normal butyl mercaptan, 20 minutes for the iso-, and 15 minutes for the secondary.

The temperature of the heating was 200°.

#### Experimental.

In the first experiments, those given in Tables A to E, the tubes used had an internal diameter of about 4.5 mm. and the rates of esterification in them seem to have been quite different from those in the smaller tubes (3.5 mm. inside diameter) used later, as will be seen from the tables that follow, though Berthelot and St. Gilles<sup>1</sup> state that it is permissible to vary the volume of the unfilled portion considerably without modifying sensibly either the rate or the limit of the reaction.

In their work alcohols and acetic acid were used which do not differ greatly in volatility, but in the present work there is much difference in volatility between benzoic acid and the butyl mercaptans.

In the earlier experiments it was found in the ester-water series that an excess of ester over water gave place to some decomposition which yielded acid, since the results gave too low values for the limit. Samples of esters heated alone in the ordinary tubes to 200° for several days gave considerable acid, showing that the ester-water results could not be relied upon, at least in the case of an excess of ester over water.

Later experiments using an excess of water were run in the smaller tubes and here results were not satisfactory, since equilibrium was not reached in the time allowed, due to the nonmiscibility of ester and water and to the small surface of contact.

— Tubes containing acid and mercaptan and others containing ester and

<sup>1</sup> *Ann. chim. phys.*, [3] 66, 50 (1862).

water in about the usual amounts were heated to  $200^{\circ}$  in a sulfuric acid bath so that the conditions obtaining in the tubes at that temperature could be observed. It was found that, while the acid and mercaptan formed a perfectly homogeneous solution at that temperature, the ester and water still remained in two distinct layers and showed no tendency to mix, separating rapidly after being shaken together. This undoubtedly shows why the esterification proceeds regularly and comparatively rapidly from the acid-mercaptan end, while the mixtures of esters and water are slow to react and yield irregular results.

The results are tabulated according to the plan adopted by Pratt and Reid and used by Sachs and Reid in the preceding article, to which reference must be made for the meaning of the terms and the methods of calculation. To save space, the weights are omitted and the substances are given only in millimols,  $b$  and  $d$  being the amounts put in and  $f$ ,  $g$ , and  $m$  or  $f$ ,  $h$ , and  $k$ , the amounts present at the end. The percentage of esterification, calculated for equivalent quantities, is given in the line marked %.

Some results which are out of harmony with others of the same series are bracketed and are not used in making the averages. All completed experiments, except a few preliminary ones and three from ester-water end, which were cut out to make the tables fit better, are given.

## Summary of Results.

The averages of the results of Tables A and E are brought together in Table L. The figure for the iso- for 4 days is the highest in the run and not the average. The averages from tables F to J are in Table M, while the averages of all experiments with esters and water are grouped in Table N.

TABLE L.—FIRST SERIES.

Esterification of Benzoic Acid by the Butyl Mercaptans.

Time in days.....	1	2	4	8	12
From table.....	A	B	C	D	E
Normal.....	11.66	13.26	12.62	12.76	13.40

Tertiary.....	49.56	48.38	74.8	76

The results of Table M are reproduced in the figure.

Figure.

Esterification of Benzoic Acid by Normal, Iso- and Secondary Butyl Mercaptans at 200°. Data from Table M.

### Discussion of Results.

A comparison of the data of Tables L and M shows that, in the first series, with the larger tubes, the values for the one- and two day periods are much higher than the corresponding values in the second series, that is, esterification went on much more rapidly in the larger tubes. The limits for the iso- and secondary mercaptans are sensibly the same and are not greatly different for the normal. Whether it was the size of the tubes, giving a larger surface of contact and causing more rapid solution, or whether the difference in velocity of esterification is due to some peculiarity of the surface of the glass, or to some unsuspected cause, it is impossible to say. It is well known that the presence of traces of catalysts and other circumstances have enormous influence on reaction velocities without changing the limits of the reactions. The object of the present study was to find the limits, and the short period experiments were run only to get an idea of the rate of approach to the limits, so as to be sure that the limits had been reached. It is remarkable that the secondary mercaptan, in the first series, reached the limit in one day's time.

The first series is to be regarded as preliminary and much more confidence is felt in the results of the second series, since the accuracy of the work increased with experience. In Tables D and E of the first series the average divergence of individual results, except those bracketed, from the accepted mean is 0.34%, while, in the corresponding Tables I and J in the second series, it is 0.19% or just about half as great.

In Table N, first part, we find that the mixtures of the normal and secondary esters and water reached limits almost exactly agreeing with those obtained from the acid-mercaptan end. There is one result, 13.18, in Table E for the isobutyl ester, which is close to the accepted limit, but most of the values for this ester are higher than this. In the results from the second series, under J, we see that none of the mixtures came anywhere near the accepted limits.

The mixtures of tertiary butyl thiolbenzoate and water do not reach limits such as we would expect. It is more likely that this is a case of decomposition, possibly into butylene and acid, rather than of saponification in the ordinary way. This decomposition seems to have gone considerably further in the large tubes than in the small. Its amount appears to bear no relation to the time of heating, as there was rather less acid found in the tubes that had been heated 28 days than in those not heated so long.

It is seen that both the rates and the limits for the normal and iso-mercaptans are nearly the same, as has been found to be the case with the corresponding alcohols. Both of these are primary mercaptans, and the fact that one is a straight chain and the other a forked chain compound seems to make little difference. The secondary mercaptan, however,

<sup>1</sup> *Compt. rend.*, 132, 38 (1901); 133, 1217 (1901).

In only a very few instances, however, were good yields obtained. Somewhat later Gautier<sup>1</sup> applied this same reaction to cyanhydrines and alkoxy-nitriles, and produced in each case the corresponding ketones.

Grignard<sup>2</sup> allowed a molecule of alkyl or aryl magnesium halide to drop into a molecule of chlorocyan, and was able to obtain fair yields of nitriles, as follows:

The bromocyan and iodocyan, however, yielded chiefly alkyl or aryl halides

By the same method of procedure with cyanogen, Grignard<sup>3</sup> was able to produce nitriles instead of ketones, which Blaise obtained when he treated the Grignard reagent with cyanogen.

Kohler<sup>4</sup> tried the action of alkyl and aryl magnesium halides on  $\alpha,\beta$ -unsaturated nitriles; 1,4-addition took place, and saturated nitriles were subsequently formed.

Several other types of organic substances exist holding a  $\alpha$ -CN group and these have not been studied; thus cyanamides and their substitution products  $\text{NH}_2\text{CN}$ ,  $\text{NHR}\text{CN}$ , or  $\text{NR}_2\text{CN}$ , acid nitriles  $\text{R} - \underset{\text{O}}{\underset{\parallel}{\text{C}}} - \text{CN}$ ,

and finally the esters of cyanic and thiocyanic acid  $\text{ROCN}$ ,  $\text{RSCN}$ . It seemed to us of scientific interest to know how these substances react with the Grignard reagent, and at the same time it was possible that certain useful synthetic processes might be discovered. As yet we have studied simply the reactions of dibenzyl cyanamide. They ran, as might be predicted, to give first a magnesium halide addition compound, which on decomposition with dilute acid, yielded the salts of substituted amidines.

<sup>1</sup> *Compt. rend.*, 152, 1100, 1259; *Ann. chim. phys.*, [8] 16, 289 (1909).

<sup>2</sup> *Ibid.*, 152, 388 (1910); *Ann. chim.*, [9] 4, 28 (1915).

<sup>3</sup> *Compt. rend.*, 155, 44 (1912).

<sup>4</sup> *Am. Chem. J.*, 35, 386 (1905).

In the laboratory, we treated in ether solution ethyl, phenyl, and tolyl magnesium halides with dibenzyl cyanamide. In each case, when we acidified the reaction mixture, white solids separated between the ether and dilute acid. The substances proved to be the amidine salts, and corresponded in amount to 75% or more of the theoretical yield. Some difficulty was experienced, however, in the purification of these salts for analysis, as they were soluble only in alcohol, water or dilute hydrochloric acid and tended to turn colored during crystallization. In the case of the tolyl we had so much trouble in getting the salt pure enough for analysis that we found it advisable to decompose the salt with sodium hydroxide, extract the free amidine with ether, and treat with phenyl isocyanate, in order to form the urea derivative which crystallized very nicely and was readily purified. The amidines themselves are not easy substances to work with, as most of them are oils or low melting, very soluble solids. Therefore, only in one case, the phenyl dibenzyl amidine, have we isolated and purified the free compound.

Another difficulty which we have just found when using dimethyl cyanamide, and which may be true in other cases, is that the amidine salt is very soluble in water or dilute acid, and so does not separate on acidification of the reaction mixture. This reaction we are studying further, as well as the action of alkyl and aryl magnesium halides on other disubstituted cyanamides, monosubstituted cyanamides, and on cyanamide itself. We expect to study also the action of the Grignard reagent on acid cyanamides, and on the esters of cyanic and thiocyanic acids.

Heretofore substituted amidines and their salts belonging to the type just described, namely,  $R_2N-C-R$ , have been prepared by one method

only, the action of secondary amines on imido-ethers, the other methods available for the amidines in general not being applicable to this particular type of substitution product.

#### Experimental.

**Dibenzylpropionamidine Hydrochloride,  $(C_6H_5CH_2)_2NC(NH)C_2H_5.HCl$ .**  
—Dissolve 2 g. of magnesium in 10 g. of ethyl bromide and dry ether. Cool in ice and allow a dry ether solution of 12 g. of dibenzylcyanamide<sup>1</sup> to flow in drop by drop. The mixture becomes milky in appearance, and solid matter separates. Decompose this directly with hydrochloric acid and ice, thus producing a yellowish solid which floats between the ether and water layers. This, when filtered and dried, weighs 15 g. The ether layer holds a small amount of unchanged dibenzylcyanamide, and

<sup>1</sup> Prepared according to the directions of Diels and Gollmann, *Ber.*, 44, 3164 (1911).

the acid layer nothing but magnesium salts. The solid obtained is soluble in alcohol and acetone, but does not crystallize well from either. From water alone or from water containing a little alcohol, the material forms beautiful rhombohedral crystals, but the yellow color does not disappear, and the m. p. in four recrystallizations does not become constant. Dilute hydrochloric acid and a little alcohol is the best combination, thus it is possible to obtain a constant melting point of  $204-204.5^{\circ}$ . During the crystallization, a very small amount of a second substance, less soluble than the main product and crystallizing in long, fibrous, white needles, is generally obtained, but this was not investigated further.

Calc. for  $C_{17}H_{11}N_2Cl$ : N, 9.69%; Cl, 12.29%. Found: N, 9.65, 9.63; Cl, 12.76, 13.06.

**Dibenzylbenzamidinium Hydrochloride**,  $(C_6H_5CH_2)_2NC(NH)C_6H_5.HCl$ .—Prepare phenyl magnesium bromide from 15 g. of magnesium, 10.2 g. of phenyl bromide and dry ether. Cool with ice and allow 13.9 g. of dibenzylcyanamide in dry ether to drop slowly in. Treat the mixture with ice and hydrochloric acid, and a solid separates between the ether and acid layers. The material on filtering and drying weighs 14 g. Trituration with ether before crystallization served to remove most of the yellowish impurity. The hydrochloride is soluble in acetone, alcohol and chloroform, but on evaporation deposits a glassy mass. The best solvent proved to be a 5% hydrochloric acid containing a little alcohol when large rhombohedra form with a m. p.  $211.5^{\circ}$ .

Calc. for  $C_{21}H_{15}N_2Cl$ : N, 8.35%; Cl, 10.57%. Found: I, N, 8.52, 8.24; Cl, 10.26, 10.38, 10.66.

**Dibenzylbenzamidinium**,  $(C_6H_5CH_2)_2NC(NH)C_6H_5$ .—Grind crystals of dibenzylbenzamidinium hydrochloride to a fine powder, make it into a paste with water, and add strong ammonium hydroxide until excess is present. The solid material changes its appearance under this treatment, and forms pasty-like bunches. Extract with ether. This extract holds all the solid, and after drying it with anhydrous calcium chloride and spontaneous evaporation, a transparent, sticky material deposits which gradually solidifies to hard, white nodules. Yield quantitative. This substance is very soluble in water and all the ordinary organic solvents, and so difficult to purify. From ether it was possible to obtain a constant melting point of  $70-71^{\circ}$ .

Calc. for  $C_{21}H_{15}N_2$ : N, 9.3%; C, 84.0%; H, 6.66%. Found: N, 9.2; C, 83.3, 84.8; H, 5.6, 7.27.

**Dibenzyltoluénylamidinium Hydrochloride**,  $(C_6H_5CH_2)_2NC(NH)C_6H_4CH_3(p).HCl$ .—Treat the Grignard reagent made from 2.1 g. magnesium, 14.5 g. of *p*-bromotoluene and dry ether, after cooling, with 10 g. of dibenzylcyanamide dissolved in ether. Allow the mixture to stand at room temperature a few hours, then decompose with ice and hydrochloric

acid. Filter and dry the solid which separates between the ether and acid layers. A quantitative yield results. This substance proved a very difficult one to purify. Although we tried different combinations of hydrochloric acid, alcohol and water, we were unable to remove the small amount of yellowish impurity, and the analyses for chlorine did not give constant values. We found it advisable, therefore, to make the free amidine and then the phenyl isocyanate derivative.

**Dibenzyltoluénylamidinemonophenyl Ureide**,  $(C_6H_5CH_2)_2NC(NCO-NHC_6H_5)C_6H_4CH_3(p)$ .—Moisten 3 g. of the amidine hydrochloride with water and add a slight excess of concentrated potassium hydroxide solution. Extract with ether, and dry the solution obtained with calcium chloride. On evaporation the free amidine, a yellowish crystalline solid melting at about  $80^\circ$ , and very soluble in all organic solvents, results. Dissolve a known weight of this material in absolute alcohol, and add the theoretical amount of phenyl isocyanate. On evaporation of this solution, fine, white needles in a quantitative yield deposit, which crystallize very readily from alcohol to a constant melting point of  $158^\circ$ .

Calc. for  $C_{29}H_{27}N_3$ : N, 10.0%; C, 80.36%; H, 6.23%. Found: N, 9.75; C, 80.38; H, 6.56.

CAMBRIDGE, MASS.

## ON THE SULFONPHTHALEIN SERIES OF INDICATORS AND THE QUINONE-PHENOLATE THEORY.<sup>1</sup>

By H. A. LUBS AND S. F. ACREE.

Received June 15, 1916.

In developing a method for the colorimetric determination of the hydrogen-ion concentration of bacteriological cultures and culture media, one of us and Clark<sup>2</sup> found that many of the available indicators were unsatisfactory for reasons previously described. On this account a number of new indicators of the methyl red and sulfonphthalein types were synthesized. The phenolsulfonphthaleins had appeared especially promising from the work of White<sup>3</sup> and one of us on this group, not only because the compounds show brilliant color changes but also because their chemical constitution is of such a nature that the substitution of suitable groups should cause their affinity constants to vary to almost any desired degree and give a series of indicators which can be used to measure a wide range of hydrogen-ion concentrations; furthermore, the new compounds ob-

tained would give evidence on the quinone-phenolate theory<sup>1</sup> proposed by one of us. The additional evidence obtained by us from a study of these new compounds and the spectrophotometric data recently by Professor J. S. Guy, confirms so beautifully the theory that there can now be hardly any doubt of its correctness. A further study of the phenolsulfonphthalein series from the standpoint of the quinone-phenolate theory will be continued by Acree and his co-workers by the use of (1) colorimetric, conductivity and catalytic methods, and (2) the hydrogen electrode in order to measure the equilibrium and ionization constants. The "normal and abnormal salt catalysis" by organic and inorganic compounds will be especially investigated by the methods outlined by one of us in earlier papers,<sup>2</sup> in order to try to obtain a series of indicators having only "normal" effects, especially in culture media for fungi. The "salt effects" of organic and inorganic compounds of various classes have been extensively investigated by Clark and Lubs in order to obtain a series of indicators as nearly free from these influences as possible. A preliminary account of this phase of their investigations on the biochemical applicability of indicators will be published shortly.

The phenolsulfonphthalein series was chosen for a further study of the quinone-phenolate theory of indicators because they possess properties which are almost ideal for allowing us to obtain certain crucial data which cannot be secured in the phenolphthalein, rosolic acid, alizarin and analogous series. This theory postulates that the change of color produced in solutions of phenolphthalein by the addition of alkalis is not due chiefly to the rearrangement of a colorless lactoid (A) and the formation of a mono-basic carboxylate salt corresponding to (F), containing a simple colored quinone group, as formerly assumed by others, but arises because of the formation of a quinone group and a phenolate group (G) or its ion. These two groups can combine and form the intensely colored inter- and intra-molecular quinone-phenolate complex (H) similar to the deeply colored double compounds, such as  $O : C_6H_4 : O \cdot 2NaOC_6H_5$ , which Jackson and Oenslager<sup>3</sup> made by combining separate molecules of quinones and alkali phenolates, and which Slagel<sup>4</sup> showed to be formed in aqueous solutions.

Although in the earlier papers the deep colors of the dibasic (carboxylate, phenolate) salts,  $(KOOCC_6H_4)C(:C_6H_4:O)(C_6H_4OK)$ , of phenolphthalein isolated by Meyer and Spengler,<sup>5</sup> and the deep blue color of the potassium and silver phenol salts of the carboxyl esters of phenol-

phthalein<sup>1</sup> and tetrabromophenolphthalein,<sup>2</sup>  $(\text{ROOCC}_6\text{H}_4)\text{C}(:\text{C}_6\text{H}_4:\text{O})-(\text{C}_6\text{H}_4\text{OK})$ , of aurine,<sup>3</sup>  $(\text{HOC}_6\text{H}_4)\text{C}(:\text{C}_6\text{H}_4:\text{O})(\text{C}_6\text{H}_4\text{OK})$ , and of analogous substances were the basis of the quinone-phenolate theory, we knew that strict logic required the present synthetic work and further quantitative verifications. In other words, the *apparent* color of the dibasic phenolphthalein salts might really arise from admixed deeply colored monobasic salts, just as sodium chloride can be made deeply colored by evaporating it with a solution of a small quantity of dye. Likewise it was clear that the *apparent* color of the phenol salts of the carboxyl esters of phenolphthalein might really arise from the saponification of small amounts of the ester group and the formation of traces of a colored *monobasic* carboxylate salt, whose anion containing a quinone and phenol group would be analogous to the anion of monobasic deeply colored aurine salts containing a quinone and phenol group. This work, therefore, did not disprove absolutely the possibility that the color in all of these cases really arises from small amounts of substances containing a quinone and a phenol group.

The disadvantages encountered in testing this theory in the phenolphthalein series can be readily overcome by using the analogous phenolsulfonphthalein compounds, which differ from the phenolphthaleins simply in that the weak carboxyl group  $-\text{COOH}$ , is replaced by the strong sulfonic acid group  $-\text{SO}_3\text{H}$ , of (D). The phenolsulfophthaleins possess the following advantages:

1. They are much more soluble in water and alcohol and exist to a large extent in the colored quinoidal form of the acid, (D) and (E), whereas the phenolphthaleins are practically only colorless lactoids, (A).

<sup>1</sup> Green and King, *Ber.*, **40**, 3724.

<sup>2</sup> Nietzki, Burckhardt, and Schraeder, *Ibid.*, **28**, 48; **30**, 177.

<sup>3</sup> Friedländer, *Ibid.*, **26**, 172.

2. Whereas the pure slightly colored monobasic salt<sup>1</sup> (F) has not been isolated in the phenolphthalein series, a number of such salts have been made<sup>2</sup> in the phenolsulfophthalein series and their colors and absorption spectra in solution have been shown to be almost identical with those of the free acid (D) and (E) and entirely different in character and intensity from those of the corresponding deeply colored dibasic salts (G) or (H).

3. Their dibasic salts (G) or (H) have been isolated<sup>3</sup> and their colors and absorption spectra in solution are as different in character and intensity from those of the acids (D) and (E) and monobasic salts (F) as are the intense colors of the phenol salts of quinoidal phenolphthalein esters,  $\text{RCOCC}(:\text{C}_6\text{H}_4:\text{O})(\text{C}_6\text{H}_4\text{OK})$  or of aurine,  $(\text{KCC}_6\text{H}_4)\text{C}(:\text{C}_6\text{H}_4:\text{O})(\text{C}_6\text{H}_4\text{OK})$ , from the fainter colors of the corresponding free ester or aurine.

The solubilities of all the phenolsulfophthaleins studied so far are about 100 times those sufficient for a satisfactory study of the color changes. For instance, White<sup>2</sup> has shown that the solubility of phenolsulfophthalein is about 0.03 gram per 100 cc. water, and the other compounds made by him and those since prepared by Lubs<sup>3</sup> and Clark have similar solubilities. The colors of these solutions indicate that considerable quantities of the quinoidal form (D) and (E) are present whose strong sulfonic acid group makes the solution markedly acid. This conclusion has been confirmed by White, who has shown by conductivity measurements that approximately 65% of the phenolsulfophthalein exists in the quinoidal form.

The strongly acid properties of the phenolsulfophthalein series are in marked contrast to those of the weak phenolphthaleins. The carboxyl and phenol groups of phenolphthaleins differ so little in strength and the alkali is partitioned between them to such an extent that visible quantities of the "dibasic quinoidal carboxylate phenolate salt" (G) and (H) are formed by the addition of the smallest quantities of standard alkalies. On the other hand, a consideration of the phenolsulfophthaleins corresponding to (D) and (E) shows that the molecule contains a very weak phenol group which is suppressed still more in ionization by the strong sulfonic acid with an affinity constant close to those of the strong mineral acids. This series was chosen for the present studies because it was predicted that they would act as "self-indicators" and that a large fraction of one molecule of alkali would be neutralized by the strong sulfonic acid group before the useful  $\text{P}_\text{H}$  range would be reached, or, to be more explicit, before any *phenol* salt could be formed and an appreciable

<sup>1</sup> Kober and Marshall, *THIS JOURNAL*, 34, 1431, 1432, isolated the colorless carbinol monobasic salts.

<sup>2</sup> White, Dissertation, New Orleans address, *Science*.

<sup>3</sup> *Loc. cit.*

change of color occur. The experimental evidence has confirmed this prediction and the quinone-phenolate theory. Small quantities of added alkali are first neutralized practically completely by the strong sulfonic group without any appreciable change of color and a simultaneous tautomeric rearrangement of (A) into (D) ensues. As fast as the sulfonic acid is neutralized the ionization of the remaining portion is suppressed more and more by the increasing amount of sulfonate anions formed and finally becomes so small that the alkali is neutralized very appreciably by the hydrogen ions from the phenol groups and the *intense, different* color of the dibasic quinone-phenolate salt and its anion appears. The amount of alkali necessary to produce this sharp change of color is about 0.85–0.87 molecule in the case of phenolsulfophthalein, and about 0.98 molecule in the case of thymolsulfophthalein, and hence will necessarily depend upon both (a) the value of the constant for the equilibrium between the lactoidal and quinoidal structure, and (b) the relative magnitudes of the affinity constants of the sulfonic acid and of the phenol. The equilibrium constants under (a) are being measured and are therefore not adequately treated in this paper. By substituting negative bromo or nitro groups in the  $-\text{C}_6\text{H}_4\text{SO}_3\text{H}$  residue, the affinity constant of the  $-\text{SO}_3\text{H}$  group is increased, while that of the phenol group and the  $P_H$  ranges are not changed.<sup>1</sup> Phenolsulfophthalein and phenol-nitrosulfophthalein<sup>1</sup> have the same  $P_H$  range, 6.8–8.4, and thymolsulfophthalein and thymolnitrosulfophthalein<sup>1</sup> have the same  $P_H$  range, 8.0–9.6. The ionization of the phenol group is simply suppressed more by the nitrosulfonic acid group and nearly one molecule of alkali can be added before the deeply colored dibasic salt is visible. By the substitution of negative bromo or nitro groups in the phenol residue, however, the affinity constant of the phenol groups is greatly increased. For example, the affinity constant of phenol, about  $10^{-10}$ , is increased about 700 times or to  $6.8 \times 10^{-8}$ , by the introduction of one nitro group in the ortho position, and increased about 2,700,000 times, or to  $2.7 \times 10^{-4}$ , by its conversion into *o,o*-dinitrophenol. It follows then that the introduction of these negative groups into the phenol residues of (D) by the ordinary substitution methods should, and does, make the phenol group much stronger and hence a smaller  $P_H$  value will still give enough phenolate anions to begin to give the color; in other words, the addition of smaller amounts of bases will cause the intense color changes in these substituted compounds. On the other hand, the substitution of methyl, isopropyl or amino groups in the phenol residues should, and does, lower the affinity constant of the phenol group and raises the  $P_H$  rays from 6.8–8.4 for phenolsulfophthalein to 7.2–8.8 for *o*-cresolsulfophthalein and 8.0–9.6 for thymolsulfophthalein. These alkyl groups, therefore, raise the 0.85

<sup>1</sup> See Lubs and Clark, *J. Wash. Acad. Sci.*, 6, 483 (1916).

mol alkali required to change the color of the phenolsulfophthalein to about 0.95–0.98 molecule of alkali required to raise the  $P_H$  value enough to give the intense color change in *o*-cresolsulfophthalein and thymolsulfophthalein. The introduction of two bromine atoms into the thymol groups then raises the affinity constant of the thymol phenol group and lowers to 0.90–0.92 molecule the amount of alkali necessary to give the  $P_H$  value required for the intense color change.

In general, the introduction of negative chloro, bromo, nitro, etc., groups into the phenol residues might be expected to change the  $P_H$  range in a fairly regular manner for all these compounds. It is, therefore, interesting to note<sup>1</sup> that the difference between the  $P_H$  ranges for thymolsulfophthalein, 8.0–9.6, and for dibromothymolsulfophthalein, 6.0–7.6, is about 2.0, which is the same as the difference between the useful  $P_H$  range for *o*-cresolsulfophthalein, 7.2–8.8, and dibromo-*o*-cresolsulfophthalein, 5.2–6.8. This value 2.0 is also just half the difference between the  $P_H$  ranges for phenolsulfophthalein, 6.8–8.4, and tetrabromophenolsulfophthalein, 2.8–4.6. We expect to study these relations for a large number of such compounds. It is only fair to state that it is difficult to purify some of these indicators and that some of the quantitative data given in this paper may be modified later.

There is now evidence<sup>2</sup> at hand to show that the source of intense color in these solutions is chiefly the inter- or intra-molecular combination of a quinone and a phenolate ion in (G) and (H) and not simply the quinone and non-ionized phenolate salt. In solutions of the free tetrabromo- and tetranitro-phenolsulfophthalein and of the dinitro-thymolsulfophthalein the phenol groups are highly ionized and give clearly, *without the addition of any alkali*, the colors characteristic of the nearly completely ionized dibasic salts. The addition of strong mineral acids suppresses the ionization of the phenol group and discharges the intense color of the quinone-phenolate ion. The intense color would not fade if it came from the nonionized quinone-phenolate grouping. That the quinone group actually combines with the phenolate ion is shown by the fact that the yellow band characteristic of the spectrum<sup>3</sup> of the free acid and monobasic salt, and hence coming from the quinone group, disappears when the dibasic salt is formed. All phases of this problem will be studied by the use of the phenolsulfophthaleins and their salts, esters, and other derivatives.

**Phenolsulfophthalein.**—White showed that when eleven parts of pure crystalline anhydride of sulfobenzoic acid are fused with 12 parts of phenol at 140° for 6 hours, as described, by Remsen,<sup>4</sup> Sohon, and Holmes,

<sup>1</sup> Lubs and Clark, *J. Wash. Acad. Sci.*, 6, 483 (1916).

<sup>3</sup> White, Dissertation, New Orleans address, *Science*.

<sup>4</sup> *Am. Chem. J.*, 20, 257; 25, 201.

the mass becomes pasty. It is allowed to cool and is boiled with water and filtered. The same compound has been made by Lubs<sup>1</sup> and Clark by heating the acid chloride and phenol. The red powder is dissolved in dilute alkali and reprecipitated by addition to hot dilute hydrochloric acid. When washed repeatedly with hot water the powder is practically pure. It can be recrystallized from phenol by the addition of ether. The acid is soluble in water to the extent of about 0.3 g. per liter. It is yellow in slightly acid solution, pink in stronger acids, and purple in weak alkalies. Stronger alkaline solutions discharge the color, probably through hydration, and the colorless solution becomes colored again on the addition of acids. When an excess of the solid is agitated with alkaline solutions, or with carbonates or with oxides of the heavy metals, yellow or orange solutions of the monobasic<sup>2</sup> salts are formed, and these salts can be isolated by evaporation of the solutions *in vacuo*. The addition of two molecules of an alkali to the acid produces the deep red dibasic salt and the addition of soluble salts of heavy metals does not produce deep red precipitates of the dibasic heavy metal salts. Solutions containing about 0.03 g. phenolsulfophthalein in 100 cc. water are yellow or orange in color. The addition of 0.01 *N* alkali produces *locally* the deep red color of the dibasic salt where the drop of alkali falls, but this color disappears immediately when the solution is stirred and the dibasic salt is changed to the yellow monobasic salt as follows:

This set of reactions can be continued until about 0.85–0.87 molecule of alkali is added and the red color becomes faint and permanent. It then requires about 2% more 0.01 *N* alkali to change the color into a decided red, which increases in intensity by the addition of more alkali. This set of color changes is characteristic of all the analogous sulfophthaleins, only the quantitative relations and colors varying in different cases.

The following data<sup>3</sup> show the amount of alkali required to produce the permanent color change. Carbon dioxide must be rigidly excluded in the titration of all these sulfophthaleins. Approximately 0.02 *N* alkali was found to be suitable for the titrations. In the column headed "Cc. NaOH, theory" are given the number of cubic centimeters of alkali calculated for the sulfophthalein as a monobasic acid, and Columns 5 and 6 give the amount and per cent. of one molecule actually required.

<sup>1</sup> *Loc. cit.*

<sup>2</sup> White, Dissertation, etc.

<sup>3</sup> A new standard alkali solution was used in this and succeeding titrations, which accounts for the fact that 8 required a larger volume of alkali than did 6, although Sample 8 was smaller than Sample 6.

No.	Wt. of phthalein.	Vol. of solution. Cc.	Cc. NaOH theory.	Cc. NaOH found.	Per cent. of 1 molecule. Eq.

Average, 86.3

Titration 1 to 6, inclusive, were made with material obtained from Hynson, Westcott & Company, Baltimore. The others were made with material of our own preparation,<sup>1</sup> 10, 11 and 12 having been crystallized from phenol by the method already described.

The color changes of phenolsulfophthalein are produced in solutions varying in hydrogen-ion concentration from  $P_H$  6.50 to  $P_H$  8.50, and are very sharp between  $P_H$  7 and  $P_H$  7.5. Six drops of a 0.012% yellow solution of the monosodium<sup>2</sup> salt make an excellent indicator when diluted with 50 cc. of water and give a distinct purple color when only 0.01 cc. 0.1 *N* alkali is added.

**Tetrabromophenolsulfophthalein.**—This substance was prepared by White by the action of bromine on phenolsulfophthalein in glacial acetic acid. It melts at  $270-1^\circ$ . A concentrated aqueous solution is orange in color with a tinge of blue. The addition of hydrochloric acid decreases the ionization of the phenol group, discharges the blue color, and makes the solution yellow or orange in color. When this solution is diluted and the phenol group ionizes more the blue color comes out strongly again and the addition of alkali makes the solution intensely blue. The addition of hydrochloric acid again discharges the blue color. For example, 12 drops of 0.04% alcoholic solution of the tetrabromo compound added to 50 cc. water gave a solution whose blue color was distinctly discharged by the addition of 0.5 cc. 0.01 *N* hydrochloric acid. The larger affinity constant of the bromophenol group causes the color changes to take place sharply between  $P_H$  3.2 and  $P_H$  4.5. Three to six drops of a 0.04% alcoholic solution of the acid make an excellent indicator.

**Tetranitrophenolsulfophthalein.**—This compound was made by White

<sup>1</sup> White, Dissertation.

<sup>2</sup> Aqueous solutions of the monosodium salts of all of the sulfophthaleins can be used as indicator solutions.

by treating phenolsulfophthalein with a mixture of concentrated sulfuric and nitric acids. The compound is yellow in strongly acid solutions, but purple in water because of the large ionization of the nitro-phenol group. The addition of alkali does not appreciably increase the depth of the purple color but the addition of strong hydrochloric acid causes this to fade to yellow, which is changed to purple again when the solution is diluted and the ionization of the nitro-phenol group is increased. The large affinity constant of the nitro-phenol group is shown by the fact that White found a molecular conductivity of about 430 for this substance in  $N/1000$  solution, of which value about 370–80 as a maximum comes from the sulfonic acid group. The nitro-phenol group is too strong an acid to allow this substance to be a valuable indicator for most work. An excess of alkali causes the purple color to fade to yellow, which immediately changes to purple again when the excess of alkali is neutralized.

***o*-Cresolsulfophthalein.**—This indicator can be prepared either by the method of Remsen and Sohon or that of Lubs and Clark. The fusion of *o*-cresol with either the anhydride or chloride of sulfobenzoic acid gives about 50% yield. The *o*-cresolsulfophthalein can be recrystallized from glacial acetic acid and is soluble in alcohol and water. It is yellow in very dilute acid solution and purple in dilute alkalies. Two to four drops of a 0.4% alcoholic solution make an excellent indicator. Six drops of a 0.2% alcoholic solution added to 50 cc. water gave a distinct color change when 0.01 cc. 0.1 *N* alkali was added. The color changes are produced in solutions having  $P_H$  7.2 to  $P_H$  8.8.<sup>1</sup> The titration of *o*-cresolsulfophthalein with dilute alkalies shows clearly that the cresol group is so weak that practically one molecule of alkali is neutralized by the sulfonic acid group before sufficient phenolate salt is formed to change the color from orange to purple. For example, 0.0567 gram required 14.5 cc. 0.01 *N* alkali, or 98% of the theory, instead of the calculated 14.83 cc. alkali. The alkaline solution shows color phenomena characteristic of nearly all of these sulfophthaleins. A deep blue color is observed in reflected light. In transmitted light the solution appears deep red and the spectrum shows only a red band.

**Thymolsulfophthalein.**—This substance was prepared by Lubs and Clark by fusing the acid chloride with thymol in the presence of dehydrated zinc chloride 4 hours at 140° with frequent stirring. The melt was boiled with water and the hardened mass was extracted with alcohol to remove the remaining thymol. The cold alcoholic solution gave a precipitate of the thymolsulfophthalein as greenish crystals. The substance is yellow in very dilute acids, pink in concentrated acids, and deep blue in dilute alkalies when viewed by reflected light but deep red in transmitted light. The color changes take place between  $P_H$  8 and  $P_H$  9.75.

<sup>1</sup> Lubs and Clark, *J. Wash. Acad. Sci.*, 6, 483.

and the useful range lies between  $P_H$  8 and  $P_H$  9.5, which is about the same as that of phenolphthalein. Three to six drops of a 0.04% alcoholic solution makes an excellent indicator. For example, 12 drops of a 0.04% alcoholic solution added to 50 cc. water give a distinct green color change when 0.01 cc. 0.1 *N* alkali is added; 0.02 cc. makes the solution blue.

The isopropyl and methyl groups lower considerably the ionization of the phenol group and make it necessary to add practically one molecule of alkali before the blue color of the dibasic salt becomes visible. Titration of samples kindly furnished by Mr. H. A. B. Dunning showed that 0.0548 g. required 11.50 cc. 0.01 *N* alkali, or about 0.98 molecule instead of the theoretical 11.75 cc. Material prepared by Lubs gave the following data: 0.0564 g. required 11.70 cc., or 0.967 molecule, instead of the theoretical 12.10 cc.; 0.0560 g. required 11.60 cc. or 0.967 molecule instead of the theoretical 12.01 cc. As it requires only about 0.02 molecule of alkali to change the color decidedly from that of the orange-free acid and monobasic salt to the deep blue of the dibasic salt, it is clear that the thymolsulfophthalein gives excellent substantiation of the quinone-phenolate theory that the intense color change is not due to a monobasic salt and simply to the quinone group, but arises from the formation of a compound formed by the union of a quinone and a phenolate ion.

**Dibromothymolsulfophthalein.**—This indicator was prepared by Lubs and Clark by the action of bromine in glacial acetic acid on the thymolsulfophthalein and is obtained in yellow crystals. It is yellow in acid solution and deep blue in dilute alkalies when viewed by reflected light but red in transmitted light. The best color changes occur between the ranges of  $P_H$  6 and  $P_H$  7.25. About 2 drops of a 0.04% alcoholic solution make an excellent indicator, and become distinctly green in 50 cc. water when 0.005 cc. 0.1 *N* alkali is added; 0.01 cc. makes the solution blue.

The influence of the negative bromo groups in increasing the ionization of the phenol group is made clearly evident by the fact that less alkali is required to give the blue color than was found to be necessary with thymolsulfophthalein. For example, 0.0628 g. of a sample prepared by Dunning required 9.2 cc. 0.01 *N* alkali, or 0.91 molecule, instead of the theoretical 10.06 cc. Of material prepared by Lubs and Clark 0.0555 g. required 7.55 cc. 0.01 *N* alkali, or about 0.85 molecule, instead of the theoretical 8.89 cc. and 0.0643 g. required 9.50 cc. 0.01 *N* alkali, or about 0.92 molecule, instead of the theoretical 10.30 cc.

**Thymolnitrosulfophthalein.**—This compound was made by Lubs and Clark by heating thymol with the acid chloride of nitrosulfobenzoic acid and dehydrated zinc chloride. The subsequent treatment was like that for thymolsulfophthalein. It forms a powder which appears red or green-

ish blue, depending upon its fineness of subdivision and the way in which it is illuminated. It is yellow in dilute acids and deep blue in dilute alkalis in reflected light and shows a red and a violet band in transmitted light. This compound was made because it was predicted that the nitro group in the benzene sulfonic acid residue would increase the affinity constant of the sulfonic acid group more than that of the phenol group and that practically one molecule of alkali must be added before the intense color of the dibasic salt is observed. The experiments verify the theory. For example, 0.0415 g. requires theoretically 8.12 cc. 0.01 *N* alkali to neutralize the sulfonic acid group. The concentrated aqueous solution of this amount of the indicator is orange in color and the addition of 7.92 cc. or 0.98 molecule produces no change of color; when 8.02 cc., or 0.99 molecule of alkali, are added the blue color of the dibasic salt just began to appear. When 8.22 cc. or about 1.01 molecule of alkali were added there was a distinct change of color. When 0.67 cc. more 0.01 *N* alkali was added the color of the solution was dark green, when 1.2 cc. were added the solution was very dark green, and when 2.15 cc. were added the solution was bluish green. A total of two or more molecules of alkali made the solution dark blue in color. In another experiment 0.0435 g. was dissolved in about 200 cc. of hot water and titrated with 0.01 *N* alkali. One molecule of alkali corresponds to about 8.6 cc. alkali, and it required 8.2 to 8.3 cc., or about 0.96 molecule to produce any noticeable change in color. The addition of 8.5 cc. 0.1 *N* alkali made the solution dark red, 8.7 cc. made the solution very dark, 9.63 cc. made the solution olive-green, and 10.0 cc. made the solution a decided green in color. The addition of an excess of alkali made the solution deep blue and boiling the solution did not cause the color to fade perceptibly through the well-known hydration phenomenon. The excellence of this indicator is shown by the fact that 4 drops of a 0.04% alcoholic solution added to 50 cc. water required only 0.01 cc. 0.1 *N* alkali to give a distinct green color; 0.02 cc. makes the solution blue. The color changes take place between  $P_H$  8.2 and  $P_H$  9.6.

#### Conclusions.

1. Solutions of sulfophthaleins having no negative bromo or nitro groups in the phenol residues are yellow or orange in color; the colors and conductivities show that the indicators exist largely in the quinoidal form. They are "self-indicators" and can be titrated with from 0.85 to 0.98 molecule of alkali before the intense color change due to the dibasic salt is observed. The monobasic sulfonic acid salt (F) has practically the same orange or faint red color as the free, nearly completely ionized acid. All these facts make untenable theories formerly proposed by others that the intense color changes in the phenolphthalein series arise simply from the quinone group. The data give further evidence for the quinone-

phenolate theory that the intense purple or blue color is produced only when appreciable quantities of the dibasic quinone-phenolate salts are formed, which then give rise to the combination of the quinone group and the phenolate anion. The introduction of negative groups into the benzenesulfonic acid residue increases the affinity constant of this group but does not alter appreciably the affinity constant of the phenol group or the  $P_H$  range.

2. Solutions of sulfophthaleins having negative bromo or nitro groups in the phenol residues have high molecular conductivities and low  $P_H$  ranges, which fact indicates considerable ionization of the phenol residue. In harmony with this idea is the fact that these solutions exhibit more or less the colors of the dibasic alkaline salts. In conformity with these conclusions is the fact that the addition of mineral acids to solutions of these sulfophthaleins suppresses the ionization of the phenol group and changes the intense color characteristic of the dibasic salts into the fainter yellow or orange characteristic of the quinone group. In the *solid state* these bromo- and nitrophenol derivatives are yellow, while the sulfophthaleins with no negative groups in the phenol residues, or having negative groups in the benzenesulfonic acid group, are generally dark brick-red.

3. The fact that 0.98 molecule of alkali can be added to *o*-cresolsulfophthalein before the deep color appears shows that practically all of the monobasic salt exists as (F) and almost none as the colorless form (B) and that practically all of the dibasic salt is in the forms (G) and (H) and practically none in the colorless form (C). This monobasic salt is, therefore, nearly an ideal indicator because practically none of the alkali and indicator is wasted in forming colorless hydrated or lactoidal salts (C) but all is consumed in the formation of the deeply colored dibasic salts (G) and (H). These relations may vary for the different members of this group. This point is very important in the proposed equilibrium studies of these compounds and no such evidence can be obtained in the phenolphthalein series.

4. The free sulfophthaleins and the monobasic salts give absorption spectra containing a yellow band characteristic of the quinones. When the dibasic salt is formed this yellow band disappears and a deep red band appears. This indicates that the quinone group as such disappears because it combines with the phenolate anion and forms a complex quinone-phenolate group.

5. Solutions of the dibasic salts of some of these sulfophthaleins have different colors when viewed in reflected and then in transmitted light. This phenomenon has been noted by one of us in solutions of crystal violet and other substances and is being investigated to learn the charac-

teristics of the "reflection and transmission spectra" for each of these substances.

6. Solutions of some sulfophthaleins which are yellow in neutral or faintly acid solutions become red in stronger acids and, hence, have been found by Mr. Homer Cloukey to be colored red by such salts as zinc chloride and stannous chloride. But even some neutral salts, such as sodium chloride, change the colors of these solutions and this "salt effect" of acids, bases and salts will be extensively investigated.

7. On account of all of these characteristics of the sulfophthaleins it has been found possible to prepare a series of indicators having a wide range of sensibility of hydrogen ions. By substituting bromo, nitro, methyl, isopropyl, amino and other groups in the benzenesulfonic acid group, and especially in the phenol residue, one is enabled to change the ionization constants of the sulfonic acid and phenol groups greatly and hence prepare indicators covering a wide range of usefulness. The phenol, thymol, and cresolsulfophthaleins, and their bromo derivatives, are highly satisfactory indicators.

CHEMISTRY OF THE UNIVERSITY OF ILLINOIS.]

## EFFECTS OF LARGE APPLICATIONS OF COMMERCIAL FERTILIZERS ON CARNATIONS.\*

BY GEORGE D. BEAL AND FRED WEAVER MUNCIE.

Received August 21, 1916.

In the investigation of the use of commercial fertilizers in growing carnations by the Illinois Agricultural Experiment Station, it has been found that the lack of appreciation by florists of the relatively high plant food concentrations and often high solubilities of commercial fertilizers, as compared with manure, has often led to a complete loss of a crop of flowers in an effort to produce an extraordinarily large one. On this account, it was considered desirable to study the causes and effects of overfeeding with the more ordinarily used commercial fertilizers.

The fertilizers chosen for the experiment were dried blood, sodium nitrate and ammonium sulfate, acid phosphate and disodium phosphate, and potassium sulfate. For comparison, sodium chloride and sodium sulfate also were used on some sections. Experimental work upon the subject was carried out during the years 1912-15.

Carnations are propagated by means of cuttings, and from these it was

\* This paper presents the data contained in the thesis presented by Mr. Muncie in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Chemistry in the Graduate School of the University of Illinois.

found impossible to secure a normal growth in either sand or water cultures. Hence, the experimental work was based upon the study of plants grown in soil carefully selected with the view to securing uniformity throughout the benches, watered to give as nearly as possible the same moisture content, and subjected very nearly to identical conditions of heat, ventilation, and illumination. For details regarding the type of soil, its preparation, arrangement of sections, etc., the reader is referred to *Bull.* 176 of the Illinois Agricultural Experiment Station.

The method consisted of weekly applications of the fertilizers at various rates upon isolated sections in the benches, beginning about October 1 and continuing until about May 1 or until injury became serious.

**Effects of Overfeeding on Condition of Plants.**—The rapidity with which the sections of carnations became affected followed in a general way the solubility of the fertilizer used.\* The solubilities\*\* of the pure substances in water per hundred parts at 0° are given in Table I.

TABLE I.—SOLUBILITIES OF PURE SALTS IN WATER AT 0°. (PARTS PER 100.)

6.3	4 (15°)	0.028	0.241	

Commercial acid phosphate consists of about equal parts of mono-calcium phosphate and calcium sulfate. Reversion to monohydrogen phosphate in presence of bases in the soil would further decrease the low solubility of the acid phosphate and by double decomposition with calcium, iron and other bases in the soil render the sodium phosphate first applied less soluble, as pointed out by Cameron and Bell.<sup>7</sup>

Dried blood, giving soluble products at a rate depending upon the rapidity with which bacterial decomposition proceeds, could not be rated as having a known solubility without a study of the bacteriological activity of the soil mixture. Tests with litmus paper showed that the surface of the soil, neutral at the beginning of the experiment, became acid seven or eight days after the addition of the dried blood. Soil to which ammonium sulfate was applied became acid as quickly also.

Single applications of ammonium sulfate and sodium chloride at the rate of 12.5 kg. per 100 sq. ft. made on December 3, 1913, produced marked injury within a week's time. Equal amounts of potassium sulfate, at this time, followed by further applications at intervals of one or two weeks, at the rate of 1.25 kg. per 100 sq. ft., produced no signs of injury

\* The impurities in the ammonium sulfate, potassium sulfate (in this case 1.26% of chloride as sodium chloride) and disodium phosphate are not sufficient to interfere with the use of the solubilities of the pure substances as a rough measure of the solubilities of the fertilizers themselves.

\*\* Van Nostrand—Chemical Annual, 1910.

until about January 15, when a lack of turgidity became noticeable, followed by a gradual stunting of growth, with the more pronounced signs appearing only after the middle of March. Signs of injury in sections treated in the same manner with sodium phosphate became evident even more slowly, while acid phosphate produced no apparent injury even in the largest applications.

The fertilizers may be grouped into the class, easily soluble and producing almost immediate injury; a second, moderately soluble and producing delayed injury; and a third, difficultly soluble and producing no apparent injury. On days of continuous sunlight a more or less pronounced softness of tissue could be detected by careful observation long before characteristic injuries became apparent.

**Effects of Overfeeding with Ammonium Sulfate.**—A marked softness of tissue was the earliest sign of overfeeding with ammonium sulfate. A complete plasmolysis took place in that portion of the stem located two and three nodes below the bud and in the portion of the stem just above the node, so that the stem bent completely over. The shoots first affected were those with buds one-half to three-quarters developed. At the same time white spots 0.25 and 1.00 mm. in diameter appeared upon the upper leaves of these and the younger shoots. Microscopic examination of these showed the chlorophyll bearing tissue entirely plasmolyzed.

In contrast to the injury from other fertilizers, practically every flower split.\* This splitting was not caused by the pressing outward of the petals as is usually the case, but by a weakening of the tissue at the line joining the sepals to form the calyx cup. Later stages resulted in the drying up of the leaf tips, and the appearance of the white depressions upon the older leaves. The sepal tips very early became brown. Later, pustule-like elevations about 1 mm. across appeared on them, caused by a crystal of ammonium sulfate beneath the epidermis. The injury from excess of ammonium sulfate was more rapid and pronounced in the presence of lime than without it.

**Effect of Overfeeding with Sodium Nitrate.**—Injury followed heavy applications of sodium nitrate within a few days, the characteristic symptom being an even lightening of color of the foliage over the plant, followed by drying of leaf tips and petals and withering of the plant.

**Effects from Large Applications of Sodium Chloride.\*\***—The first appearance of injury from large amounts of sodium chloride was two days after its application, a plasmolysis of the cells of the stem, causing it to lose its rigidity at the crown. When held within supports the plants appeared

\* Splits is a trade term denoting flowers with split calyces.

\*\* Sodium chloride, while not strictly a fertilizer, was used in the experiments because of its presence in considerable amounts in kainite and in some grades of commercial potassium sulfate.

normal. Gradually, however, the plants lost their turgidity and the chlorophyll disappeared evenly throughout the entire plant. Tests made in the spring of 1915 with heavy applications of sodium chloride and potassium chloride (12 kg. per 100 sq. ft.) showed the same effect from each of them, while sodium sulfate, like potassium sulfate, showed less injury and that only after a longer period.

**Effects of Overfeeding with Potassium Sulfate.**—In earlier stages partial wilting occurred on days of sunshine. Drying up of the tips of the leaves and curling of the leaves upward upon their long axis followed, with often, also, a peculiar inhibition of growth on one edge of the leaf, with the same on the opposite edge of another portion, giving the leaf a wavy outline.

A marked stunting of growth was observable. This affected most noticeably the lengthening of the stem, resulting in the later shoots assuming a rosette appearance, due to the leaves of normal length upon a stem with undeveloped internodes less than an inch in length. (The internode in full grown shoots is ordinarily three or four inches long.) The edges of the petals of the flowers after about the middle of January became quite generally withered or crinkled. Those in the center of the flower remained closed quite tightly, while the other two or three rows opened normally. Later, the buds remained closed, although the pistil often pushed its way out and might be seen extending an inch above the top of the bud.

A marked increase in exudation of nectar in the flower was found to have caused the gluing together of the petals, and so prevented their opening. On cloudy days very frequently a calyx cup would be found completely filled with this exudation. The exudation was most plentiful in the flowers from plants receiving a moderately heavy application of potassium sulfate over a long period of time while the heavier applications caused a noticeable but less plentiful increase. A small amount of nectar is found in normal flowers, and somewhat larger amounts in the flowers from plants receiving large applications of sodium phosphate, sodium chloride, ammonium sulfate, or potassium chloride, but not so generally nor in such large amounts as in the sections treated with potassium sulfate. Injury was less marked when ground limestone was added to the soil, in contrast to the effect of liming on the production of injury by ammonium sulfate.

**Effects of Overfeeding with Sodium Phosphate.**—When moderately large amounts of sodium phosphate were added over a long period (as in 1913-14) no injury was noticeable until about the middle of March, when a retardation of growth was evident from the decrease in height of the plants and abnormally small buds and flowers. These signs of inhibition became steadily more pronounced until the plants were removed from the

benches, about May first. When larger amounts were used (as 12 kg. per 100 sq. ft. in 1914-15), loss of turgidity in the plants, longitudinal rolling of the leaves, death of the leaf tips and softness of the petals of the blossom were evident. These signs of injury appeared, however, only after the middle of January and then only gradually. Injury was less when the soil was limed than when not.

**Effects of Overfeeding with Dried Blood.**—In none of the experiments with dried blood did injury appear until about the middle of January. At that time a softness of the petals and irregularity of their arrangement, due to the partial opening of the inner and crinkling of the outer ones, became more or less common. The flowers became susceptible to browning when a drop of water from syringing lodged on a petal in a position to be reached by the rays of the sun. The height of the plants was below normal in the spring but rather above in the fall; the color was good. If the applications of dried blood were not continued after signs of injury became apparent, the plants gradually recovered. The same held true for plants overfed with ammonium sulfate in contrast to those which had been injured by potassium sulfate, sodium phosphate, and sodium chloride.

**Effects of Overfeeding on the Mineral and Nitrogen Content of Plants.**

—Effects upon the dry weight and ash are shown in Table II, the samples being the foliage from the shoots gathered January 9, 1915.

TABLE II.—DRY WEIGHT AND ASH IN FOLIAGE.

Section No.	Treatment.	Moist weight.	Dry weight.	%.	Ash (sulfated) per cent. of dry weight.
269.	Check.	G. 27.6.	17.8.		13.68.
271	125 P*	32.4	17.6		13.93
273	250 P	32.2	18.3		12.89
275	500 P	30.6	18.9		14.28
277	125 K	26.1	18.4		15.37
279	250 K	36.8	20.4		15.45
281	500 K	32.8	22.6		15.59
283	Check	28.2	19.2		13.19
285	125 NaCl	42.9	22.8		14.45

The increase in both values as the applications of any one fertilizer in a series were increased is shown in the table. The higher values for plants treated with potassium sulfate and sodium chloride over those treated with sodium phosphate correspond to the higher osmotic pressure values obtained from the sap of these plants as well as to the more rapid injury from potassium sulfate.

Determination of the total nitrogen and mineral content of the ash

\* N, P and K in the tables are used to indicate ammonium sulfate, disodium phosphate and potassium sulfate, respectively, while NaCl indicates sodium chloride and A. P., commercial acid phosphate. The figures preceding the letters indicate the number of grams applied weekly per 20 sq. ft. of bench space.

from various samples of plants treated with potassium sulfate gave the following values:

TABLE III.—EFFECT OF POTASSIUM SULFATE.  
Analyses. Per cent.

Treatment.	$\text{Na}_2\text{O}$ .	$\text{K}_2\text{O}$ .	$\text{SO}_3$ .	N(total).	$\text{P}_2\text{O}_5$ .
Check	1.09	5.38	1.07	2.58	0.72
K	1.25	6.62	1.91	2.53	0.70
	0.16	1.24	0.84	—0.05	—0.02

The data show an increased sodium,\* potassium and sulfur content, with practically a constant percentage of nitrogen and phosphorus.

A similar study of plants to which ammonium sulfate had been applied gave the results shown in Table IV.

Plants to which sodium phosphate was applied showed a higher phosphorus content, 0.60%  $\text{P}_2\text{O}_5$  and 1.17%  $\text{P}_2\text{O}_5$  in a sample of 1915 in which the calcium content was decreased (2.31 and 1.63%  $\text{CaO}$ , respectively, in the last set of samples); the nitrogen content was increased by applications of sodium phosphate, the values 1.99%, 2.84% and 3.30% being obtained from plants to which had been applied, respectively, none, 250 g. and 500 g. of sodium phosphate per 20 sq. ft. of bench space per week for several weeks.

TABLE IV.—EFFECT OF AMMONIUM SULFATE.  
Analyses. Per cent.

Treatment.	N(total).	N(by $\text{MgO}$ ).	$\text{SO}_3$ .	$\text{P}_2\text{O}_5$ .
Check	2.05	0.168	0.75	0.93
N	2.93	0.364	2.10	1.14
	0.88	0.196	1.35	0.21

The ratio  $2\text{N}/\text{SO}_3$  in ammonium sulfate is  $28/80 = 0.351$ , that of total nitrogen to sulfur increase is 0.652; and of nitrogen by  $\text{MgO}$  0.145. The intake of sulfur when this fertilizer is used is less than is required for the nitrogen then, but in excess of that required to be combined with the nitrogen determined by  $\text{MgO}$ .\*\* Limestone was found to depress the sulfur intake from ammonium sulfate. Since injury was greater in sections so treated, the injury is not proportional to the intake of sulfur. The intake of phosphorus was increased by the addition of ammonium sulfate, probably due to acidity developed in the soil.

Table V shows the total nitrogen content of some plants from Sections 264 (ammonium sulfate and lime) and 281 (ammonium sulfate). Samples

\* Mayer<sup>22</sup> states that the addition of soluble potassium salts to a soil causes a partial replacement of the sodium.

\*\* The author would not care to report the presence of ammonium salts in plants not fed with it. It seems, rather, that  $\text{MgO}$  has caused some decomposition of the organic material; the error due to this is assumed to be the same in both samples.

were collected on April 25, 1914. Section 281 had received but one application at the rate of 12.5 kilos per 100 sq. ft. on December 3, 1913, while applications at the rate of 1250 g. per 100 sq. ft. were made to Section 264 at 15 different intervals of about two weeks after December 20, 1913. Analyses were made of upper and lower portions of the plant separately in order to show any localization of nitrogen in the more vigorously growing portion of the plant.

TABLE V.—TOTAL NITROGEN DETERMINATION ON FOLIAGE.

Sample No.	Plant No.	Section.	Portion.	Condition.	Nitrogen. %.
1	1	264-E	upper	half dead	4.58
2			lower	half dead	4.07
3	4	264-P	upper	half dead	7.78
4			lower	half dead	5.64
5	1	264-P	upper	dead	6.14
6			lower	dead	3.41
7	11	264-E	upper	alive	6.69
8			lower	alive	5.70
9	4	264-E	upper	half dead	7.01
10			lower	half dead	3.34
11	11-15	281-E	upper	dead	4.60
12			lower	dead	3.02
13	16	281-E	upper	partially affected	4.73
14			lower	partially affected	3.78
15	20	281-E	upper	half dead	4.73
16			lower	half dead	2.94
17	7	281-E	upper	slightly affected	4.47
18			lower	slightly affected	3.21

The total nitrogen content of the plants varied from once and a half to more than twice the normal value found in the previous set. Average values for the plants from Section 264 are 6.44% and 4.43%, respectively; for those from Section 281, 4.63% and 3.24%. In each case the more vigorously growing portion contained the larger percentage of nitrogen and the increase over the lower portion is considerably greater in the section to which the smaller applications were made during the entire season. No clear relation is shown between the nitrogen content and the degree of injury. Considerable tolerance for ammonium sulfate is shown when it was applied to the soil in quantities not heavy enough to produce immediate, serious injury. The fact that the dead plants had no higher total nitrogen content than those only injured is evidence that part of the nitrogen when added in small quantities was changed to a nontoxic form, since the dead plants were in this condition as early as March 21, while the living ones though injured undoubtedly continued to take up the salt in solution until samples were taken.

A series of ammonia determinations was made on the sap from "checks" and ammonium sulfate fed plants of the set of 12-9-14. Folin's micro-method for the determination of free<sup>14</sup> ammonia was used, the excess of

sulfuric acid (0.01550) being titrated back with potassium hydroxide 0.02130 with sodium alizarin sulfonate as the indicator. Results are given in Table VI.

TABLE VI.—FREE AMMONIA IN PLANT SAPS.\*

Sample No.	Treatment.	Appearance.	Nitrogen. Mg. N per cc.
5	check	normal	none
8	250 N	normal	0.1834
7	500 N	normal	0.1372
2	1000 N	slightly injured	0.6390
1	1000 N	badly injured	1.0560

The white spots on the leaves of plants treated with ammonium sulfate, and of crystals imbedded beneath the epidermis of the sepals were studied by microchemical methods.<sup>4</sup>

1. January 21, 1914. Plant Number 4, Section 281, White Enchantress. Plant apparently normal. A drop of sap from the stem of a shoot was treated with a drop of ammonia-free hydrochloric acid and chloroplatinic acid, and evaporated at room temperature under a loosely covering watch-glass. A few crystal masses, tetrahedral and often aggregated in shape of a cross, appeared. They were yellow in color. Sap from Number 8, somewhat injured, and Number 12, badly affected, gave these characteristic crystals, also.

2. A section of the leaf showing white blotches was immersed in chloroplatinic acid after removal of the epidermis and allowed to remain overnight. Large and perfect crystals appeared, arranged usually around the injured spot, never in it. They were insoluble in 95% alcohol which removed the excess of chloroplatinic acid.

3. A drop of sap from plant Number 4, Section 281 was distilled with a pinch of sodium carbonate over a micro-burner and the distillate caught in a hanging drop of hydrochloric acid in a cover glass placed on a glass ring above it. Treatment as above gave small, yellow tetrahedra insoluble in 95% alcohol.

Ammonium salts were evidently present and apparently caused plasmolysis of certain of the chlorophyll bearing cells. Why injury of this type is caused by ammonium sulfate in contrast to the even lightening of the color of the whole leaf by the other soluble salts, sodium nitrate and sodium chloride, is not known.

Nitrate determinations according to the phenolsulfonic method of Mason<sup>21</sup> were made upon the sap of a "check" and an ammonium sulfate fed plant from the set of March 9, 1915. The values of 0.01 and 0.40 mg. N as nitrate per cc. of sap, respectively, showed that nitrification was proceeding in the soil although it was quite strongly acid.<sup>17</sup>

\* In earlier stages of feeding with ammonium sulfate, samples have been taken in which no  $\text{NH}_3$  was detected by this method.

Total solids and ash were determined on the sap of the set of 12-9-14. The results, given in Table VII, are calculated to milligrams per cc. of sap.

TABLE VII.—TOTAL SOLIDS AND ASH OF SAP.

The average total solids content of the sap was 85.1 mg. per cc. and the ash content 14.9 mg. The influence of the fertilizer applications is seen in the increase in both values as the applications of any fertilizer were increased in a series of sections. Sample 3 of the first set and 6 and 7 of the second, all of which were from plants to which large applications of potassium sulfate had been made, showed particularly high values.\*\*\* The first set of data was obtained by drying the samples in a Sargent electric oven at 60-70°, the second in a vacuum oven heated to 50° for 12 hours. The actual value for total solids depended on the length of heating but experiments with both sets of data given showed the same relative values after several successive heatings.

\* Ash determinations upon the sap were made by careful incineration of the solids in 1 cc. of sap in platinum dishes over a low flame to prevent mechanical loss of particles of the ash. The low chloride content obviates the danger of volatilization of potassium chloride by high temperatures.

\*\* For some reason total solids and ash determinations always ran higher in sap from plants in Section 283 than from those in other "check" sections. The same discrepancy is seen in the osmotic pressure data for these two sets.

\*\*\* The determination of total solids with accuracy is not possible on account of the uncrystallizable solutes in the sap, and on this account the mean molecular-weight calculations which often accompany osmotic pressure data were not made. Drying on the water bath was found to cause charring of the sap from plants which had been treated with ammonium or potassium sulfate. The first showed a higher acidity value, the second a higher sugar content.

Determinations of sodium and potassium in the ash from sap obtained on January 9, 1915, from plants treated with potassium sulfate, were made in order to show the increased intake of potassium. Similarly, determinations of phosphorus were made upon the sap from plants fertilized with disodium phosphate. The results, calculated to milligrams per cc. of sap, are given in Table VIII.

**Effect of Overfeeding on Osmotic Pressure of Sap.**—Sap was expressed from the stems of shoots after freezing them with an ice-salt\* mixture, and the lowering of the freezing point determined by the method of Harris and Gortner\*\* of allowing supercooling until the solution froze and correcting the value of  $\Delta'$  obtained by the formula

$$\Delta = \Delta' - 0.0125 u \Delta'$$

where  $\Delta'$  is the maximum temperature attained in the system and  $u$  the difference between this value and the minimum temperature. The relation between  $\Delta$  and the osmotic pressure given by Lewis<sup>19</sup> in the approximate equation

$$\pi = 12.06 \Delta$$

was used in calculating the value for  $\pi$ .

**Description of Experimental Method.**—Choosing a time when for two or more hours previous no appreciable draft had been stirring the air in the greenhouse, from four to eight shoots at the same stage of growth were removed from each of the sections of plants and quickly taken to

\* Care was taken to select samples from the check and affected plants at the same time of day and shoots in the same stage of growth were taken, to insure freedom from variations in osmotic pressure due to differences in location and illumination, while the fact that the sections studied were usually adjacent obviated the difficulty that differences in temperature change the osmotic pressure of plants. See Dixon and Atkins,<sup>11</sup> Atkins,<sup>3</sup> Ewart,<sup>13</sup> Drabble and Drabble,<sup>12</sup> Cavara.<sup>8</sup>

\*\* The method in general was an adaptation of that recommended by Gortner and Harris.<sup>16-18</sup> André<sup>1</sup> and also Dixon and Atkins<sup>11</sup> have shown that successive portions of sap expressed from unfrozen tissue become more concentrated, while the latter have shown that the sap from frozen tissue always has a lower freezing point than that from unfrozen, and that successive portions gave nearly identical lowerings, leading to the conclusion that sap so expressed is representative of that originally within the tissue.

the laboratory. After removal of the foliage from the stems, they were broken at the nodes and placed in hard glass test tubes (25 mm.  $\times$  150 mm.), stoppered with rubber stoppers and sealed with oil paper and rubber bands. Freezing was produced by the use of the ice and salt bath,\* giving a temperature of  $-15^{\circ}$  or lower and allowing the tubes to remain in the refrigerator overnight. The tubes were then removed from the bath and after the walls had been cleaned with distilled water and wiped dry, the portions of shoots were removed, thawed gradually, and the sap expressed by pressure from the screw of a tincture press set perpendicular to the wall upon two pieces of  $\frac{3}{8}$  inch plate glass. After a first expression, the shoots were rearranged and pressure again applied. The sap was filtered through an S. & S. 589 filter—with a watch glass over the funnel to minimize evaporation—into a small test tube; a drop of xylene was added as a preservative and the tubes placed at once in a refrigerator, at about  $10^{\circ}$ . The sap after filtration was usually a clear, brown liquid without sediment.

As soon as convenient the freezing-point determinations were made. A thermometer was used having a bulb about 5 mm. by 35 mm., the mercury tube enclosed in a hollow jacket, and graduated to  $-6.5^{\circ}$  in tenths of degrees, upon which, by the aid of a lens, hundredths of a degree could be read without danger from parallax. A stirrer of platinum wire and the thermometer were placed in the 5 cc. of sap contained in a test tube of Bohemian glass (15  $\times$  120 mm.) and the whole cooled to about  $+2^{\circ}$  in an ice and salt bath in a beaker. The tube was wiped free from water and placed within a hard glass test tube (25 mm.  $\times$  150 mm.) set two-thirds way into the ice and salt-freezing mixture. It was found saving of time to place this bath in a Dewar bulb, with inside diameter of 35  $\times$  130 mm.; the top was closed with a piece of cork; the bath so arranged remaining effective for three hours or more of use. During the entire cooling, the sap was constantly stirred to prevent its freezing about the sides of the tube. The lowest temperature obtained was read to one-tenth, and the maximum, by the aid of a lens, to one-hundredth degree. The tube was removed to a beaker of water, and after the temperature had risen to about  $10^{\circ}$ , the determination duplicated to within  $0.01^{\circ}$ , usually without difficulty on the first trial. A typical determination gave the following values:

$$\begin{array}{lll} \Delta' = 1.28 & u = 4.12 & \Delta = 1.214 \\ \Delta' = 1.27 & u = 3.43 & \Delta = 1.216 \\ \text{Average } 1.215 \text{ from which } \pi = 14.64 \text{ atmospheres.} \end{array}$$

\* It was found convenient in case less than a dozen tubes of material were frozen, to place the ice and salt bath in one or two one-liter Jena beakers. In this way the ice can be packed about the upper portions of the test tubes, and the beakers, with five or six test tubes in them, are narrow enough to keep the tops of the test tubes from touching the solution.

**Discussion of Results.**—No comparison can be made between the values for the osmotic pressure determined in successive sets on account of variations due to temperature, physiological scarcity of water, etc., but the values obtained from plants in adjacent sections at the one time are regular enough to be comparable.

From the values for osmotic pressure of Samples 7, 8, 2 and 1 of the set of 12-9-14 the conclusion was drawn that the osmotic pressure within the plants increased as the quantity of ammonium sulfate applied to the soil was increased. Samples 2, 3 and 4, and 5, 6 and 7 of the set of 1-9-15 gave similar results with increasing applications of sodium phosphate and potassium sulfate. The values obtained from the application of sodium phosphate were in every case lower than those obtained from application of equal quantities of potassium sulfate or ammonium sulfate. The

samples taken on 11-12-14 and 11-20-14 gave higher values for the sap from plants overfed with potassium sulfate than those treated with ammonium sulfate, but later in the year in the set of 12-9-14 (Samples 1 and 2) the relative values are reversed.

In the set of 12-9-14 plants treated with potassium sulfate at the rate of 1000 g. per section per application were still apparently normal, although the osmotic pressure amounted to 15.25 atmospheres, while plants treated with one-half this weight of ammonium sulfate possessed an osmotic pressure of only 14.16 atmospheres and showed signs of injury. Injury, on the other hand, had not appeared on plants treated with ammonium sulfate (250 g. per section per application) when the osmotic pressure amounted to 12.42 atmospheres as compared to 11.34 atmospheres in the adjacent "check" section (12-9-14—10 A.M.).

The higher value of Sample 1 over Sample 2 (of the set of 12-9-14—10 A.M.) was correlated with a greater degree of injury by the ammonium sulfate. Injury appeared on the plants from sections to which potassium sulfate was applied, only when an osmotic pressure of over twenty atmospheres was reached (1-9-15), and an osmotic pressure value up to 15.50 atmospheres was found in plants on soil treated with sodium phosphate, without injury being apparent. The determination of the value on the sap from plants treated with acid phosphate gave 16.11 atmospheres, yet these plants exceeded in size and vigor those to which no fertilizer was applied (1-9-15). The conclusion to be drawn from these facts is that, with a single fertilizer, injury from overfeeding becomes apparent when a certain osmotic pressure is reached, but that this value is different for different fertilizers.

The injury from applications of sodium chloride at the rate of 125 g. per section per application, occurred at approximately the same time, was very similar to, and was of about the same degree as that from applications of potassium sulfate, in four times these quantities. The relative osmotic pressure values are given in Samples 9 and 10 (1-9-15). The solubilities of these salts, as pointed out on page 2785, at 0° are 35.7 and 8.5, respectively, giving a ratio roughly of 4 to 1.

**Effects of Overfeeding on the Total Acidity of the Cell Sap.**—Reaction tests with litmus paper showed that the soil receiving no fertilizer or only manure was neutral or slightly alkaline in the fall, and that a gradual change to slight acidity took place during the winter. Commercial acid phosphate, dried blood and ammonium sulfate upon the soil each increased the total acidity,\* the first one immediately after application,

\* It is not likely that the hydrogen-ion concentration of the soil solution was greatly increased by addition of commercial acid phosphate, since the formula used in its preparation prevents the presence of free sulfuric acid by providing a slight excess of tricalcium phosphate. Salm,<sup>23</sup> using a hydrogen electrode apparatus, found  $[H] = 3.3 \times 10^{-5}$  for the di-hydrogen sodium phosphate at 18° in 0.1 N sol.

the latter two within about a week's time. In the case of these fertilizers, the surface of the soil became acid after the lower portions. When disodium phosphate was applied, the surface of the soil became alkaline to litmus, the deeper parts becoming alkaline more slowly. Tests on Section 275 (500 P) on February 18, 1915, and on 291 (1000 P) on March 22, 1915, showed that the soil at each successive inch to the bottom of the bench, was alkaline to litmus. In so far as could be determined by this method, applications of potassium sulfate and of sodium chloride did not change the reaction of the soil.\* Hence an opportunity was given to study the effect, upon the acidity of the cell sap, of fertilizers producing increased acidity in the soil, alkalinity, and no change in reaction, and upon the relation the changes bore to injury from overfeeding with the fertilizer.

Determinations were made by titrating at about  $15^{\circ}$  with  $\text{CO}_2$ -free KOH, approximately 0.02 N, 1 cc. portions of sap diluted to 6 cc. with  $\text{CO}_2$ -free water, using phenolphthalein as the indicator. Results are calculated as cc. of normal acid per cc. sap.\*\*

TABLE X.—ACIDITY OF PLANT SAP.\*\*\*

\* See, however, Maschaft.<sup>20</sup>

\*\* For memoir on acidity in plants, see Astruc.<sup>2</sup>

\*\*\* Boiling a solution of  $\text{CO}_2$  in distilled water under diminished pressure by warming the test tube with the hand was found completely to remove the  $\text{CO}_2$ . Similar treatment of sap gave identical values for acidity before and after. Hence, the acidity was not due to dissolved  $\text{CO}_2$ .

Acidity values remained about the same when potassium sulfate was applied, but increased after applications of acid phosphate, ammonium sulfate or disodium phosphate, being proportional in each case to the amount put on the soil. The increased total acidity following applications of disodium phosphate (which is alkaline to phenolphthalein) was unexpected and a more detailed study was made of the sap from these plants. Ether-soluble acids were absent and none of the phosphate was extracted by moisture-free ether. Phosphate was determined in 1 cc. portions of Samples 12-15 and the total acidity of the solution calculated on the assumption of the phosphorus being present (1) as orthophosphoric acid, and (2) mono-alkali phosphate,\* the values being given in Table XI.

TABLE XI.—ACIDITY OF SAP BY TITRATION AND CALCULATION.  
Acidity.

Sample No.	Treatment.	Mg <sub>2</sub> P <sub>2</sub> O <sub>7</sub> .	As H <sub>3</sub> PO <sub>4</sub> .	As XH <sub>2</sub> PO <sub>4</sub> .	By titration.
12	check	0.0015	0.02692	0.01346	0.01977
13	125 P	0.0061	0.10768	0.05384	0.05035
14	250 P	0.0075	0.13460	0.06730	0.06438
15	500 P	0.0096	0.16348	0.08174	0.07415

The values calculated as XH<sub>2</sub>PO<sub>4</sub> agree more closely than those for H<sub>3</sub>PO<sub>4</sub>, pointing to the presence of the phosphate as mono-alkali phosphates. Subtraction of the "check" value for Mg<sub>2</sub>P<sub>2</sub>O<sub>7</sub> from each of the other values to obtain the increase in phosphate intake due to applications of disodium phosphate and comparison of the titratable acidity calculated from these results with the excess of acidity of the solutions over that of the "check" gives the following results:

TABLE XII.—ACIDITY AND PHOSPHORUS CONTENT DUE TO OVERFEEDING.  
Increase in P<sub>2</sub>O<sub>5</sub>.

(1) As Mg <sub>2</sub> P <sub>2</sub> O <sub>7</sub> .	(2) As Mg <sub>2</sub> H.	(3) As Mg <sub>2</sub> H.	Ratio. (3)/(2).
0.0046	0.03999	0.03058	0.765
0.0060	0.05388	0.04461	0.827
0.0081	0.07276	0.05438	0.747

The ratio between the value of H determined by titration and by the gravimetric method at 15° was determined to be 0.905, so that the ratios obtained are in the same direction, although the lower values for the sap indicate that some of the phosphate may have been present as the mono-hydrogen phosphate.

This method was applied to the problem of determining the salt in form of which phosphorus enters the plants. In every case increasing applications of disodium phosphate gave higher acidity values. When brown rock phosphate was used (nasturtiums grown in sand culture with Hopkin's nutrient solution omitting phosphorus after the first application) a regular increase up to a maximum in size of plants followed by a

\* Two hydrogens of orthophosphoric acid and one of monosodium phosphate when the solution is concentrated at 0° and phenolphthalein is the indicator.\* At higher temperatures, hydrolysis of the salt increases the alkalinity of the solution.

decrease was obtained, without a consistent variation in the acidity of the sap. Rock phosphate fertilizer apparently is not taken into the plant as mono-calcium phosphate.

Reaction of the soil to litmus paper was determined from time to time. After the first applications of sodium phosphate the soil reacted alkaline to litmus on the surface, with decreasing alkalinity or acidity as the distance below the surface increased. On March 22, 1915, Section 295 (to which applications of 1000 g. of sodium phosphate had been made) was found to have an alkaline reaction to litmus paper when tested for each inch of soil down to the bottom of the bench (5 inches). Two shoots each from plant Number 4, badly injured, and plant Number 12, apparently normal, were taken and the sap expressed without previous freezing. The sap reacted acid to phenolphthalein in each case.

The power of soils to absorb bases from salts is well known.<sup>6</sup> With this in mind, a liter of solution of disodium phosphate was made up with carbon dioxide-free water, and aliquot portions titrated with standard sulfuric acid to a faint rose coloration, using phenolphthalein as the indicator. Six carnation cuttings, rooted in water, were cleansed by repeated washing with distilled water and floated on the surface of 500 cc. of the solution by placing them in holes of a paraffined cork. They were placed in the greenhouse for six days, covered with a large bell jar and shaded during the daytime. The cuttings were taken out, the solution carefully rinsed off and after removal of the roots the remainder of the shoots was frozen, the sap expressed, and 1 cc. portions titrated with standard alkali, using phenolphthalein as the indicator. Comparison was made with the acidity of the sap from cuttings taken from the cutting bench and prepared as in the former case for sap expression.

STRENGTH OF SOLUTION 2 G. $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ PER LITER.			
Titration of 10 cc. portions $\text{H}_2\text{SO}_4$ (0.01550 <i>N</i> ).		Titration of plant sap. KOH (0.02130 <i>N</i> ).	
(1).	(2).	(1) Check.	(2) Treated.
0.32 cc.	0.31 cc.	0.92 cc.	1.31 cc.
0.0048 cc. <i>N</i> alkali per cc.			

In the absence of soil, the sap had become more acid when the plants were grown in the disodium phosphate solution, hence the increased acidity could not be attributed, at least entirely, to the absorptive power of the soil for bases.

**Effect of Large Applications of Potassium Sulfate on Carbohydrate Content of Sap and Foliage.**—The increased exudation of nectar and gluing together of the petals in the flowers on plants which had been treated with large amounts of potassium sulfate has been listed among the characteristic signs of overfeeding with this fertilizer (page 2787). An attempt was made to determine the cause of this increased flow.

The amount of nectar present in an affected flower amounted to as much as 1 cc. in the spring of 1912-13, when applications of potassium sulfate,

moderate when compared with those used in 1914-15, were made weekly during the season October to May. In 1914-15 the flow was not so plentiful, although noticeably greater than in the "check" flowers. In the former year, the nectar was a brownish liquid with a sweet and bitter taste, miscible with water, while in the latter year it was a clear, colorless liquid. It had a sweet taste, and was neutral to litmus and phenolphthalein. It charred on ignition on a platinum foil, with the odor of burnt sugar, leaving a small amount of ash which was alkaline to moist litmus paper and to phenolphthalein. Sodium and potassium flame tests were positive, calcium doubtful. No indication of tannin was given by tests with neutral ferric chloride and with potassium ferricyanide and ammonia. A solution made by washing off the nectar with distilled water reduced Fehling's solution. A heavy osazone precipitate of bright yellow color was thrown down upon heating it in a boiling water bath with phenylhydrazine, acetic acid and a crystal of sodium acetate, after three minutes' boiling. Ten minutes' boiling increased the amount. A much heavier osazone precipitate was given after a few minutes' boiling with hydrochloric acid, and a portion of the solution inverted by the Clerget method gave a heavier osazone precipitate than a similar amount before inversion. The rotation in a 1 dm. tube of 1.5° Ventzke was changed to 1.18° V. after the Clerget inversion. Hence, glucose and sucrose were present. The precipitate formed in the hot solution was filtered off and the filtrate again boiled till no further precipitate separated. On cooling the filtrate a further precipitate of sodium acetate and osazone separated. This osazone possessed a roset structure characteristic of maltosazone, and was soluble in the boiling solution and reprecipitated from it on cooling as is maltosazone. Not enough of the precipitate could be obtained after recrystallization for a melting-point determination.\* Tests\*\* made with a guaiacol solution and neutral hydrogen peroxide gave a negative test with the exudation, but an equally intensive color with sections of petal, ovary, leaf and stem of both normal and affected plants. Neither of the reagents used alone gave a reaction. Microscopic examination of the lower, plasmolyzed portions of the petals showed the cell walls intact and of normal thickness. It was concluded from this that the increased amount of sugar was not due to breaking down of these cell walls, but was an exudation. Experiments were then undertaken to compare the sugar content of the sap expressed from the stems of the plants not fertilized and of those receiving applications of potassium sulfate. Evidence that a larger amount of sugars was present in the sap of the latter plants was

\* Brown and Morris<sup>4</sup> used 200 g. of leaf tissue in order to obtain enough for preparation of maltosazone.

\*\* Grüss<sup>18</sup> believed gummosis might be caused by an excess of diastatic enzyme, and used this reagent as a means of detecting it.

found during the determination of total solids of the sap (*vide supra*), when the residue from this sap was of greater weight and charred at a lower temperature than that of the check.

The comparative optical rotations\* and copper-reducing powers of sap from "check" sections and those which had received applications of potassium sulfate are shown in Table XV.

In view of the work of Davis, Daish and Sawyer,<sup>9</sup> it seems possible, though not proven, that the quantitative relationships of the sugars in expressed sap may not represent the condition within the living tissue. The consistently higher values obtained by both methods of estimation, showed, however, that the application of potash to the soil had resulted in an increased carbohydrate production, in a more rapid hydrolysis of starch, or in a greater permeability of the cell membranes in the mesophyll tissue, so that a larger amount of sugar was found within the conducting and storage tissues.

Leaf tissue (Set 2-10-15) dried at 50-70° was extracted with 80% alcohol (1 g. pptd. CaCO<sub>3</sub> being added to neutralize acids present) and the extracts, after removal of alcohol, cleared with 5 cc. neutral lead acetate, 1 cc. basic lead acetate and alumina cream. The extracts from 7 g.

\* A. Schmidt and Häusch half-shadow polariscope, with tubes 4 dm. long, was used. CuO values were obtained by using Defren's<sup>10</sup> solution, the copper being determined by Low's method (Treadwell and Hall, p. 682).

277	125 K	652.8	1873.6	1990.4

The results are similar to those in Table XV.

Examination was made for starch in carnation leaves taken from the plant after a day of sunshine by boiling them for some time in alcohol, then in water, and testing leaf sections with an alcoholic solution of iodine; starch was found to be plentiful. Comparative determinations of the starch content\* were made upon the residues from sugar extractions, using a diastase solution prepared by extraction of ground malt with mono-sodium phosphate solution at ice-box temperature, but not dialyzed.\*\* Fifty cubic centimeters of water were added to the residue and the starch gelatinized by boiling for five minutes, with continuous stirring. After cooling to 60°, 5 cc. of the diastase solution were added with a pipet and digestion allowed to proceed for an hour. The mixture was again heated to boiling and 5 cc. of diastase again added and after an hour the mixture was filtered and washed thoroughly. The maltose in the filtrate was hydrolyzed to glucose by the modified Sachsse method and glucose determined with Fehling's solution, correction being made for maltose in the diastase solution. The values obtained for samples from sets of 2-10-15 and 2-17-15 are shown in Table XVII.

TABLE XVII.—STARCH CONTENT OF CARNATION LEAVES.

Treatment.	Starch per cent.	
	2-10-15.	2-17-15.
check	2.72	3.44
K	1.94	3.09

A lower starch content in "check" tissue is indicated by the results. While these analyses were not made over a long enough period to form a basis for a conception of the effect produced by potash upon carbohydrate production and transformations, the higher sugar with lower starch content is interesting in view of the work of Sherman and Thomas<sup>24</sup> upon the activating action of potassium sulfate upon diastase.

### Summary.

The purpose of the investigation was to determine the effects upon the plants of large applications of certain commercial fertilizers to the soil on which carnations were grown.

\* Brown and Morris<sup>5</sup> state that preliminary washing with cold water as in the O'Sullivan method, is unnecessary in *Tropaeolum majus*.

\*\* Sherman and Schlesinger, *THIS JOURNAL*, 25, 1619 (1913).

The injuries characteristic of an excess of each fertilizer are recorded from observations made in the greenhouse.

Determinations of dry weight and ash made upon the foliage of the plants, showed an increase in both values with increased applications of the fertilizers.

A sufficient number of determinations of the mineral constituents of the foliage was made to show the increased content of the fertilizing salts in the plants after large applications of them to the soil.

Total nitrogen determinations made upon plants in different stages of injury showed an increased intake of nitrogen when ammonium sulfate was applied but an acquired tolerance by the plant when successive small applications were made. Injury from ammonium sulfate is not proportional to the total nitrogen content.

The sap was expressed from the stems of the plants after freezing to render the plasma membrane permeable to the contents of the cells. Osmotic pressure determinations made upon this sap proved that with each fertilizer used the degree of injury varied with the osmotic pressure, but that not the same degree of injury was caused by different fertilizers at the same osmotic pressure. Injury is not a result of increased osmotic pressure exclusively.

The increase in the osmotic pressure in a series of plants on soil receiving increasing applications of commercial fertilizers was accompanied by an increase in the total solids and ash of the sap and in the amount of the fertilizer taken up by the plant.

Determinations of total acidity showed an increase in the total acidity of the sap of plants fed with ammonium sulfate, disodium phosphate and monocalcium phosphate, when phenolphthalein was used as the indicator.

The relation between the increase in total acidity and in the phosphorus content of the sap when the plants were fed with disodium phosphate proved that the phosphorus was taken in the form of dihydrogen phosphate, due, as was shown, not entirely at least to absorption of the base by the soil but to the selective action of the plant. Applications of potassium sulfate had no effect upon the acidity of the sap.

The sap from the stems of plants grown on soil to which large applications of potassium sulfate had been made showed a higher total sugar content, the same results being obtained with extracts of foliage. The starch content of the foliage of such plants was lower. These data indicate a more rapid hydrolysis of the starch in the foliage in the presence of an excess of potassium sulfate. The increased exudation of nectar in the flowers of these plants probably resulted from this increase in sugar content.

## SOME CONSTITUENTS OF JAMBUL.

BY MERRILL C. HART AND FREDERICK W. HEYL.

Received August 30, 1916.

The Jambul Tree (*Syzygium Jambolana*), well known to the natives of the East Indies and Malay regions from China to New South Wales, for its edible fruit, is a large tree belonging to the *Myrtaceae*, sometimes attaining the height of ninety feet. A careful gleaner of the medical literature finds that three parts, the seed, pericarp and bark, have been employed in the treatment of *diabetes mellitus* with questionable results, but is perhaps impressed by some beneficent results reported. Two parts of the plant, the bark and the pericarp, have been recognized in the pharmacopeia of the Netherlands.<sup>1</sup>

The berry-like, sour fruit is about as large as the olive, and apparently forms a readily procurable commodity in the European market, whereas the term Jambul as used in this country refers to the flinty, hard seed contained in the pericarp. There is also some difference in opinion as to the part of the plant which should be employed in the manufacture of the fluid extract.

The early chemical studies showed the presence, in the bark, of tannin,<sup>2</sup> in the seed, of gallic acid.<sup>3</sup> The seed yields a trace of ethereal oil, 0.37% fat, and 0.3% resin, and pharmaceutical shrewdness, rather than chemical investigation, or conformance with a rational system of nomenclature, has given the name "antimellin" to an alleged glucosidic constituent.<sup>4</sup> This finding of Börsch could not be substantiated by Power and Callan.<sup>5</sup> The statement of Pottiez<sup>6</sup> concerning the presence of quercitol and cinnamic acid could not be confirmed by these chemists. Stephenson<sup>7</sup> found that the diastatic hydrolysis of starch was appreciably reduced by the presence of the extract of the fresh kernels.

Several preparations of German origin are marketed, *e. g.*, Djoeat, Bauers, Glykosolvol and Pavykol, which probably contain, in part, extracts from the bark or pericarps, and Djoeatin (Börsch) which is alleged to contain the above-mentioned "antimellin." The presence of tannin has recommended its use among the natives as an astringent, but on the whole, as stated in the Dispensatory, "it has failed to establish itself as a practical medicament."

The recent work of Power and Callan on Jambul seed, leaves the ques-

tion as to the pharmaceutical value of the pericarp. It was our plan to make a comparative study of the seed and pericarp, and we decided to investigate independently the seed, while awaiting a promised supply of pericarp, which unfortunately will not be available at present and we therefore report our work on the seed.

Our sample of Jambul seed, which was badly worm eaten, was received from Bombay. It was picked over and 91 pounds were rejected from a 200-pound shipment. The material contained 8.0% moisture and 2.9% ash. Ligroin extracted 1.2%, ether 1.3%, and alcohol 16.1%. The residue insoluble in alcohol had the following composition: crude fiber, 2.3%; pentosans, 2.1%; protein, 6.3%; starch, 41.4%; dextrin, 2.1%. The alcohol extract showed the presence of 0.3% sucrose and 3.3% reducing sugars. Tannin amounted to 6.0%.

The products present in the alcoholic percolate, and soluble in water, besides the sugars and tannin, are ellagic and gallic acids.

The study of the resin gave, in general, the same results as those reported by Power and Callan, *i. e.*, from the ligroin extract, oleic, linoleic, palmitic and stearic acids; from the ethyl acetate and alcoholic extracts, chiefly ellagic acid. We are, however, able to describe more fully the presence in the ligroin extract of myricyl alcohol, of a hydrocarbon very probably hentriacontane, and of a phytosterol,  $C_{27}H_{46}O$ , melting at  $135-135.5^{\circ}$  that formed an acetate, melting at  $119-120^{\circ}$ . The ether extract as well as the chloroform extract yielded in addition a phytosterolin,  $C_{33}H_{56}O_6$ , which we have described in detail.

We endeavored to repeat Stephenson's work which would indicate the presence of something in Jambul that would retard diastatic hydrolysis. In using the iodine method of Sherman, Kendall and Clark,<sup>1</sup> it was found to be impossible to read the end points of a diastatic hydrolysis because the presence of gallic acid in the extract decolorized the iodine solution. In the same way the reducing action of a Jambul extract is sufficiently great to render inaccurate their excellent gravimetric method employed for finding the activity of pancreatin.

### Experimental.

(A) **Proximate Analysis.**—A sample of the air-dried seed after grinding and sieving was quantitatively extracted with various solvents, with the following results:

Extract.	Per cent.
Ligroin (35-55°).....	1.2
Volatile ether extract.....	0.2
Ether.....	1.3
Alcoholic.....	16.1

The proximate analyses were conducted in accordance with the usual methods, and gave the result tabulated below:

<sup>1</sup> THIS JOURNAL, 32, 1073 (1910).

	Per cent.		Per cent.
Moisture.....	8.0	Protein.....	6.3
Starch (diastase).....	41.4, 40.3	Ash.....	2.9
Crude fiber.....	2.3	Dextrin.....	2.1
Pentosans.....	2.1	Tannin <sup>1</sup> .....	6.0

The quantitative examination of the alcohol-soluble carbohydrates resulted as follows:

100 g. of Jambul seeds were extracted with boiling 95% alcohol. The alcoholic extract was concentrated to a syrup, precipitated with a slight excess of lead subacetate and made to a volume of 200 cc. The direct and invert readings at 22° in 2 dcm. tube are —2.6V, and 3.2V, respectively. The invert reading at 86° in a 2 dcm. tube was 0.35V. Hence sucrose = 0.23%, fructose = 2.3%, and glucose = 2.1%, respectively. Gravimetric determinations by the Walker-Munson process gave sucrose 0.33% and reducing sugar 3.3%.

(B) **Examination of Alcoholic Extract.**—For this purpose 45.4 kg. were exhausted by percolation with wood alcohol at room temperatures. Power and Callan extracted the seed with hot ethyl alcohol. The percolate (397 l.) was concentrated under diminished pressure to a volume of 12.5 liters. This concentrated extract on standing deposited 230 g. of yellowish material which was quite insoluble in the usual organic solvents. It could be redissolved in dilute alkali and then reprecipitated by the addition of acetic acid. After being digested with ether, and with ethyl acetate, this material was crystallized from pyridine. Brown needles were obtained that gave the characteristic tests for ellagic acid.

The filtered alcoholic extract was poured into 25 l. of distilled water and vigorously agitated. After long standing the resin was removed by filtration. The aqueous alcoholic filtrate was concentrated under reduced pressure in order to remove the alcohol. When this solution was diluted with distilled water, further precipitation took place even after diluting to a volume of 80 liters. The solution was allowed to stand overnight and the precipitate (372 g.) was filtered off. This material was of the nature of a phlobaphene. The filtrate was concentrated to a volume of 9.77 l. It now deposited 84 g. of ellagic acid. This deposit was digested with ether and with ethyl acetate and crystallized three times from pyridine. The crystals were washed successively with water, ethyl acetate and ether, dried at 150° and analyzed.

Calc. for  $C_{14}H_6O_8$ : C, 55.6; H, 2.0 Found: C, 55.6; H, 2.1.

The aqueous solution containing 5276 g. of water-soluble plant extractive was divided and a quantity containing 3750 g. was extracted repeatedly with large volumes of ether, which extracted 524 g. of a greenish white solid, which proved to be gallic acid. This amounts to 1.63% of the drug. A portion of this crude gallic acid was digested with fresh ether, which removed the color. The residue crystallized from water in colorless

<sup>1</sup> Both the Hide powder method, and the Proctor-Lowenthal method gave the same results.

needles, decomposing at about  $240^{\circ}$ . It was dried at  $115^{\circ}$  and identified as gallic acid:

Calc. for  $C_7H_6O_5$ : C, 49.4; H, 3.5. Found: C, 49.4; H, 3.4.

The dark green ethereal filtrate from the purified gallic acid was exhaustively examined, and a small quantity of sulfur melting at  $114-115^{\circ}$  was identified as a constituent.

The aqueous solution which had been completely extracted with ether, was now extracted with chloroform, which extracted only 3 g. of material. This was redissolved in chloroform and fractionally extracted with the usual alkaline solvents which yielded nothing definite. The neutral solution upon evaporation yielded a minute quantity of crystalline material melting at  $115-121^{\circ}$ . This gave the color tests of the phytosterol group.

The aqueous solution which had been completely extracted with ether and chloroform was now extracted repeatedly with hot amyl alcohol. During this extraction there ensued a gradual precipitation of ellagic acid. The material extracted with amyl alcohol weighed 742 g., equivalent to 2.2% of the drug. This extract contains a considerable quantity of ellagic acid. The amyl alcoholic extract could be prepared as a greyish white powder, by precipitation with petroleic ether. From dilute alcohol and from pyridine solutions, ellagic acid separated. A part (58 g.) of the amyl alcoholic extract was redissolved in this solvent and the solution was extracted with the usual alkaline solvents, but nothing crystalline was separated by this procedure. Another part (127 g.) was hydrolyzed by boiling for several hours in the presence of 5% sulfuric acid, but no crystalline hydrolytic products were found. Eighty-four grams were hydrolyzed by boiling for one minute with 10% potassium hydroxide solution. The mixture was cooled and poured into an excess of dilute sulfuric acid, and then steam distilled. From the contents of the flask a quantity of gallic acid, melting at  $240-242^{\circ}$ , was isolated.

A quantity (171 g.) was boiled with a large volume of water and then vigorously steam distilled. Ellagic acid separated. The solution was concentrated and further quantities of ellagic acid separated. At length, after evaporation to dryness, the residue was boiled with ethyl acetate and some insoluble material (ellagic acid) was removed by filtration. It was impossible to obtain crystals from this solution. The ethyl acetate solution was evaporated to dryness, and again taken up in dry ethyl acetate, in which it was freely soluble, but nothing definite could be obtained from it. The amyl alcoholic extract is not glucosidic.

The aqueous liquid which had been extracted with ether, chloroform, and with amyl alcohol, was freed from the latter immiscible solvent by a vigorous steam distillation. The distribution of nitrogen in this solution was as follows: Total soluble nitrogen, 0.0649%; ammonia nitrogen, 0.0079%; lead subacetate precipitable nitrogen, 0.0197%.

In order to test for acid amides, one-fifth of the solution was precipitated with mercuric acetate solution, but the results were negative.

The remainder of the solution was precipitated with basic lead acetate, filtered, and the precipitate was found to consist essentially of lead tannate.

The filtrate from the lead tannate was freed from lead with hydrogen sulfide and sharply concentrated. Although this syrup yields a precipitate with phosphotungstic acid, no nitrogenous bases were isolated from this fraction. The only product found was sugar, a crystalline deposit of a *d*-phenylglucosazone melting at 207–208° being readily prepared. Pentose sugars were absent.

**The Examination of the Resin.**—The resin which precipitated when the alcoholic extract was poured into water weighed about 699 g., equivalent to 1.5% of the drug. It was dissolved in wood alcohol, poured upon purified sawdust, transferred to a continuous extractor, and extracted with the following results:

Ligroin (40–60°).....	433 g.
Ether.....	20
Chloroform.....	13
Ethyl acetate.....	79
Alcohol.....	109

---

Total, 654 g.

**The Ligroin Extract.**—Three hundred grams were dissolved in ether and shaken with solutions of potassium hydroxide (5% and 10%). The alkaline extractions were acidified and extracted with ether. This ethereal solution was successfully extracted with a solution of ammonium carbonate (10%) but these extracts yielded nothing but a small quantity of smeary material precipitable with acid.

The ethereal solution was now extracted with solutions of potassium carbonate, and the fatty acids occurring free in the plant were removed. The alkaline extract containing the potassium salts of these fatty acids was acidified and extracted with ether. The ethereal solution of fatty acids was dried over anhydrous sodium sulfate. The ether was removed and a residue of about 92 g. obtained. This was distilled under diminished pressure. The boiling point was 215–250° at 20 mm., and the iodine number of the distilled acids which solidified in the receiving tube was found to be 88.7. A very considerable quantity of this material could not be distilled and it remained as a tar in the flask. These fatty acids were studied in connection with those obtained upon the subsequent hydrolysis of the glycerides.

The ether solution which had been extracted with ammonium carbonate and potassium carbonate was now extracted with a solution of potassium hydroxide. The alkaline extract was acidified and a quantity

of tarry material (15 g.) precipitated. This was dissolved in alcohol and subjected to acid and alkaline hydrolysis, but nothing crystalline could be separated in either case.

The ether solution which had been extracted with solutions of ammonium carbonate, potassium carbonate and potassium hydroxide contained 17 g. of neutral material belonging to the unsaponifiable material. It boiled at 120–250° at 15 mm., and yielded oily distillates exactly corresponding to those described among the unsaponifiable products of the fat.

The original ethereal solution of the fat which had been extracted with solutions of potassium hydroxide was evaporated to dryness and the residue was saponified by boiling with 250 cc. of 10% alcoholic potash for about five hours. The alcohol was removed and water added to completely precipitate the unsaponifiable material, which was extracted with ether.

**Examination of the Unsaponifiable Matter.**—The dried solution was evaporated to dryness and the residue was an orange-colored oil amounting to 47 g. It was dissolved in absolute alcohol and upon standing 0.15 g. of material separated. The melting point was indefinite (62–76°) and suggested, as stated by Power and Callan, a mixture of hydrocarbon and a higher alcohol. By means of the phthalic acid fusion, and subsequent extraction with sodium carbonate, a small quantity of a hydrocarbon melting at 61° was isolated. Three crystallizations from ethyl acetate raised this melting point to 63°. It separated in colorless leaflets and was perhaps impure hentriacontane.

Calc. for  $C_{31}H_{64}$ : C, 85.3; H, 14.7. Found: C, 85.1; H, 14.1.

A small quantity of a sodium salt of an acid phthalic ester was isolated and boiled with alcoholic potash. A product separated which had the melting point of myricyl alcohol, 82–84°. It crystallized from alcohol in leaflets, which softened at 82° and melted at 85°.

Calc. for  $C_{30}H_{62}O$ : C, 82.2; H, 14.1. Found: C, 81.7; H, 13.5.

The alcoholic solution from which the hydrocarbon and myricyl alcohol had separated yielded no further crystallizations even from concentrated solutions after the addition of small quantities of water. This residue was distilled under diminished pressure.

Fraction I (b. p. 120–160° at 10 mm.). This was a colorless, limpid oil with a fragrant odor. The weight was 11 g.

Fraction II (b. p. 160–200° at 10 mm.). This was a colorless oil, less mobile than the first fraction, and of about the same weight. A systematic fractional distillation of I and II effected no separations.

Fraction III (b. p. 200–250° at 10 mm.). This was a thick viscid oil which partially solidified. It weighed about 5 g.

The fractions collected above 250° at 10 mm. solidified in the receiver. The fraction boiling at 280–340° at 10 mm. was crystallized from ethyl

acetate. The material melted at about  $132^{\circ}$ , but softened somewhat lower. It was necessary to separate a small quantity of low-melting material ( $70-75^{\circ}$ ) by a fractional crystallization and phytosterol then separated in glistening plates, melting sharply at  $135-135.5^{\circ}$ .

Calc. for  $C_{27}H_{46}O.H_2O$ :  $H_2O$ , 4.5. Found: 5.6%.

Calc. for  $C_{27}H_{46}O$ : C, 83.9; H, 11.9. Found: C, 83.8; H, 11.6.

0.1163 g. of the anhydrous phytosterol made up to 20 cc. with chloroform showed a rotation of  $-0.489$  in a 2 dcm. tube, whence  $[\alpha]_D^{25} = -42.04^{\circ}$ .

It yielded an acetyl derivative that separated from acetic anhydride in thin plates which melted at  $119-120^{\circ}$ .

**Examination of the Fatty Acids.**—The alkaline solution from which the unsaponifiable matter had been extracted with ether was acidified and the liberated fatty acids were extracted with ether. The ether solution was dried over anhydrous sodium sulfate, concentrated to a small volume and then largely diluted with ligroin which precipitated some tarry material. This was removed by filtration, and the solvent was distilled from the fatty acids. These boiled chiefly at  $230-260^{\circ}$  at 15–20 mm. A small fraction distilled at  $260-280^{\circ}$  at 20 mm. The weight of distilled acids was 30.1 g., and the iodine number was 98.3.

These acids were mixed with those which had been extracted with potassium carbonate solution. A portion weighing 22.5 g. was converted into the lead salts, which were treated with ether. The liquid acids obtained from the lead salts soluble in ether weighed 12.9 g. (57.3%). These boiled chiefly at  $235-245^{\circ}$  at 32–34 mm.

Calc. for  $C_{18}H_{34}O_2$ : C, 76.6; H, 12.1; iodine no., 90.1; for  $C_{18}H_{32}O_2$ : C, 77.1; H, 11.4; iodine no., 181.4. Found: C, 76.6; 76.7; H, 11.3, 11.55; iodine no., 131.7.

The liquid acids therefore consist of a mixture of oleic and linoleic acids.

The lead salts of the fatty acids, insoluble in ether, were decomposed with hydrochloric acid and the solid fatty acids separated in the usual manner. When dissolved in absolute alcohol with the object of separating any of the more insoluble acids by crystallization, it was found that the acids were very readily soluble and no satisfactory crystallization could be obtained even from very concentrated solutions. The alcoholic solution was fractionally precipitated with an alcoholic solution of barium acetate. This yielded Fractions I and II. Fraction III was precipitated by the addition of water.

1. Melting at  $51-53^{\circ}$ . C, 75.8; H, 12.4; N. v., 204.3.

III. This fraction was an oil and gave entirely anomalous analytical data. Iodine no., 35.2, 34.7; neutralization value, 34.9; and saponification value, 140.2.

The solid acids are therefore a mixture of palmitic and stearic acids.

Calc. for  $C_{16}H_{22}O_2$ : C, 75.0; H, 12.5; N. v., 219.1.  $C_{18}H_{26}O_2$ : C, 76.1; H, 12.7; N. v., 197.5.

**The Ether Extract of the Resin**, which amounted to 20 g., contained a quantity (2 g.) of an insoluble white solid. This was filtered off. When this substance was dissolved in chloroform, in the presence of a few drops of acetic anhydride, and sulfuric acid was added, a play of colors resulted showing at first transient pink; then blue, and finally a beautiful green. It was crystallized several times from dilute pyridine, and then melted at  $275-285^\circ$ . It was a phytosterolin. After being dried to constant weight at  $120^\circ$  it was analyzed.

Calc. for  $C_{33}H_{50}O_6$ : C, 72.3; H, 10.2. Found: C, 72.3; H, 10.2.

A portion of this was converted into an acetate, which crystallized from dilute alcohol in colorless, glistening leaflets melting at  $167-168^\circ$ .

0.5036 g. of the anhydrous phytosterolin acetate, when made up to 20 cc. with chloroform, showed a rotation of  $-1.21^\circ$  in a 2 dcm. tube, whence  $[\alpha]_D^{23} = -24.1$ .

One gram of this phytosterolin was hydrolyzed according to the method outlined by Power and Salway.<sup>1</sup> It was dissolved in 60 cc. of hot amyl alcohol and 20 cc. of an aqueous 15% solution of hydrochloric acid added, together with sufficient ethyl alcohol to form a homogeneous liquid. After heating for three hours in a reflux apparatus, steam was passed through the mixture to remove the amyl alcohol, and the contents of the flask then filtered. A solid substance was thus collected, which after several crystallizations from ethyl acetate, alcohol, and dilute alcohol, separated in glistening leaflets melting at  $134-135^\circ$ . The mother liquors from this crystallization contained a relatively large quantity of an oily resinous material which had evidently been formed from the phytosterolin by too prolonged hydrolysis. The crystals gave the phytosterol color reaction.

0.0983 g. made up to 20 cc. with chloroform had a rotation of  $0.38^\circ$  in a 2 dcm. tube, whence  $[\alpha]_D^{25} = -38.8$ .

Calc. for  $C_{27}H_{46}O$ : C, 83.9; H, 11.9. Found: C, 83.3; H, 11.3.

The acid aqueous liquid, from which the phytosterol had been separated by filtration, was exactly neutralized with sodium carbonate, evaporated to dryness, the residue digested with absolute alcohol, and the mixture filtered. On evaporating the alcoholic filtrate a small amount of syrupy residue was obtained, which reduced Fehling's solution, and yielded an osazone melting and decomposing at  $212^\circ$ . It was thus evident that the sugar was glucose.

Thus this phytosterolin is shown to be phytosterol-*d*-glucoside.

The ether extract from which the phytosterolin had been separated was fractionally extracted with varying strengths of alkali. The potas-

<sup>1</sup> *J. Chem. Soc.*, 103, 399 (1913).

sium hydroxide extracts removed practically all the dissolved matter as a green oil which after some time became semi-solid. This could not be crystallized and was unchanged when boiled for several hours in the presence of an alcoholic solution of 5% sulfuric acid solution.

**The Chloroform Extract of the Resin** weighed 13 g. Part of this extract was quite insoluble in ethyl acetate and alcohol with which it was digested. This part was crystallized twice from dilute pyridine and melted at 280–295°. This gave the usual color test for a phytosterolin. After crystallization it weighed 3 g. Altogether the phytosterolin isolated from the ether and chloroform extracts amounted to 5 g. or 0.011% of the air-dried drug.

The filtrate from the above phytosterolin was evaporated to dryness, taken up in chloroform, and then fractionally extracted with varying strengths of alkali. Nothing of a crystalline nature was obtained by this procedure.

**The Ethyl Acetate Extract of the Resin** was a mixture of ellagic acid and tannin-like substances. Upon distilling off a portion of the ethyl acetate about half of it separated as crude ellagic acid, which when crystallized once from alcohol yielded 13 g. of pure acid that did not melt at 350°. The mother liquor from this separation was a smear, that colored ferric chloride solution black, and precipitated a gelatin solution.

The part soluble in ethyl acetate was thoroughly examined but nothing was isolated.

**The Alcoholic Extract of the Resin** yielded 15 g. further of ellagic acid. The total ellagic acid separated amounts to 1.2% of the plant. Neither an acid hydrolysis or a potash fusion gave any interesting decomposition products. Neither the ethyl acetate fraction nor the alcoholic extract was glucosidic.

KALAMAZOO, MICH.

## NEW BOOKS.

**Laboratory Manual of Inorganic Chemistry for Colleges.** By LYMAN C. NEWELL, Ph.D., Professor of Chemistry, Boston University. Boston: D. C. Heath & Co. Pp. vi + 240.

Although this book is prepared primarily to be used as a laboratory guide in connection with the author's "Inorganic Chemistry for Colleges," the experiments are of such a nature and scope that it could be used advantageously with any standard text. The directions for the experiments are clear and definite, and are based on the author's long experience as a laboratory teacher. A large number of experiments of graded difficulty are given, and provision is thus made for students of widely different preparation in chemistry. The apparatus required for most of the work is simple and inexpensive. The book appears to be one that

could be used profitably in a large laboratory where students are unable to have the directions for the experiments frequently interpreted by an instructor.

JAMES F. NORRIS.

**Elementary Qualitative Analysis.** By BENTON DALES, Professor of Chemistry, University of Nebraska, and OSCAR LEONARD BARNEBY, Instructor of Chemistry, University of Wisconsin. Pp. 206. John Wiley and Sons, N. Y.

True to title, this book contains little theory, few novelties in methods, no rare elements or unusual compounds. That the student may learn to work understandingly, that he may see the reasons for the processes he uses and become able to devise simple methods of separation, are ends apparently held as important as analytical results.

The first half of the book aims to extend the student's knowledge of general chemistry, particularly as to those facts on which the qualitative scheme is based. The first 25 pages are devoted to the ionic theory, equilibrium, nomenclature, reactions and equations, a treatment too condensed to give true ideas of these subjects to one meeting them for the first time. Apparently no use of the ionic theory or equilibrium is subsequently made. For example, the double salt theory is used to explain the non-precipitation of such compounds as manganese and magnesium hydroxides by ammonia in the presence of ammonium chloride.

About 70 pages are occupied by statements of properties and reactions of acids and bases, which the student is expected to verify experimentally. This is excellent, perhaps too extensive for an elementary course. Here and throughout the book are many lists of well selected questions. If the student is held rigidly to this work and to the questions, he can scarcely fail to secure a large amount of knowledge of analytical methods before he reaches the formal scheme for the analysis of "unknowns." His work can hardly become mechanical thereafter. It would probably increase his interest, give point to the testing and help to fix the facts in mind, if, instead of first working through the whole 70 pages, he were permitted after testing through a group of metals to take up the separation of that group.

Another good feature is a list of reagents in which concentration is given in terms of normality and the corresponding number of grams per liter. Yet another is a chapter on short processes and deductions, based on a table of solubilities and the properties studied in the general testing. This should appeal to the student as a time-saver and also prevent mechanical habits.

W. S. HENDRIXSON.

<b>ACETANILIDE</b> soly. in $\text{Et}_2\text{O-CHCl}_3$ solns., 1242; soly. in acetone-benzene solns. ....	1244
Acetanisidine hydriodide. ....	145
Acetanisidine hydriodo-diiodide. ....	148
Acetochlorogalactose. ....	1226
Acetone detn. of, in systems of $\text{MeOH}$ , $\text{H}_2\text{O}$ and $\text{KF}$ and equil. in systems of $\text{Me Et}$ ketone, $\text{H}_2\text{O}$ and inorg. salts. ....	1136
Acetophenone, action of aqua regia on. ....	1820
Acetphenetidine hydriodide. ....	145
Acetphenetidine hydriodo-diiodide. ....	145
Acetphenetidine hydriodo-tetraiodide. ....	146
3-Acetyl-4-benzalhydantoin. ....	1092
Acetylene, colorimetric detn. of, 352, 653; action upon anhydrous and upon alc. solns. of $\text{AlCl}_3$ . .	1383
Acidimetry, indicator for. ....	1606
Acids, conductivities of certain org., in abs. $\text{EtOH}$ , 121; catalyses with weak, 901; addition compds. of phenols with org., 1309; relations between constants of dibasic, and of amphoteric electrolytes, 1503; catalysis (I) addition compds. of esters with org., 1712; reaction of both ions and nonionized forms of, bases and salts. ....	2145
Acönitic acid, cond. in abs. $\text{EtOH}$ . ....	126
Acrylic acid, $\text{NH}_4$ salt of. ....	1796
Adsorption of invertase, 1109; of gases by solids, 2267; exptl. evidence, that is chem. phenomena, 2269; phenomena at higher gas pressures, 2282; hy porous bodies. ....	2285
Air from Sanitary Standpoint (Woodman, Norton, book review) ....	735
Alcoholimetry, Alcoholometric Tables (Thorpe, book review). ....	163
Alcohols, zingiberol, 430; compressibility of certain typical, 989; reaction between, and aq. solns. of $\text{HCl}$ and $\text{HBr}$ , 1071; reversible replacement of, in aldehydealcoholates, 1821; partition of lower, between $\text{H}_2\text{O}$ and cottonseed oil, 2316; action of oxalyl chloride on primary, secondary and tertiary, 2514; action of aromatic, on aromatic compds. in presence of $\text{AlCl}_3$ . ....	2527
Aldehydealcoholates, reversible replacement of alcs. in. ....	1821
Aldehydes, condensation of thiobarbituric acid with aromatic. ....	2416
Alfalfa seed oil. ....	480
Alkalies action on certain $\text{Zn}$ salts. ....	785
Alkali metal formates, behavior in (anhydrous) formic acid. ....	271
Alkali metal halides, changes in vol. on soln. in water of (II), 70; densities and cubical coeffs. of expansion of. ....	259
Alkali metals, sepn. of $\text{Li}$ from other. ....	2326
Alkalimetry, indicator for. ....	1606
Alkylcyanoacetic acids. ....	909
Alkyl isothiocyanates, utilization of tetrachloromethylmercaptan for the prepn. of. ....	1860
Allotropy of $\text{NH}_4\text{Br}$ . ....	1261
Alloys, Analysis of Non-Ferrous (Ibbotson, Aitchison, book review). ....	488
Allylmalonic acid, cond. in abs. $\text{EtOH}$ . ....	125
Allylmalonic acid, $\text{NH}_4$ salt of. ....	1799
Allyl mustard oil, action of aqua regia on. ....	1817
Alpha particles, interaction of $\text{H}$ and $\text{Cl}$ under influence of. ....	280
Aluminium detn. as oxide. ....	1282
Aluminium chloride, action of anhydrous, on unsatd. compds., 1382; action of aromatic alcohols on aromatic compds. in presence of. ....	2527
Aluminium oxide, system: $\text{CaO-Al}_2\text{O}_3\text{-MgO}$ , 568; hydrogels. ....	588
Amides, pyrogenetic decompn. of. ....	2503, 2505
Amidines synthesis from cyanamides. ....	2768
Amines, 381, 2135; utilization of hypochlorite color reactions in establishing mechanism of action of $\text{MeSO}_4$ on aniline. ....	2507
Amino acids, spectrophotometric study of $\text{Cu}$ complex of, 457; Physiology of the (Underhill, book review). ....	943
Aminobenzoic acids, cond. in abs. $\text{EtOH}$ of <i>o</i> - and <i>p</i> -. ....	126, 127
2-Amino-4,6-dibromoacetanilide. ....	686
Aminoethyl alcohol in brain lecithin. ....	922
<i>p</i> -Aminophenol, action of aqua regia on. ....	1817
Ammonia, efficiency of aeration method for distg., 2568; presence in diseased plants—its significance with regard to crop rotation and soil depletion. ....	2572

Ammonium acetate solubilities of sulfates of Ba, Sr, Ca and Pb in, solns. at 25° and criticism of present methods for sepn. of these substances by means of, solns. ....	310
Ammonium bromide, allotropy and solubilities in H <sub>2</sub> O of. ....	1261
Ammonium iodide, its solubilities and the absence of a transition point. ....	1500
Amphoteric electrolytes, relation between constants of dibasic acids and. ....	1503
Amylase of <i>Aspergillus oryzae</i> , 1638; products of action of certain, on sol. starch, with special reference to formation of glucose. ....	1877
Analysis, bath used for soln. of samples in O-free atm., 374; of Non-Ferrous Alloys (Ibbotson, Aitchison, book review), 488; Representative Procedures in Quant. Chem. (Gooch, book review), 940; Manual of Quant. Chem. (Frank, Clemens, book review), 941; Qual. (Treadwell, Hall, book review), 1645; petrographic microscope in, 1647; electro-analytical method for detn. and sepn. of metals of Cu-Sn group, 1660; systematic sepn. of anions of group I— anions whose Ag salts are insol. in nitric acid, 2000; Elementary Qual. (Dales, book review). ....	2814
Aniline, action of aqua regia on, 1818; utilization of hypochlorite color reactions in establishing mechanism of action of MeSO <sub>4</sub> on, 2507; identification of. ....	2725
Aniline black, action of aqua regia on. ....	1819
Aniline chlorate, prepn. of. ....	1080
Anions, systematic sepn. of, of group I— anions whose Ag salts are insol. in HNO <sub>3</sub> . ....	2000
Anisalcohol. ....	1212
Anisic acid cond. in abs. EtOH. ....	127
$\beta$ -Anisoxypropionic acid. ....	1533
Antimony, use of HF in sepn. of heavy metals from, by means of elec. current, 640; sepn. of As, Sn and, 1011; detn. of. ....	1672
Antipyrine periodide. ....	2166
Aqua regia chlorination with, 1809; formation of chloropicrin and tetrachloroquinone by action of, on org. substances. ....	1813
Aromatic compounds, some reactions resulting in cleavage of polynuclear, 1205; action of aromatic alcohols on, in presence of AlCl <sub>3</sub> . ....	2527
Arsenic, sepn. of Sb, Sn and, 1011; silver arsenate test for. ....	1280
Arsenic acid, action of H <sub>2</sub> S on. ....	52
Arsenic pentoxide, equil. in system PbO, As <sub>2</sub> O <sub>5</sub> , H <sub>2</sub> O. ....	2366
Arsenious oxide, density and cubical coeff. of expansion of. ....	266
<i>Aspergillus oryzae</i> , amylase of. ....	1638
Atomic weights, 23rd ann. rept.—detns. published during 1915, 489; ann. rept. of Intern. Comm., 1917, 2219; see also the various elements.	
Atomistics, Introduction to Principles of Physical Chemistry, from Standpoint of Modern, and Thermodynamics (Washburn, book review). ....	944
Atomic structure. ....	169
Atoms, the, and the mol. ....	762
Azobenzene, action of aqua regia on. ....	1819
<b>BACTERIA</b> , Boden-Bakterien und Boden-Fruchtbarkeit (Löbner, book review). ....	945
Baly's theory of chem. reaction and reactivity. ....	1, 15, 227
Barbituric acid, comparison of, thiobarbituric acid and malonylguanidine as quant. precipitants for furfural. ....	2156
Barium sulfates, soly. in AcONH <sub>4</sub> solns. at 25° and criticism of present methods for sepn. of the sulfates of Ba, Sr, Ca and Pb by means of AcONH <sub>4</sub> solns. ....	310
Bases, reaction of both ions and nonionized forms of acids, salts, and. ....	2145
Bath for soln. of ssmpls in an O-free atmosphere. ....	374
Behenic acid in alfalfa seed oil. ....	485
$\beta$ -Benzal- $\beta$ -anisoxydimethylmalonic acid, Me ester of. ....	1526
Benzal- $\beta$ -anisoxypropionic acids. ....	1531
$\alpha$ -Benzal- $\gamma$ -anisylocrotonolactone. ....	1530
4-Benzalhydantoin-1-acetic acid and Et ester. ....	1092, 1093
Benzal- $\beta$ -phenylethylamine. ....	383
Benzamide, action of aqua regia on. ....	1819
Benzene, electronic formula of, and the substitution rule, 1323; mol. wt. of some alcoholates of chloral and butylchloral in, soln. ....	2533
Benzene derivatives, electronic tautomerism of. ....	1333
Benzene series, presence of benzene homologs in high boiling distillates of petroleum. ....	393
Benzenesulfonic acid, action of aqua regia on. ....	1819
Benzhydrol, action of oxalyl chloride on. ....	2518
Benzidine, action of aqua regia on. ....	1819
Benzilic acid, cond. in abs. EtOH. ....	125

Benzoic acid, cond. in abs. EtOH, 126; soly. in Et <sub>2</sub> O-CHCl <sub>3</sub> solns., 1243; soly. in acetone-benzene and in EtOAc-benzene solns., 1244; esterification by isomeric butyl mercaptans.....	2757
Benzophenone, action of aqua regia on, 1820; identification of.....	2724
Benzophenonechloroimide, attempt to effect rearrangement of.....	2094
Benzotriphenylmethylamide.....	2087
o-Benzoylbenzoic acid, Me ester of.....	1228
o-Benzoylbenzoyl chloride.....	1142
o-Benzoylbenzoyl cyanide.....	1143
Benzyl alcohol, action of oxalyl chloride on.....	2517
Benzylamine chlorate.....	1082
4-Benzylhydantoin.....	1094
4-Benzylhydantoin-1-acetic acid, Et ester of.....	1095
Benzylethylamine chlorate.....	1082
4-Benzylhydantoin-1-acetic acid.....	1095
Benzylidenehydrazinoacetic-isobutyric acid, K salt of.....	1780
Benzylidenehydrazinoacetic-propionic acid, Na salt of.....	1780
Benzylidenehydrazinodiacetic acid.....	1778
Benzylidenehydrazinodipropionic acid, K salt of.....	1781
Benzylmalonic acid, cond. in abs. EtOH, 125; NH <sub>4</sub> salt of.....	1799
Benzylmethylaniline chlorate.....	1082
Benzyl-β-phenylethylamine.....	383
Beryllium, extn. from gadolinite.....	875
Beryllium vanadates.....	2361
Binary mixtures, properties of H <sub>2</sub> SO <sub>4</sub> -H <sub>2</sub> O mixts.....	555
Bismuth, detn. of.....	1672
Biuret reaction, spectrophotometric study of Cu complexes and.....	457
Blood, distribution of urea in, of certain vertebrates with especial reference to the hen, 1615; detn. of hippuric acid in.....	2188
<b>BOOKS, NEW: REVIEWS</b> —Chem. Manual of Inorg. Chemistry for Colleges (Newell).....	
Bromates detn. of periodates, iodates, chlorates and, in presence of each other.....	330
Brometone acetic ester.....	2740
Bromides, systematic sepn. of anions of group I.....	2000
Bromination of hydrocarbons by means of Br and HNO <sub>3</sub> .....	2545
Bromine, mechanism of action of, on 2-mercaptopyrimidines.....	1557
Bromine compounds, free energy of.....	2348
Bromoacetylglucose, prep. of.....	2187
Bromodinitrophenoltetrachlorophthalein.....	2492
p-Bromohydrazobenzene, velocity of decompn. of.....	1753
3-Bromo-4-methoxybenzylhydrol.....	1215

$\gamma$ -Bromo- $\gamma$ -nitro- $\beta$ -phenyl- $\alpha$ -bromobutyrophenone.....	897
$\gamma$ -Bromo- $\gamma$ -nitro- $\beta$ -phenylbutyrophenone.....	894
$\gamma$ -Bromo- $\gamma$ -nitro- $\beta$ -phenylvalerophenone.....	
Bromopalmitic acid, cond. in abs. EtOH, 124; $\text{NH}_4$ salt of $\alpha$ .....	1794
<i>p</i> -Bromophenyl- <i>p</i> -chlorophenylphenylmethylchloroamine.....	2100
<i>p</i> -Bromophenyldiphenylmethylhydroxylamine.....	2071
<i>p</i> -Bromophenyldiphenylmethylhydroxylamine hydrochloride, rearrangement of.....	2074
<i>p</i> -Bromophenyldiphenylmethyl- $\beta$ -methylhydroxylamines, rearrangement of.....	2067, 2068
Bromopropionic acid, action on hydrazine hydrate, 1782; $\text{NH}_4$ salt of $\alpha$ .....	1790
$\alpha$ -Bromostearic acid, $\text{NH}_4$ salt of.....	1795
Bromosuccinic acid, cond. in abs. EtOH, 125; $\text{NH}_4$ salt of.....	1800
Brain, nitrogenous constituents of, lecithin, 922; cephalin.....	1375
Bread, digestibility of (I) salivary digestion <i>in vitro</i> .....	1245
Butyl alcohol, action of aqua regia on.....	1816
Butyl bromides, rearrangement of iso-, into tertiary.....	653
Butylchloral alcoholate, mol. wt. of some, in benzene soln.....	2533
Butylmalonic acid, cond. in abs. EtOH, 125; $\text{NH}_4$ salt of.....	1799
Butyl mercaptans, esterification of benzoic acid by isomeric.....	2757
1,3,5-Butylxylene, chlorination of.....	1812
<b>CADMIUM</b> , revision of at. wt. of (IV) electrolytic detn. of Cd in $\text{CdBr}_2$ .....	857
Cadmium bromide, detn. of Cd in.....	857
Caesium. See <i>Cesium</i> .	
Caffeine, action of aqua regia on.....	1817
Calcium, influence Ca ion upon ferri-ferrocyanide potential, 1928; estn. in ash of forage plants and animal carcasses.....	1996
Calcium carbonate, complete solubility curve of.....	975
Calcium chloride efficiency as drying agent.....	2038
Calcium oxide system: $\text{CaO}-\text{Al}_2\text{O}_3-\text{MgO}$ .....	568
Calcium sulfate soly. in $\text{AcONH}_4$ soln. at $25^\circ$ and criticism of present methods for sepn. of the sulfates of Ba, Sr, Ca and Pb by means of $\text{AcONH}_4$ solns.....	310
Calcium tartrate, crystn. of.....	2519
Calorimeter, adiabatic.....	1473
Camphoric acid, cond. in abs. EtOH.....	127
Capric acid, $\text{NH}_4$ salt of.....	1793
Caprylic acid, $\text{NH}_4$ salt of.....	1793
Carbamide, action of aqua regia on.....	1817
Carbon dioxide, specific cond. of pure $\text{H}_2\text{O}$ in equil. with atmospheric.....	1480
Carbonic acid, detn. of, combined and free, in soln. particularly in natural waters.....	947
Carcass, estn. of Ca in ash of animal.....	1996
Carnations, effects of large applications of commercial fertilizers on.....	2784
Carnaubic acid in alfalfa seed oil.....	485
Catalysis with weak acids, 901; studies on (I) addition compds. of esters with org. acids, 1712; decompn. of $\text{H}_2\text{O}_2$ in certain nonaqueous solns.....	1956, 2145
Cathode, occlusion of H by Pd.....	2577
Cellose, optical rotatory powers of some acetylated derivs. of maltose, and lactose.....	1867
Cells, voltaic for detg. H-ion concn., 936; calomel standard.....	20, 889
Cephalin brain.....	1375
Cerium, 42; vol. detn. by means of $\text{KMnO}_4$ .....	66
Cesium formate, behavior in (anhydrous) formic acid.....	271
Cesium halides, changes in vol. upon soln. in water of, 70; densities and cubical coeffs. of expansion of.....	259
Chamaecyparissobtusa, essential oil of, wood.....	699
Chemical compounds, color of.....	783
Chemical Constitution and Physiological Action (Spiegel, book review), 165; theories of.....	2225
Chemistry, Lab. Exercises Arranged to Accompany "First Course in Chemistry" (McPherson, Henderson, book review), 168; Practical Elementary (McFarland, book review), 487; in High School (Schoch, book review), 1437; Annual Reports of Progress of, for 1915 (book review).....	2576
Chemistry, Agricultural, Journal of Assoc. of Official Agricultural Chemists (book review).....	736
Chemistry, Biological, Practical Org. and Biochemistry (Plimmer, book review), 164; Physiological Chemistry (Mathews, book review), 165; Quant. Laws in (Arrhenius, book review), 939; Lab. Course in Org. and (Lothrop, book review).....	1905
Chemistry, Inorganic, Text-book of (Friend, book review), 730; Lab. Manual of, for Colleges (Newell, book review).....	2813

Chemistry, Mineralogical, Handbuch der Mineralchemie (Doelter, <i>et al.</i> , book review).....	732
Chemistry, Organic, Practical Org. and Biochemistry (Plimmer, book review), 164; Lab. Course in, and Physiological Chemistry (Lothrop, book review).....	1905
Chemistry, Physical, Introduction to Principles of, from Standpoint of Modern Atomistics and Thermodynamics (Washburn, book review), 944; Elements of (Jones, book review), 1144; Annuaire pour l'an 1916 (book review), 1260; Practical (Gray, book review), 1905; System of (Lewis, book review).....	2217
Chloral alcoholate, mol. wt. of some, in benzene soln. ....	2533
Chloral hydrate, action of aqua regia on.....	1817
Chloranil, prepn. of.....	1820
Chlorates, detn. of periodates, iodates, bromates and, in presence of each other.....	330
Chloric acid as reagent in org. chemistry.....	1079
Chlorides, equil. of $\text{HgCl}_2$ with other, 1272; dissociation tensions of certain hydrated, and vapor pressures of their satd. solns., 1439; in presence of thiocyanates, 1953; systematic sepn. of anions of group (I).....	2000
Chlorination with aqua regia—, of hydrocarbons.....	1809
Chlorine, interaction of H and, under influence of $\alpha$ -particles, 280; H and Cl ion activities of solns. of KCl in 0.1 molal HCl.....	1986
<i>p</i> -Chloroaniline, identification of.....	2725
<i>m</i> -Chlorobenzoic acid, cond. in abs. EtOH.....	126
Chlorobenzophenone, identification of.....	2724
Chlorocrotonic acid, $\text{NH}_4$ salt of.....	1796
Chloroform, action of aqua regia on.....	1817
Chlorofumaric acid, $\text{NH}_4$ salt of.....	1802
$\beta$ -Chlorolactic acid, $\text{NH}_4$ salt of.....	1791
Chloropentanes, hydrolysis of, as affected by high pressure.....	1368
<i>p</i> -Chlorophenyl- <i>p</i> -bromophenylphenylcarbinol.....	2078
<i>p</i> -Chlorophenyl- <i>p</i> -bromophenylphenylmethylamine hydrochloride.....	2100
<i>p</i> -Chlorophenyl- <i>p</i> -bromophenylphenylmethyl chloride.....	2079
<i>p</i> -Chlorophenyl- <i>p</i> -bromophenylphenylmethylhydroxylamine and hydrochloride.....	2079, 2080
<i>p</i> -Chlorophenyldiphenylmethylamine.....	2092
<i>p</i> -Chlorophenyl-diphenylmethylazide.....	2723
<i>p</i> -Chlorophenyldiphenylmethylchloroamine, rearrangement of.....	2093
<i>sym.-bis.-p</i> Chlorophenyl-diphenylmethylhydrazine.....	2733
<i>p</i> -Chlorophenyl-diphenylmethylhydrazine hydrochloride.....	2722
Chloropirrin, formation by action of aqua regia on org. substances.....	1813
Chlorotoluenes, action of Na methylate on products of nitration of <i>o</i> -, <i>p</i> - and <i>m</i> -.....	1327
Choline in brain lecithin.....	922
Chondrosamine pentacetates, isomeric.....	1431, 2216
Chromic acid, constitution of.....	1303
Chromium chlorides, dialysis of colloidal soln. of hydrous chromic oxide in $\text{CrCl}_3$ .....	1961
Chromium oxides, dialysis of colloidal soln. of hydrous chromic oxide in $\text{CrCl}_3$ .....	1961
Chromyl chloride, action on P trihalides.....	1923
Cinchona alkaloids, rates of conversion of stereoisomeric, into their toxins.....	901
Cinchonidine, conversion rate to cinchotoxine.....	904
Cinchonine, conversion rate to cinchotoxine.....	904
Cinchotoxine.....	903, 904
Cinnamic acid, cond. in abs. EtOH.....	127
Citric acid, modification of Pratt method for detn. of.....	2193
Cleveite, density of radio-lead from pure Norwegian.....	1658
Cobaltamines, studies on (I) various ionization types as detd. by f. p. lowering in aqueous soln., together with conductance measurements.....	2643
Cobalt chloride, dissociation tensions of hydrated, and vapor pressure of satd. solns. of the same.....	1439
Cobaltcyanides of rare earths.....	1497
Cobalt salts, detection of Ni in.....	1705
Colloid-chemistry, oxidation and reduction without addition of acid (II) reaction between $\text{SnCl}_4$ and $\text{K}_2\text{Cr}_2\text{O}_7$ , 47; Handbook of (Ostwald, book review).....	733
Colloids, effect of freezing on certain inorg. hydrogels, 588; solid solns., 613; dialysis of colloidal soln. of hydrous chromic oxide in $\text{CrCl}_3$ , 1961; colloidal arsenates and phosphates of Fe, 1970; theory of.....	1982
Color of chem. compds.....	783
Colorimetry, possible source of error in.....	716
Compressibility of certain typical hydrocarbons, alcohols and ketones.....	989
Condition equation, equation of state for gases and liquids.....	528

Conductivity, electric, of certain org. acids in abs. EtOH, 121; behavior of alkali metal formates in (anhydrous) formic acid, 271; extrapolation of values, 788; of solns. of certain iodides in isoamyl and propyl alcs., 1178; of solns. at different frequencies, 2396, 2403, 2415; measurement of (I) theory of design of cond. cells.....	2431
Conductivity cells, theory of design of.....	2431
Conductivity water, prepn. of.....	2460
Copper, estn. of, 884; accuracy of, voltmeters, 1156; bottle for iodimetric titration of, 1308; detn. of.....	1668
Copper chlorides, dissociation tensions of hydrated CuCl <sub>2</sub> and vapor pressure of satd. solns. of the same.....	1439
Copper compounds, spectrophotometric study of Cu complexes and biuret reaction.....	457
Copper sulfate, density of aq. solns. of, and H <sub>2</sub> SO <sub>4</sub> , 1021; basic.....	1947
Copper-tin group, electro-analytical method for detn. and sepn. of metals of.....	1660
Cottonseed oil, partition of lower alcohols between H <sub>2</sub> O and.....	2316
Coumaric acid, formation of.....	450
Coumarin, some derivs. of.....	446
Cresols, action of aqua regia on <i>p</i> -, <i>m</i> - and <i>o</i> -.....	1818, 1819
Crop rotation, presence of nitrites and NH <sub>3</sub> in diseased plants—its significance with regard to.....	2572
Crucible "fork".....	1203
Cryoscopy, measurements at low temps.....	615
<i>Cryptomeria japonica</i> , essential oil of leaves of.....	687
Crystallization, effect of dissolved substances on velocity of, of water, 317; effect of dissolved substances on velocity of, of H <sub>2</sub> O—(II) existence of hydrates in soln. as explanation of retarding effect of solute on velocity of crystn. of H <sub>2</sub> O, 1161; structure of, 2222; structure from viewpoint of chem. theory.....	2230
Crystals, forces between atoms in.....	2235
Cyanamides, synthesis of amidines from.....	2768
Cyanides, systematic sepn. of anions of group (I).....	2000
Cyanoacetic acids, alkyl.....	909
Cyan radical, action of the Grignard reagent on compds. contg.....	2768
Cyclopentadiene series, studies in.....	2535
Cyclopentadienodihydropyridazines, formation of.....	2535
<i>p</i> -Cymene monocarboxylic acids, synthesis of, together with certain of their derivs.....	1349, 1904
<b>D</b>	
<b>DATURIC ACID</b> in alfalfa seed oil.....	485
Density, floating equil., 1000; supposed effect of form of container on, of a gas, 1017; of aq. solns. of CuSO <sub>4</sub> and H <sub>2</sub> SO <sub>4</sub> .....	1021
Dialysis, temp. effect in, 1270; studies in (I) dialysis of colloidal soln. of hydrous chromic oxide in CrCl <sub>3</sub> .....	1961
Dialyzer, inexpensive, for class use, 1204; simple rapid.....	1270
1,3-Diamines, synthesis by reduction of 2-mercapto-6-oxypyrimidines.....	1854
<i>p</i> -Diaminodiphenylamine, action of aqua regia on.....	1818
2,4-Diaminophenol, action of aqua regia on.....	1818
Diaminophenoltetrachlorophthalein and dihydrochloride.....	2494, 2495
Diarylhydrazines, thermal decompn. of symmetrical.....	1736
Dibenzyl, chlorination of.....	1812
Dibromodinitrophenoltetrachlorophthalein.....	2493
3,5-Dibromo-4-hydroxybenzhydrol.....	1215
$\gamma$ , $\gamma$ -Dibromo- $\gamma$ -nitro- $\beta$ -phenyl- $\alpha$ -bromobutyrophenone.....	897
$\gamma$ , $\gamma$ -Dibromo- $\gamma$ -nitro- $\beta$ -phenylbutyrophenone.....	895
Di- <i>p</i> -bromophenylphenylmethylhydroxylamine and hydrochloride.....	2077
Dibromopyrocatechindisulfonic acid and salts.....	680
Dibromosuccinic acid, cond. in abs. EtOH, 125; NH <sub>4</sub> salt of.....	1801
2,4-Dichloroaniline, action of aqua regia on.....	1819
2,4-Dichloroazobenzene.....	1748
2,4-Dichlorohydrazobenzene, velocity of decompn. of.....	1753
Di- <i>p</i> -chlorophenylphenylmethylamine hydrochloride.....	2096
<i>p</i> -Dichlorophenylphenylmethylchloroamine.....	2097
Di- <i>p</i> -chlorophenylphenylmethylhydroxylamine.....	2074
Dichlorophthalic acid, cond. in abs. EtOH.....	127
Di- <i>p</i> -cymyl-[ <i>bb</i> ]-furodiazoles.....	1359, 1365
$\alpha$ , $\alpha'$ -3,3'-Di- <i>p</i> -cymyl- <i>N</i> -phenyl-[ <i>bb</i> ]-pyrroldiazole.....	1366
<i>p</i> -Diethylaminobenzhydrol ethyl ether.....	1209
Diethylamino- <i>m</i> -hydroxybenzoyltetrachlorobenzoic acid and some of its derivs.....	2101

Diethyl ketone, action of aqua regia on.....	1817
Diethylmalonic acid, cond. in abs. EtOH.....	124
Diethylphenylbenzylammonium chlorate.....	1085
Diffusion of I in KI solns.....	253
Digestion, salivary, of bread <i>in vitro</i> .....	1245
Dihydronaphthoic acids, structure of.....	400, 419
Dilution, free energy of, and f. p. lowerings in solns. of some salts of various types of ionization, and of salt mixts.....	2658
<i>p</i> -Dimethylaminobenzhydrol, reactions with Br, HNO <sub>2</sub> and HNO <sub>3</sub> .....	1208, 1209
Dimethyldiisopropyl dibenzoylhydrazines.....	1358, 1365
Dimethylethylcarbinol, action of oxalyl chloride on.....	2518
Dimethylmalonic acid, NH <sub>4</sub> salt of.....	1798
1,4-Dimethyl-6-nitro-2,3-cyclopentadieno-1,4-dihydropyridazine.....	2540
Dimethylphenylbenzylammonium chlorate.....	1085
3,6-Dimethyl-4,5-pyridazinedicarboxylic acid.....	2541
Dimethyl sulfate, utilization of hypochlorite color reactions in establishing mechanism of action of, on aniline.....	2507
5,5-Dimethyl-3-R-2-thiohydantoin.....	2523
1,3,5-Dinitrobenzoic acid, cond. in abs. EtOH.....	126
Dinitrobenzole urea.....	1611
Dinitrophenoltetrachlorophthalein and derivs.....	2489
Dinitropyrocolls, constitution of the 3 symmetrical.....	1065
Diphenylamine, action of aqua regia on.....	1818
1,4-Diphenyl-6-nitro-2,3-cyclopentadienodihydropyridazine.....	2544
Dipropylmalonic acid, cond. in abs. EtOH, 125; NH <sub>4</sub> salt of.....	1798
Dissociation of hydrogen into atoms, 1145; of solids and kinetic interpretation of phase rule.....	2263
Dissociation tensions of certain hydrated chlorides and the vapor pressures of their satd. solns.....	1439
Dissociation theory, modification of electrolytic.....	57
Dissolution, changes in vol. on, in water of the halogen salts of alkali metals (II), 70; bath used for, of samples in O-free atm.....	374
Drop weight method for detn. of surface tension.....	228
Drying agents, efficiency of CaCl <sub>2</sub> , NaOH and KOH as.....	2038
Dysprosium.....	45
<b>ELECTRODES</b> , lead, 792; convenient dip, 652; study of 0.1 N HCl-calomel, 2310; potential of Hg, against mercurous ion, 2356; effect of pressure on potential of H.....	
Electrons, effect of gases on, emission from heated metals as evidence of presence of stable absorbed films.....	2278
Elements, periodic system and properties of, 169; <i>Electrische Spectroanalyse Chemischer Atome</i> (Stark, book review).....	732
Energy, free, of HCl in aq. soln., 737; free, and heat capacity.....	2629, 2631
Enzyme action, studies on—corrections, 921; starch as substrate for.....	1885
Enzymes, certain conditions which affect activity of proteolytic, in wheat flour.....	1098
Equation of state. See <i>Condition equation</i> .	
Erbium, sepn. from Yt.....	1198
Erucic acid, NH <sub>4</sub> salt of.....	1797
Esterification, studies in.....	2746, 2757
Esters, action of salts with and without water of hydration on velocity of sapon. of, 105; sapon. of, 888; catalysis (I) addition compds. of, with org. acids.....	1712
Ethyl alcohol, conductivities of certain org. acids in abs., 121; <i>Alcoholometric Tables</i> (Thorpe, book review), 163; oxidation by means of KMnO <sub>4</sub> , 375; viscosity of certain solns. in, 833; partition between H <sub>2</sub> O and cottonseed oil, 2316; detn. in fermentation mixts.....	2561
Ethylbenzene, chlorination of.....	1811
Ethyl-di-(4-dimethylaminophenyl) carbinol.....	1210
Ethylene, action upon AlCl <sub>3</sub> .....	1384
Ethylenediamine chlorate.....	1083
Ethylmalonic acid, cond. in abs. EtOH.....	124
Ethyl mercaptan, esterification of <i>o</i> -, <i>m</i> - and <i>p</i> -toluic acids by.....	2746
Eudiometer, improvement of Hoffman's.....	1203
Europium.....	45
Euthamia caroliniana, volatile oil of (L) Greene.....	1398
<b>FATTY ACIDS</b> in alfalfa seed oil, 480; brain cephalin.....	
Feeding, Feed and (Henry, Morrison, book review).....	942

Feeding stuffs and Feeding (Henry, Morrison, book review), 942; nonprotein nitrogenous constituents of, 1425; estn. of Ca in ash of forage plants.....	1996
Fermentation mixtures, detn. of alcohol in.....	2561
Ferrieyanide, influence of K ion and of Ca ion upon ferri-ferrocyanide potential, 1928; systematic sepn. of anions of group I.....	2000
Ferrocyanide, influence of K ion and of Ca ion upon ferri-, potential, 1928; systematic sepn. of anions of group I.....	2000
Fertilizers, effects on large applications of commercial, on carnations.....	2784
Floating equilibrium.....	1000
Flour, certain conditions which affect activity of proteolytic enzymes in wheat.....	1098
Food from Sanitary Standpoint (Woodman, Norton, book review), 735; Analysis, Typical Method and Interpretation of Results (Woodman, book review), 941; Changes in, Supply and their Relation to Nutrition (Mendel, book review).....	1437
Formamides, reactions of—pyrazolone derivs., 1510; reactions.....	1841
Formic acid, behavior of alkali metal formates in (anhydrous).....	271
Freezing effect on certain inorg. hydrogels.....	588
Freezing point, free energy of dilution and, lowerings in solns. of some salts of various types of ionization, and of salt mixts., 2658; lowerings in aq. solns. of salts and mixts. of salts and of salt with nonelectrolyte.....	2676
Fumaric acid, cond. in abs. EtOH.....	125
Furfural, comparison of barbituric acid, thiobarbituric acid and malonylguanidine as quant. precipitants for.....	2156
Fusel oil, synthetic.....	1368
<b>GADOLINITE</b> , extn. of Be from.....	875
Gadolinium.....	45
Gadolinium sodium sulfate.....	873
Galactose pentacetate, fourth cryst., and some related compds.....	1223
Galactose tetracetate.....	1223
Gallic acid, action of aqua regia on.....	1820
Gases, equation of state for, 528; supposed effect of form of container on density of, 1017; adsorption by solids.....	2267
Gentiobiose, rotation of.....	1569
German Chem. (Phillips, book review).....	161
Ginger oil, zingiberol in.....	430
$\alpha$ -Glucosheptose hexacetates, isomeric.....	1575
Glucosamine pentacetates, isomeric.....	1431, 2216
Glucose, role of atm. O in oxidation of, with $\text{KMnO}_4$ in presence of varying amts. of alkali—products of oxidation, 150; effects of commercial, when fed to white rats, 930; action of aqua regia on, 1817; products of action of certain amylases on sol. starch, with special reference to formation of.....	1877
Glycerol, action of aqua regia on.....	1816
Glycol, action of oxalyl chloride on.....	2518
Glycolic acid, $\text{NH}_4$ salt of.....	1788
Grignard reagent, action on CN compds.....	2768
Guanidine, action of aqua regia on.....	1817
Guanidine chlorate.....	1683
<b>HALOGENATION</b> , chloric acid as reagent in org. chemistry.....	1079, 1809, 1813, 2545, 2736
Halogens, detection and detn. in org. compds., 711; and their Allies (Martin, Lancaster, book review).....	730
Heat capacity, free energy and.....	2629, 2631
Hen, distribution of urea in the blood and tissues of.....	1615
Hexahydropyrimidine, hydrolysis of.....	2466
Hexamethylenetetramine, action of aqua regia on.....	1817
Hinoki wood, essential oil of.....	699
Hippuric acid, quant. detn. in urine, blood, muscles and liver.....	2188
Holmium.....	45
Hydantoins, synthesis of phenylalanylglycinhydantoin.....	1087
Hydrates, action on the velocity of sapon. of esters.....	105
Hydrazine, oxidation of (VII) role of $\text{HNO}_2$ in formation of $\text{HN}_3$ .....	285
Hydrazine hydrate, action of bromopropionic acid on.....	1782
Hydrazines, attempts to rearrange unsymmetrical.....	2735
Hydrazino diacids.....	1771
Hydrazobenzene, thermal decompn. products of asymmetrical, 1750; effect of mol. H on.....	1760

Hydrazones, attempts to rearrange unsymmetrical.....	2735
Hydrazopropionic acid, ethyl ester of.....	1783
Hydrobromic acid, reaction between alcs. and aq. solns. of.....	1071
Hydrocarbons, compressibility of certain typical, 989; chlorination of, 1809; bromination by means of Br and HNO <sub>3</sub> .....	2545
Hydrochloric acid, free energy of, in aqueous soln., 737; reaction between alcs. and aq. solns. of, 1071; study of 0.1 N, calomel electrode.....	2310
Hydrocoumarinsulfonic acid, salts of.....	447, 449
Hydrocyanic acid, detn. of small quantities of.....	1230, 1645
Hydrofluoric acid, use in sepn. of heavy metals from Sn, Sb, W and Mo by means of elec. current.....	640
Hydrogels, effect of freezing on certain inorg.....	588
Hydrogen, interaction of, and Cl under influence of $\alpha$ -particles, 280; dissociation of, into atoms, 1145; effect of pressure on potential of, electrode, 2391; occlusion by Pd cathode.....	2577
Hydrogen ion, cell for detg. concn., 936; new and sensitive indicator for detn. of concns. between limits of 6 and 8 on the Sorensen scale, 1606; and chlorine ion activities of solns. of KCl in 0.1 molal HCl.....	1986
Hydrogen peroxide, partition coeffs. of, between water and org. solvents, 633; catalytic decompn. of, in certain nonaqueous solns.....	1956
Hydrogen sulfide, action on arsenic acid.....	52
Hydrolimettin sodium sulfonate.....	452
Hydronitric acid, role of HNO <sub>2</sub> in formation of.....	285
Hydroxybenzal- $\beta$ -phenylethylamine.....	384, 385
<i>p</i> -Hydroxybenzhydrol.....	1212
<i>p</i> -Hydroxybenzoic acid, action of aqua regia on.....	1818
<i>o</i> -Hydroxybenzylidenehydrazinodiacetic acid, monopotassium salt.....	1779
Hydroxybenzyl- $\beta$ -phenylethylamines.....	384, 385
Hydroxyisobutyric acid, cond. in abs. EtOH.....	124
Hydroxylamine hydrochloride, electrolytic prepn. of.....	2042
<b>I MINOACETIC-PROPIONIC ACID</b> , hydrochloride of.....	1780
Indicators, study of, for detn. of temporary hardness in water, 877; new and sensitive, for acidimetry and alkalimetry, and for detn. of H-ion concns. between limits of 6 and 8 on the Sorensen scale, 1606; sulfonphthalein series of.....	2772
Invertase, influence of certain substances on activity of, 722; adsorption of.....	1109
Iodates, detn. of periodates, bromates, chlorates and, in presence of each other.....	330
Iodides, conductance of solns. of certain, in isoamyl and propyl alcs., 1178; systematic sepn. of anions of group I.....	2000
Iodimetry, differential, 330; decompn. of tetrathionates in alk. soln. as source of error in.....	625
Iodine, diffusion in KI solns..... 253; source of error in certain titrations, 625; soly. in EtO-CCHCl <sub>3</sub> solns.....	1243
Iodoantipyrine periodide.....	2166
$\beta$ -Iodopropionic acid, NH <sub>4</sub> salt of.....	1791
Iodoxybenzene.....	1085
Iodoxyesitylene.....	1086
Iodoxytoluenes, <i>o</i> - and <i>p</i> -.....	1086
Iodoxyxylenes.....	1086
Ionization, theory of multiple, 57; cobaltammines (I) various, types as detd. by f. p. lowering in aq. soln., together with conductance measurements, 2643; free energy of dilution and f. p. lowerings in solns. of some salts of various types of, and of salt mixts., 2658; and solubility relations of salts of higher types.....	2679
Ions, app. for detg., in soln., 1711; intermediate, in solns. of uni-bivalent salts, and of lanthanum iodate.....	2679
Iron, anodic, relations of passive—polarization potentials as influenced by external gas pressures, 362; estn. of.....	884
Iron arsenate, colloidal.....	1970
Iron chlorides, oxidation-reduction reactions without the addition of acid—FeCl <sub>3</sub> and KMnO <sub>4</sub> .....	2607
Iron oxide, prepn. of colloidal hydrous ferric oxide.....	2607
Iron oxides, effect of freezing on ferric oxide hydrogels, 588; solid soln. in system Fe <sub>2</sub> O <sub>3</sub> -Fe <sub>3</sub> O <sub>4</sub> , 807; dissociation of Fe <sub>3</sub> O <sub>4</sub> in air.....	1188
Iron phosphates, colloidal.....	1970
Isoamyl alcohol, conductance of solns. of certain iodides in, 1178; partition between H <sub>2</sub> O and cottonseed oil, 2316; action of oxalyl chloride on.....	2517
Isoamyl bromide, influence of some solvents on rate of action of Na with.....	1128

Isobutyl alcohol, action of aqua regia on, 1816; partition between $H_2O$ and cottonseed oil, 2316; action of oxalyl chloride on.....	2517
Isobutyl bromide, rearrangement of, into tertiary butyl bromide.....	653
Isopropyl alcohol, action of aqua regia on.....	1816
Isopropyl-malonic acid, $NH_4$ salt of.....	1798
Isothiocyanates, thiocyanates and.....	1550, 1860
Isothiocyanacetic acid, Et ester of.....	1550
Itaconic acid, cond. in abs. EtOH.....	126
<b>JAMBUL</b> , some constituents of.....	2805
<b>KETONES</b> , compressibility of certain typical.....	989
Kinetics of heterogeneous reaction.....	2286
Kinetic Theory (Lewis, book review).....	2217
Kjeldahl method, comparative study of aeration and heat distn. in, for detn. of N.....	916
<b>LABORATORY</b> exercises, Arranged to Accompany "First Course in Chemistry" (McPherson, Henderson, book review).....	168
Lactose, optical rotatory powers of some acetylated derivs. of maltose, cellose and.....	1867
Lanthanum.....	44
Lanthanum iodate, intermediate ions in solns. of uni-bivalent salts, and of.....	2679
Lauric acid, $NH_4$ salt of.....	1793
Lead, density of, from radioactive minerals, 221; electrode, 792; density of radio-, from pure Norwegian cleveite, 1658; detn. of, 1673; at. wt. of, of radioactive origin,.....	2613
Lead acetate, factors controlling reactions of $Pb(NO_3)_2$ and, with $Na_2HAsO_4$ .....	2014
Lead arsenates.....	2014, 2027, 2366
Lead bromide, density and cubical coeff. of expansion of.....	266
Lead chloride, density and cubical coeff. of expansion of.....	266
Lead iodide, thermodynamic properties of.....	2295
Lead monoxide, equil. in system: $PbO$ , $As_2O_3$ , $H_2O$ .....	2366
Lead nitrate, factors controlling reactions of, and lead acetate with $Na_2HAsO_4$ .....	2014
Lead sulfate, soly. in $AcONH_4$ soln. at $25^\circ$ and criticism of present methods for sepn. of the sulfates of Ba, Sr, Ca and Pb by means of $AcONH_4$ solns.....	310
Lecithin, nitrogenous constituents of brain.....	922
Life process, Temperatur und Lebensvorgänge (Kanitz, book review).....	167
Lime-sulfur, estn. of thiosulfate S in, solns. by I titration.....	1701
Limettin.....	451
Linoleic acid in alfalfa seed oil, 484; in alfalfa seed oil.....	484
Liquids, app. for detn. of surface tension at interface between two, 236; surface tension at the interface between two, 242; equation of state for, 528; properties of mixed, 555; properties of mixed, 844; supersatd. solns. of, in, 1166; constitution and fundamental properties of, 2221; solubilities of, in liquids.....	2316
Lithium, sepn. from other alkali metals.....	2326
Lithium ethylate, reaction of MeI with, at $0^\circ$ .....	2145
Lithium formate, behavior in (anhydrous) formic acid.....	271
Lithium halides, changes in vol. upon soln. in water of.....	70
Liver, detn. of hippuric acid in.....	2188
<b>MAGNESIUM</b> , action on solns. of KCl.....	2594
Magnesium chloride, dissociation tensions of hydrated, and vapor pressures of satd. solns. of the same.....	1439
Magnesium oxide, system: $CaO-Al_2O_3-MgO$ .....	568
Maleic acid, cond. in abs. EtOH.....	125
Malonic acid, cond. in abs. EtOH.....	124
Malonylguanidine, comparison of barbituric acid, thiobarbituric acid and, as quant. precipitants for furfural.....	2156
Maltose, action of aqua regia on, 1816; optical rotatory powers of some acetylated derivs. of, cellose and lactose.....	1867
Mandelic acid, cond. in abs. EtOH.....	127
Manganese, oxidation of, solns. in presence of air.....	638
Manninotriose, rotation of.....	1569
Mechanics, Thermodynamics and Statistical (Lewis, book review).....	2217
Melibiose, rotation of.....	1568
Menthol, action of oxalyl chloride on.....	2518

Menthylamine chlorate.....	1083
2-Mercapto-6-chloropyrimidines, reduction of.....	1385
2-Mercapto-6-oxypyrimidines, synthesis of 1,3-diamines by reduction of.....	1854
2-Mercaptopyrimidines, mechanism of action of Br on.....	1557
Mercurous ion, potential of Hg electrode against.....	2356
Mercury, potential of, electrode against mercurous ion.....	2356
Mercury chlorides, dissociation pressures of HgCl, 801; calomel standard cell, 20, 889; equilibria of HgCl <sub>2</sub> with other chlorides, 1272; study of 0.1 N HCl-calomel electrode.....	2310
Mesaconic acid, cond. in abs. EtOH.....	126
Metals, effect of gases on electron emission from heated, as evidence of presence of stable absorbed films.....	2278
Methacetin, periodides of.....	140
<i>p</i> -Methoxybenzal- $\beta$ -phenylethylamine.....	384
<i>p</i> -Methoxybenzhydrol.....	1213
Methoxybenzhydrol ethyl ether.....	1214
<i>p</i> -Methoxybenzyl- $\beta$ -phenylethylamine.....	384
3-Methoxy-4-hydroxybenzal- $\beta$ -phenylethylamine.....	386
3-Methoxy-4-hydroxybenzyl- $\beta$ -phenylethylamine.....	386
Methyl alcohol, viscosity of certain solns. in, 833; detn. of acetone in systems of, H <sub>2</sub> O and KF, 1136; partition between H <sub>2</sub> O and cottonseed oil.....	2316
Methylbenzylidenaminohydantoic acid.....	1784
Methylethylenediamine, synthesis of.....	2135
Methyl ethyl ketone, equil. in systems of H <sub>2</sub> O, inorg. salts and, 1136; action of aqua regia on.....	1817
$\beta$ -Methyl fructoside, cryst., and its tetracetate.....	1216
Methyl iodide, reaction with Na, K and Li ethylates at 0°.....	2145
Methylisopropylhippuric acids and Et ester.....	1357, 1367
$\gamma$ -Methyl- $\gamma$ -nitro- $\beta$ -phenyl- $\alpha$ -bromovalerophenone.....	900
$\gamma$ -Methyl- $\gamma$ -nitro- $\beta$ -phenylvalerophenone.....	899
Methyl orange, action of aqua regia on.....	1819
Methyl-1-phenyl-2-anisoyltrimethylenedicarboxylic acid.....	1523
Methylphenyl-(3-bromo-4-dimethylaminophenyl)carbinol.....	1211
2-Methyltetraabromobenzacetimidazole.....	687
Methyltriphenylmethylchloroamine, attempts to rearrange.....	2090
Microscope, petrographic, in analysis.....	1647
Mineralogy, Handbuch der Mineralchemie (Doelter, <i>et al.</i> , book review).....	732
Minerals, density of Pb from radioactive.....	221
Molecular rearrangements, theory of, 2046; of triarylmethylazides, 2718; of <i>sym.-bis.-triarylmethyl-</i> methylhydrazines.....	2727
Molecules, the atom and.....	762
Molybdenum, use of HF in sepn. of heavy metals from, by means of elec. current.....	640
Monazite sand, sepn. of rare earths giving the more sol. double sulfates from Brazilian.....	41
Morphine, quant. detn. of, in various organs when injected into cats and rabbits.....	1873
Muscles, detn. of hippuric acid in.....	2188
Myristic acid, NH <sub>4</sub> salt of.....	1794
<b>NAPHTHOLS</b> , action of aqua regia on $\alpha$ - and $\beta$ -.....	1820
Naphthyl-(4-dimethylaminophenyl) carbinol.....	1210
Neodymium, 45; at. wt. of.....	302
Neodymium chloride, density and cubical coeff. of expansion of.....	266
Neodymium cobalticyanide.....	1497
Neurokeratin, compn. of.....	2558
New books. See <i>Books, new (Reviews)</i> .	
Nickel, detection in Co salts.....	1705
Nickel chlorides, dissociation tensions of hydrated, and vapor pressure of satd. solns. of the same.....	1439
Nitriles, prepn. of, (II) prepn. of aliphatic nitriles, 2120; prepn. of, (III) catalytic prepn. ....	2128
Nitrites, titrametric detn. of, 1683; presence in diseased plants—its significance with regard to crop rotation and soil depletion.....	2572
Nitroamines, application of nitrometer for detn. of constitution and estn. of N in.....	2552
<i>m</i> -Nitroaniline, action of aqua regia on.....	1819
<i>m</i> -Nitrobenzoic acid, cond. in abs. EtOH.....	126
Nitro compounds, addition of aliphatic, to unsatd. compds., 889; application of nitrometer for detn. of constitution and estn. of N in a class of.....	2552
Nitro-fibroin, hydrolysis with HCl.....	1392
Nitrogen, comparative study of aeration and heat distn. in Kjeldahl method for detn. of, 916;	

- non-protein, of feeding stuffs, 1425; application of nitrometer for detn. of constitution and estn. of, in a class of nitro compds. (nitroamines), 2552; efficiency of aeration method for distg.  $\text{NH}_3$  in detg. N by the Kjeldahl method. . . . . 2568
- Nitrometer, application for detn. of constitution and estn. of N in a class of nitro compds. (nitroamines) . . . . . 2552
- 4-Nitro-5-methyl-2-sulfobenzoic acid, and some of its derivs. . . . . 1338
- Nitrophenols, action of aqua regia on . . . . . 1818, 1819
- o*-Nitrophenylacetic acid,  $\text{NH}_4$  salt of . . . . . 1786
- $\gamma$ -Nitro- $\beta$ -phenyl- $\alpha$ -bromobutyrophenone . . . . . 896
- $\gamma$ -Nitro- $\beta$ -phenyl- $\alpha$ -bromovalerophenone . . . . . 898
- $\gamma$ -Nitro- $\beta$ -phenylbutyrophenone . . . . . 893
- Nitrophenyl ethers, mono- . . . . . 1534
- $\gamma$ -Nitro- $\beta$ -phenyl- $\alpha$ -iodobutyrophenone . . . . . 896
- $\gamma$ -Nitro- $\beta$ -phenylvalerophenone . . . . . 897
- Nitrous acid, role in formation of  $\text{HN}_2$  . . . . . 285
- Nucleosides, secondary-pyrimidine-, and their unique behavior on hydrolysis . . . . . 1844
- Nutrition, changes in Food Supply and Their Relation to (Mendel, book review) . . . . . 1437
- OCCCLUSION**, of H by Pd cathode . . . . . 2577
- Oils, zingiberol in, of ginger, 430; of Sugi leaves, 687; of Formosan Hinoki wood, 699; of *Euthamia caroliniana* (L). Greene . . . . . 1398
- Oleic acid in alfalfa seed oil . . . . . 484
- Organic acids. See *Acids*.
- Organic compounds, mol., 702; detection and detn. of halogens in, 711; addition of aliphatic nitro compds. to unsatd. compds., 889; action of anhydrous  $\text{NH}_4\text{Cl}$  on unsatd. compds., 1382; see also *Aromatic compounds*.
- Organs*, reaction of pancreas and other . . . . . 1115
- Oscillaria prolifica, chem. compn. of . . . . . 1402
- Osmosis, relation of, of solns. of electrolytes to membrane potentials, 1029; of some solns. of electrolytes with porcelain membranes, and relation of osmose to membrane potential. . . . . 1036
- Osmotic pressure, of sucrose solns. at  $30^\circ$  . . . . . 1907
- Oxalic acid, action of soln. of KOH in alc. on esters of . . . . . 1803
- Oxalyl chloride, action on primary, secondary and tertiary alcohols . . . . . 2514
- Oxalylhydrazide, estn. by its interactions with halogens and halogen oxyacids . . . . . 2736
- Oxidation and reduction without addition of acid (II) reaction between  $\text{SnCl}_2$  and  $\text{K}_2\text{Cr}_2\text{O}_7$ , 47; role of atm. O in, of glucose with  $\text{KMnO}_4$  in presence of varying amts. of alkali—products of . . . . . 150
- Oxidation-reduction reactions without addition of acid . . . . . 2607
- Oxygen, role of atmospheric, in the oxidation of glucose with  $\text{KMnO}_4$  in the presence of alkali, 150; sodium pyrogallate as reagent for detn. of . . . . . 1687
- PALLADIUM**, occlusion of H by, cathode . . . . . 2577
- Pancreas, reaction of . . . . . 1115
- Paraffin, soly. in water . . . . . 1003
- Partition of lower alcohols between  $\text{H}_2\text{O}$  and cottonseed oil . . . . . 2316
- Partition coefficients of  $\text{H}_2\text{O}_2$  between  $\text{H}_2\text{O}$  and certain org. solvents . . . . . 633
- Passivity, anodic behavior of passive Fe . . . . . 362
- Peptides, spectrophotometric study of Cu complexes of . . . . . 457
- Periodates, detn. of iodates, bromates, chlorates and, in presence of each other . . . . . 330
- Periodic system and properties of elements, 169; Ueber das periodische System der chemischen Elemente (Bilecki, book review) . . . . . 732
- Periodides, org., (I) of phenacetin, methacetin and triphenin, 140; organic . . . . . 2166
- Petroleum, presence of  $\text{C}_6\text{H}_6$  homologs in high boiling distillates of . . . . . 393
- Pharmacognosy, Scientific and Applied (Kraemer, book review) . . . . . 162
- Phase rule, statement of, 983; dissociation of solids and kinetic interpretation of . . . . . 2263
- Phenacetin, periodide of . . . . . 140
- Phenol, properties of  $\text{PhOH-H}_2\text{O}$  and of  $\text{NEt}_3\text{-H}_2\text{O}$  mixts . . . . . 844
- Phenols, addition compds. of, with org. acids, 1309; catalytic decompn. of certain, silver salts . . . . . 1761
- Phenoltetrachlorophthalein, nitration products of, and some of their derivs . . . . . 2486
- Phenylacetic acid, cond. in abs. EtOH . . . . . 124

Phenylenediamines, action of aqua regia on.....	1819
<i>p</i> -Phenylenediamine chlorate.....	1681
Phenyl ethers, bibliography of.....	1547
$\beta$ -Phenylethylamine, formation of Schiff bases from, and their reduction to alkyl derivs. of this amine.....	381
Phenylhydrazine, action of aqua regia on.....	1819
Phenylmethylcarbinol, action of oxalyl chloride on.....	2518
Phenylpropionic acid, cond. in abs. EtOH.....	126
Phenyltolylcarbinol.....	1215
Phosphorus, black, 609; blackening of yellow.....	887
Phosphorus compounds in starch.....	472
Phosphorus trihalides, action of chromyl chloride on.....	1923
Phthalic acids, cond. in abs. EtOH.....	127
Physics, Elementes de física geral (Gomez, Machado, book review).....	939
Physiological action, Chem. Constitution and (Spiegel, book review).....	165
Picric acid, cond. in abs. EtOH.....	126
Piezometer.....	992
Pinacone, action of oxalyl chloride on.....	2519
Piperazine chlorate.....	1083
Pipet, double, for liquid reagents in gas analysis.....	1683
Plants, Soil Conditions and, Growth (Russell, book review), 944; estn. of Ca in ash of forage, 1996; presence of nitrites and $\text{NH}_4$ in diseased—its significance with regard to crop rotation and soil.....	2572
Plum, chem. changes occurring during ripening of wild goose plum.....	718
Poison ivy, constituents of.....	1421
Poison oak, poisonous principle of.....	1417
Polarization, anodic behavior of passive Fe—polarization potentials as influenced by external gas pressures.....	362
Polypeptide-hydantoin, synthesis of.....	1087
Potassium chloride, H and Cl ion activities of solns. of KCl in 0.1 molal HCl, 1985; action of Mg on solns. of.....	2594
Potassium dichromate, reaction between $\text{SnCl}_2$ and.....	47
Potassium ethylates, reaction of MeI with, at $0^\circ$ .....	2145
Potassium fluoride, detn. of acetone in systems of MeOH, $\text{H}_2\text{O}$ and.....	1136
Potassium halides, changes in vol. upon soln. in water of, 70; densities and cubical coeffs. of expansion of.....	259
Potassium hydroxide, action of a soln. of, in alc. on oxalic esters, 1833; efficiency, as drying agent.....	2038
Potassium iodide, diffusion of I in, solns.....	253
Potassium ion, influence on ferri-ferrocyanide potential.....	1928
Potassium permanganate, oxidation of EtOH by means of, 375; oxidation-reduction reactions without the addition of acid— $\text{FeCl}_2$ and.....	2607
Potential, electric, influence of K ion and of Ca ion on ferri-ferrocyanide potential, 1928; of Hg electrode against mercurous ion, 2356; effect of pressure on, of H electrode.....	2391
Potentiometer, practical installation of double combination.....	1266
Praseodymium.....	44
Pressure, influence on solubility.....	2632
Propiophenetidine hydriodo-diiodide.....	149
Propiophenetidine hydriodotetraiodide.....	150
Propyl alcohol, conductance of solns. of certain iodides in, 1178; action of aqua regia on, 1816; partition between $\text{H}_2\text{O}$ and cottonseed oil, 2316; action of oxalyl chloride on <i>N</i> -.....	2517
Propylmalonic acid, cond. in abs. EtOH.....	124
Proteins, spectrophotometric study of Cu complexes of, 457; nitrated.....	1392
Proteolysis, examn. of certain methods for study of proteolytic action.....	2199
Pump, device for regulating, used in exhausting vacuum oven.....	1063
Pyramidone periodide.....	2166
Pyrazolone derivs. of the formamidines.....	1510
Pyridine, action of aqua regia on.....	1870
Pyridine chlorate.....	1083
Pyrimidine-nucleosides, secondary, and their unique behavior on hydrolysis.....	1844
Pyrimidines, researches on.....	1385, 1557, 1844, 1854
Pyrogallal acid, action of aqua regia on.....	1820

<b>QUINAZOLINES</b> .....	1606
Quinoline, action of aqua regia on.....	1820
Quinoline chlorate, prepn. of.....	1084
Quinone-phenolate theory, sulfonphthalein series on indicators and.....	2772
<b>RADIO-LEAD</b> . See <i>Lead</i> .	
Raoult's Law.....	1452
Rare earth cobalticyanides.....	1497
Rare earths, sepn. of, giving the more sol. double sulfates from Brazilian monazite sand, 41; Their Occurrence, Chemistry and Technology (Levy, book review), 733; Industry (Johnstone, book review).....	734
$\alpha$ -Rays, Interaction of H and Cl under influence of.....	280
Reactions, Baly's theory of chem., 1, 15, 227; in non-aqueous solvents, 1923; of both the ions and non-ionized forms of acids, bases and salts—reaction of MeI with Na, K and Li ethylates at 0°, 2145; kinetics of heterogeneous.....	2286
Reactivity, Baly's theory of chem.....	1, 15, 227
Reduction, oxidation and, without addition of acid (II) reaction between SnCl <sub>2</sub> and K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> .....	47
Resorcinol, action of aqua regia on, 1820; colors produced by, in solns. of certain salts and use of these colors as means of detecting resorcinol in presence of other phenols.....	2182
Rhus diversiloba, poisonous principle of.....	1417
Rhus toxicodendron, constituents of.....	1421
Rubidium formate, behavior, in (anhydrous) formic acid.....	271
Rubidium halides, changes in vol. upon soln. in water of, 70; densities and cubical coeffs. of expansion of.....	259
<b>SACCHARIN</b> , action of aqua regia on.....	1820
Saliva, digestion of bread by, <i>in vitro</i> .....	1245
Salts, action of, with and without water of hydration on velocity of sapon. of esters, 105; equil. in systems of Me Et ketone, H <sub>2</sub> O and inorg., 1136; reaction of both ions and nonionized forms of acids, bases and, 2145; free energy of dilution and f. p. lowerings in solns. of some, of various types of ionization, and of salt mixts., 2658; freezing-point lowerings in aq. solns. of, and mixts. of salts and of salt with non-electrolyte, 2676; ionization and solubility relations of, of higher types, (IV) intermediate ions in solns. of uni-bivalent salts, and of lanthanum iodate, 2679; effect of, on solubility of other salts—solubility relations of very sol. bi-univalent salt.....	2709, 2714
Samarium.....	45
Saponification, action of salts with and without water of hydration on velocity of, of esters, 105; of esters.....	888
Schiff bases, formation from $\beta$ -phenylethylamine and their reduction to alkyl deriva. of this amine.....	381
Sebacic acid, cond. in abs. EtOH.....	125
Semicarbazide, estn. by its interactions with halogens and halogen oxyacids.....	2736
Semicarbazinodipropionic acid, ethyl ester of.....	1783
Semioxamazine, estn. by its interactions with halogens and halogen oxyacids.....	2736
Silica, hydrogels, 588; quant. detn. of.....	1050
Silver, electroanalysis of, with solns. of AgCl in NH <sub>3</sub> , 1682; inclusions in, voltameter.....	2044
Silver fulminate, stability under water.....	486
Silver iodide, thermodynamic properties of.....	2295
Silver salts, catalytic decompn. of certain phenol.....	1761
Silver voltameter, inclusions in, deposits.....	496
Sodium, influence of some solvents on rate of action of, with isoamyl bromide.....	1128
Sodium aci-nitrophenylbutyropheneone.....	893
Sodium arsenate, factors controlling reactions of Pb nitrate and Pb acetate with Na <sub>2</sub> HAsO <sub>4</sub> .....	2014
Sodium ethylate, reaction of MeI with, at 0°.....	2145
Sodium formate, behavior in (anhydrous) formic acid.....	271
Sodium gadolinium sulfate.....	873
Sodium halides, changes in vol. upon soln. in water of, 70; densities and cubical coeffs. of expansion of.....	259
Sodium hydroxide, efficiency as drying agents.....	2038
Sodium methylate, action on products of nitration of <i>o</i> -, <i>p</i> - and <i>m</i> -chlorotoluenes.....	1327
Sodium pyrogallate, as reagent for detn. of O.....	1687
Soils, Conditions and Plant Growth (Russell, book review), 944; Boden-Bakterien und Boden-Fruchtbarkeit (Löhnis, book review), 945; presence of nitrites and NH <sub>3</sub> in diseased plants—its significance with regard to depletion of.....	2572

Solids, constitution and fundamental properties of, 2221; sublimation of, 2249; adsorption of gases by.....	2267
Solubility of several substances in mixed nonaq., 1235, 1452; of liquids in liquids, 2316; influence of pressure on, 2632; ionization and, relations of salts of higher types, 2679; effect of salts on, of other salts—solubility relations of very sol. bi-univalent salts.....	2709, 2714
Solute, retarding effect of, on velocity of crystn. of $H_2O$ .....	1161
Solutions, vapor pressure of, 515; nonideal—activity of a difficultly sol. component, 626; viscosity of certain alcoholic, 833; supersaturated, of liquids in liquids, 1166; studies in measurement of elec. cond. of, at different frequencies, 2396, 2403, 2415; free energy of dilution and f. p. lowerings in, of some salts of various types of ionization, and of salt mixts., 2658; freezing-point lowerings in aq., of salts and mixts. of salts and of salt with non-electrolyte, 2676; see also <i>Dissolution</i> .	
Solutions, solid, in system $Fe_2O_3-Fe_3O_4$ .....	807
Solvents, solubilities of several substances in mixed nonaq. solns., 1235; reactions in non-aqueous.	1923
Spectroanalysis, <i>Electrische Spectroanalyse Chemischer Atome</i> (Stark, book review).....	732
Spectrophotometry, of Cu complexes and biuret reaction.....	457
Starch, phosphoric acid in, 472; action of aqua regia on, 1817; products of action of certain amylases upon sol., with special reference to formation of glucose, 1877; as substrate for enzyme action.....	1885
Strontium sulfate, soly. in $AcONH_4$ soln. at $25^\circ$ and criticism of present methods for sepn. of the sulfates of Ba, Sr, Ca and Pb by means of $AcONH_4$ solns.....	310
Strychnine, soly. in $Et_2O-CHCl_3$ solns.....	1242
Suberic acid, $NH_4$ salt of.....	1801
Sucrose, action of aqua regia on, 1816; osmotic pressure of, solns. at $30^\circ$ .....	1907
Sucrose groups, rotatory powers of sugars of.....	1566, 1570
Sugars, numerical relations among rotatory powers of compound, 1566, 1904; prepn. of bromoacetyl.....	2187
Sugi leaves, essential oil of.....	687
Sulfanilic acid, action of aqua regia on.....	1818
Sulfonphthalein series of indicators.....	2772
Sulfosalicylic acid, cond. in abs. $EtOH$ .....	126
Sulfuric acid, properties of $H_2SO_4-H_2O$ mixts., 555; density of aq. solns. of $CuSO_4$ and.....	1021
Sumbul root, constituents of.....	432
Supersaturation, solns. of liquids in liquids.....	1166
Surface tension, drop wt. method for detn. of, 228; app. for detn. of, at interface between 2 liquids, 236; at interface between two liquids and effect of acids, salts and bases on interfacial tension, 242; app. for detn. of, with metal thermoregulator.....	246
<b>TANNIC ACID</b> , action of aqua regia on.....	1820
Tartaric acid, action of aqua regia on, 1817; crystn. of Ca salt of.....	2519
Tautomerism, 1,4,5,6-tetrahydroxynaphthalene, 387, 1144; electronic, of benzene derivs., 1333; of triarylcannabinols.....	1577
Temperature, <i>Temperatur und Lebensvorgänge</i> (Kanitz, book review).....	167
Temperature, low, cryoscopic measurements at.....	615
Terbium.....	45

1,2,4-Triphenyl-6-nitro-2,3-cyclopentadienodihydropyridazine.....	2544
Trypsin, assumed destruction of, by pepsin and acid.....	1620
Tungsten, use of HF in sepn. of heavy metals from, by means of elec. current.....	640
Tungsten derivatives, analysis of certain, 2377; new.....	2383
<b>UNSATURATED COMPOUNDS, addition of aliphatic nitro compds. to, 889; action of anhydrous AlCl<sub>3</sub> upon.....</b>	
Urea, distribution of, in blood and tissues of certain vertebrates with especial reference to the hen.....	1615
Ureas, action of certain acid reagents on the substituted, and thiazole (II).....	131
Uric acid, action of aqua regia on.....	1817
Urine, detn. of hippuric acid in.....	2188
<b>VACUUM OVEN, device for regulating pump used in exhausting.....</b>	
Vanadic acid, estn. of, after reduction by metallic Ag, 1297; reduction by HI.....	1063
Vanadium, electrometric titration.....	2369
	341

- Vapor pressure of solns.—lowering of, of water produced by dissolved KCl, 515; dissociation tensions of certain hydrated chlorides and the vapor pressures of their satd. solns. . . . . 1439
- Viscosity, sources of error in, measurement of, 27; of certain alcoholic solns. . . . . 833
- Vitiatine, structure of. . . . . 2135
- Voltameter, inclusions in silver, deposits, 496; accuracy of copper, 1156; inclusions in Ag. . . . . 2044
- Volume, changes in, on soln. in water of halogen salts of alkali metals (II). . . . . 70
- Vreeland oscillator, measurement of elec. cond. of solns. at different frequencies—(V) use of, and other sources of current for cond. measurements. . . . . 2396
- WASH BOTTLE**, non-spattering. . . . . 1502
- Water, effect of dissolved substances on velocity of crystn. of, 317; lowering of vapor pressure of, produced by dissolved KCl, 515; properties of  $\text{H}_2\text{SO}_4\text{-H}_2\text{O}$  mixts., 555; from Sanitary Standpoint (Woodman, Norton, book review), 735; properties of phenol- $\text{H}_2\text{O}$  mixts., 844; indicators for detn. of temporary hardness in, 877; detn. of carbonic acid, combined and free, in soln. particularly in natural waters, 947; detn. of acetone in systems of MeOH, KF and, and equil. in systems of Me Et ketone,  $\text{H}_2\text{O}$  and inorg. salts, 1136; effect of dissolved substances on velocity of crystn. of, (II) existence of hydrates in soln. as explanation of retarding effect of solute on velocity of crystn. of  $\text{H}_2\text{O}$ , 1161; specific cond. of pure, in equil. with atmospheric  $\text{CO}_2$ , 1480; partition of lower alcohols between, and cottonseed oil, 2316; equil. in system  $\text{PbO}$ ,  $\text{As}_2\text{O}_5$ ,  $\text{H}_2\text{O}$ , 2366; prepn. of conductivity. . . . . 2460
- m*-**XYLENES**, chlorination of. . . . . 1809, 1810, 1811
- YTTRIUM**, 46; sepn. of erbium from, 1198; purification and at. wt. of. . . . . 2332
- Yttrium cobalticyanide. . . . . 1490
- ZINC**, revision of at. wt. of—electrolytic detn. of Zn in  $\text{ZnBr}_2$ . . . . . 868
- Zinc bromide, detn. of Zn in. . . . . 868
- Zinc salts, action of alkali on certain. . . . . 785
- Zingiberol. . . . . 430

PROCEEDINGS

OF THE

American Chemical Society

---

FOR THE YEAR 1916

---

EASTON, PA.:  
ESCHENBACH PRINTING COMPANY  
1916

# PROCEEDINGS.

## Contents.

### January.

General Society Minutes and Reports.....	1
Report of the Secretary of the American Chemical Society for the year 1915.	
Report of the Editor of the Journal of the American Chemical Society for the year 1915. Report of the Editor of Chemical Abstracts for the year 1915.	
Report of the Editor of the Journal of Industrial and Engineering Chemistry for the year 1915.	
Minutes of the Directors Meeting.....	8
Conucil.....	11
Members elected between November 15 and December 15, 1915.....	11
Meetings of the Sections:	
Lexington Section.....	15
The Effect of the European War on Drug Supplies, L. A. Brown. The Stability of Silver Fulminate under Water, A. M. Peter. The Translocation of the Mineral Constituents of Certain Seeds during Growth, G. D. Buckner. A Review of the Literature on the Distribution and Sources of Iodine in Plant and Animal Life, P. L. Blumenthal.	
Chicago Section.....	16
The Manufacture of Gasoline and Benzole from Petroleum and Other Hydrocarbons, Walter F. Rittman.	
Ames Section.....	16
Peculiarities of the Chemistry and Physics of Silicate Industries, Homer F. Staley.	
Maryland Section.....	16
Partition or Neutral Solubility, E. E. Reid and B. B. Wroth. Methods of Toxicological Examinations, W. B. D. Penniman.	
Louisiana Section.....	16
Some Aspects of Illuminating Gas Manufacture, C. Hartogh. Journal Reviews, Philip Asher. The Manufacture and Usages of White Lead, and The Crime of Carelessness (motion pictures).	
Wisconsin Section.....	16
The Influence of Impurities on the Rate of Growth of Ice Crystals, J. H. Walton, Jr. The Nature of Radiant Energy, R. A. Millikan.	
Cincinnati Section.....	17
University of Michigan Section.....	17
A Study of the Hydrochloric Acid Concentration Cell with Respect to Activity and Concentration, Boundary Potential and Transparent Members, A. L. Ferguson. Ferro-Tungsten as an Industry, R. L. Session.	
New York Section.....	17
University and Industry, Richard C. Maclaurin, Henry P. Talbot, William H. Walker, Arthur D. Little. The Naval Consulting Board of the United States, L. H. Baekeland and W. R. Whitney.	
Puget Sound Section.....	17
University of Illinois Section.....	17

# IV

Northeastern Section.....	17
The Chemistry of Amorphous Solids, Warren K. Lewis.	
Western New York Section.....	18
Electrons, Atoms, and Energy Quanta, Saul Dushman.	
California Section.....	18
The Equilibrium of Oxidation Reactions, Arthur A. Noyes. Hydrocarbon Reactions at High Temperature, Walter F. Rittman.	
Oregon Section.....	18
Some Modern Views of Matter, W. C. Morgan.	
Detroit Section.....	18
Formaldehyzed Capsules, Wilbur L. Scoville. Dental Surgery, Charles H. Oakman. A Piece of Cheese, John W. M. Bunker.	
Minnesota Section.....	18
The Nature of the Proteins Extracted from Wheat Flour by Various Processes, C. H. Bailey. Recent Advances in Chemotherapy, A. D. Hirschfelder. Flavoring Extracts and Baking Powders, Wm. Kennedy. The Polymerization of China Wood Oil, Carl Schuman. The Swelling of Rubber in Organic Liquids, I. H. Derby.	
Southern California Section.....	18
Carbon Tetrachlorid, L. H. Buck.	
New Haven Section.....	19
The Disposal of City Sewage, C. E.-A. Winslow and Anna M. R. Lauder.	
Rochester Section.....	19
American Resources in Fertilizer Materials, Frank K. Cameron.	
Washington Section.....	19
Some Examples of Metal Failures (illustrated), G. K. Burgess. Chemical Factors Affecting Electrolytic Corrosion in Soils and Reinforced Concrete, B. McCollom. The Action of Natural Waters on Boilers, R. B. Dole.	
Milwaukee Section.....	19
Development in the Marketing of Coal—Specifications, Storage, etc., S. W. Parr.	
Cleveland Section.....	19
The Electron Theory and Some of its Applications, A. G. Worthing.	
Nebraska Section.....	19
Our National Chemical Industries, Chancellor Samuel Avery.	
Columbus Section.....	19
The Life and Work of John Ulric Nef, W. L. Evans.	
Philadelphia Section.....	20
The Decomposition of Hydrocarbon Oils under High Temperatures and Pressures, and the Industrial Applications of the Process, Walter F. Rittman.	
Virginia Section.....	20
Some Mechanical Analogies in Electricity and Magnetism, W. S. Franklin.	
Pittsburgh Section.....	20
Demonstration of a Portable Gas Detector, G. A. Burrell. The Mechanism of Corrosion, James Aston. The Manufacture of Refractories, R. H. H. Pierce. Hydrometallurgy of Copper, Raymond F. Bacon. The Removal of Iron from a Municipal Water Supply, S. Buka.	
Connecticut Valley Section.....	20
Smoking Opium in the United States, H. L. Thompson. The Rittman Gasoline Process, E. C. Stone.	
Deceased Members.....	20

## February.

Council.....	21
Treasurer's Report.....	
Members elected between December 15, 1915 and January 15, 1916.....	25
Meetings of the Sections:	
Eastern New York Section.....	30
Garbage Reduction, W. W. Chadsey. Treatment of Sewage, W. E. Weller.	
Cincinnati Section.....	30
The Trend of American Technical Chemistry (illustrated), Thomas H. Norton. An Outline of Studies by the U. S. Public Health Service on the Pollution of the Ohio River (illustrated), W. H. Frost.	
Indiana Section.....	30
Commercial Applications of Oxygen, Philip J. Kroll.	
Washington Section.....	30
The Chemical Analysis of Animal Nutrition, C. L. Alsberg.	
Rochester Section.....	31
Thermal Reactions among Hydrocarbons in a Single Phase System, W. F. Rittman. Oils, F. R. Baxter. The Manufacture of Acids, M. H. Eisenhart.	
Connecticut Valley Section.....	31
Our Experience with Nickel Anodes, C. H. Corbin. Some Experiments in Making Electrolytic Copper Pipe, C. F. Wessell. Mechanical Plating and Polishing, G. B. Hoogaboom.	
Philadelphia Section.....	31
Pittsburgh Section.....	31
The Hydrometallurgy of Copper, Raymond F. Bacon. The Removal of Iron from a Municipal Water Supply, S. Buka.	
University of Missouri Section.....	32
Southern California Section.....	32
The Manufacture of the Illuminating Mantle, M. N. Lando.	
Ames Section.....	32
Compounds of Ammonia and Certain Metallic Salts, G. J. Fink. Is the Hydrochloric Acid of the Gastric Juice Efficient as a Germicide, C. C. Fowler.	
Columbus Section.....	32
Some Interesting Physical and Chemical Properties of Clay (illustrated), Arthur S. Watt. The Contributions of Chemistry to the Production and Preparation of Human Food, John F. Lyman. The American Chemist and the War Problem, James R. Withrow. The Fertilizer Resources of the United States, Frank K. Cameron.	
St. Louis Section.....	32
The Gasoline Situation in America, Walter F. Rittman. Some Relations between Chemical Constitution and Physiological Action, A. C. Bolyston. The Silver Coulometer, F. O. Anderegg.	
Virginia Section.....	33
Tannin, (paper read by Frank R. Elder).	
Nashville Section.....	33
The Simultaneous Developing and Fixing of Photographic Plates, James F. Norris.	
Cleveland Section.....	33
Experiment on the Electrolysis of Cyanide Solutions, M. F. Coobaugh.	
Lexington Section.....	33
Report on the Annual Convention of the Association of Official Agricultural	

## VI

Chemists, for 1915, Wm. Rodes, Jr. · Note on a Specimen of Ferric Phosphate from Laurel County, Kentucky, A. M. Peter. Chemical Changes Occurring during the Ripening of the Wild Goose Plum, J. S. McHargue.	
Wisconsin Section .....	33
Some Experiments on Animal Oxidations, A. S. Loevenhart.	
New York Section.....	33
Milwaukee Section .....	33
Kansas City Section.....	33
Deceased Members.....	33

## March.

Council .....	35
Members elected between January 15th and February 15th.....	37
Meetings of the Sections:	
California Section .....	40
Electrochemical Possibilities of California as Compared with those of Sweden and Norway, J. W. Beckman. Solutions of Metals in Liquid Ammonia, W. L. Argo.	
Northern Intermountain Section.....	40
Notes on the Homedale Nitrate and Potash Deposits, C. C. Todd. The Effect of Dihydroxystearic Acid and Uvitonic Acid in Soil and in Water Solution, P. P. Peterson. Gluten Formation in Wheat Kernel, George A. Olson.	
Lexington Section .....	40
Total Nitrogen as a Measure of the Organic Matter in Soils (Review), S. D. Averitt. Variation in the Mineral Composition of the Sap, Leaves and Stems of the Wild Grape Vine and the Sugar Maple Tree, O. M. Shedd.	
Indiana Section .....	41
Technical Application of Oxygen (illustrated), Philip J. Kroll. An Official View of Food Control Work, T. J. Bryan.	
Pittsburgh Section.....	41
Lubricating Greases: Their Composition and Methods of Analysis, Joseph E. Babb. Thermal Reactions among Hydrocarbons at High Temperatures, W. F. Rittman. The Corrosive Resistance of Copper Steel, D. M. Buck and J. O. Handy.	
Detroit Section .....	41
Formaldehyzed Capsules, Wilbur L. Scoville. The Theory and Practice of Case Hardening, Herman G. Kiefer.	
Virginia Section .....	41
Some Research Problems, J. B. Weems. Sulfides in Flowers of Sulfur, R. F. McCrackan, O. L. Barden and R. C. Courtney. Chemical Methods for Differentiating Cotton, Wool and Silk, E. C. L. Miller and J. C. Ford.	
New Haven Section.....	41
Oregon Section .....	42
Some Modern Views of Matter, Conger Morgan. The Synthesis of Metals, A. K. Knowlton.	
Georgia Section .....	42
Rhode Island Section.....	42
Green Gills in Oysters, P. H. Mitchell. Sympathetic on Induced Reactions, A. B. Lamb.	
Chicago Section.....	42
The Chemistry of Glass Making, Alexander Silverman.	

## VII

Philadelphia Section.....	42
The Extraction and Recovery of Radium and Vanadium from Carnotite, Charles L. Parsons.	
Minnesota Section.....	42
Animal Pigments, Ross A. Gortner. The Physiological and Biochemical Significance of Hydrogen Ion Concentration, J. F. McClendon. The Chemist and the Flour Industry, F. W. Emmons. Nonideal Solutions, E. K. Strachan.	
Puget Sound Section.....	42
Plasticity of Clays (illustrated), R. F. McMichael.	
University of Michigan Section.....	42
The Determination of Thorium in Monazite Sand, R. J. Carney.	
Cornell Section.....	43
The Electrolytic Production of Perchlorates, E. L. Mack. The Nitration Products of Phenoltetrachlorophthalein and Some of its Derivatives, J. J. Kennedy. The Electrolysis of Solutions of the Rare Earths, A. B. Ray.	
University of Illinois Section.....	43
Syntheses in the Naphthalene Series, H. B. McCluggage and Oliver Kamm. Triphenylmethyl, Laurence C. Johnson. Qualitative Tests for Drugs Con- taining Emodin, Ruth E. Okey and G. D. Beal. Preparation and Charac- terization of Trimethyleneoxide, C. G. Derick and D. W. Bissell. The Preparation of Conductivity Water, E. W. Washburn and H. J. Wieland.	
Kansas City Section.....	43
The Metallurgy of Vanadium, R. L. Grider. The Chemistry of Vanadium, P. V. Faragher. Vanadium Steels, Clarence Estes.	
Rochester Section.....	43
Sulfur, Alexander Smith.	
Wisconsin Section.....	43
A Neglected Principle of Chemistry, L. Kahlenberg.	
Connecticut Valley Section.....	43
The Chemistry of Synthetic Caoutchouc, Joseph S. Chamberlain. The Color Problem in the Paper Industry, R. F. Hatch.	
Maryland Section.....	43
The Estimation of Sugar in the Blood, Geo. Peirce.	
Cleveland Section.....	43
Radium and Radio-Activity, Chas. H. Viol.	
Columbus Section.....	43
Some Problems in Municipal Chemistry, C. B. Hoover. The Present Chemical Situation as Related to Problems in Water Purification, Charles P. Hoover.	
Western New York Section.....	44
Manufacture and Bacteriology of Ice Cream, H. F. Lichtenberg.	
Deceased Members.....	44
<b>April.</b>	
Council .....	47
Members elected between February 15 and March 15, 1916.....	49
Meetings of the Sections:	
Eastern New York Section.....	52
The Electrolytic Refining of Copper, F. D. Easterbrook.	
New York Section.....	52
Electrochemical War Supplies (read by title), Lawrence Addicks. Air Salt-	

# VIII

peter, W. S. Landis. Hydrogen for Military Purposes, E. D. Ardrey. New War Products, A. H. Hooker. Magnesium, W. M. Grosvenor. Liquid Chlorine, G. Ornstein. Electrolytic Zinc, W. R. Ingalls. The Acetyl Derivatives of the Sugars, C. S. Hudson. Development of the Bureau of Chemistry, Carl L. Alsberg.	
Milwaukee Section .....	53
The Uses of Wood Flour, Especially the Manufacture of Linoleum (illustrated), F. W. Kressmann.	
California Section .....	53
The Fundamental Principles Underlying Flotation, Joel H. Hildebrand.	
Eastern New York Section .....	53
The Great Telescopes of the World and the Discoveries Made by Their Use, John A. Brashear. Ultra-Violet Light, R. D. Kleeman. The Electrolytic Refining of Copper, F. D. Easterbrook.	
University of Missouri Section .....	53
Some Aspects of Fat Metabolism, New Physiological, C. W. Greene.	
Kansas City Section .....	53
The Fate of Food Protein in the Animal Body, P. A. Shaffer. High Alloy Steels for Long Span Bridges, J. A. L. Waddell. A Picric-Phosphotungstic Acid Clarifier for Sugar in Meat Extracts, W. B. Smith. Flotation, George Belchic. Heat Value of Gas of the Mid-Continental Field, H. C. Allen.	
Chicago Section .....	54
The Present Status of Fertilizer Theory and Practice, W. D. Richardson. The Chemistry and Metabolism of the Nucleic Acids, H. Gideon Wells.	
Cincinnati Section .....	54
The Application of Physical Chemistry to Some Geological Problems, Otto Charles von Schlichten. Various Aspects of the Smoke Problem, Osborn Monnett.	
Puget Sound Section .....	54
The Electrical Fixation of Nitrogen, J. D. Roso. Fisheries Products, Geo. H. Stillman. Potash from Kelp, I. F. Laucks and H. Mahschmedt. Potash from Mineral Resources, G. A. Newhall. Phosphate Rocks, G. E. Weaver.	
Nashville Section .....	54
The Utilization of Waste in the Manufacture of Copper, J. T. McGill. Estimation of Extract of Beef, E. A. Ruddiman.	
Nebraska Section .....	54
The Laboratory Examination of Clays, George Borrowman.	
Louisiana Section .....	54
The Oxidation of Ethyl Alcohol by Means of Potassium Permanganate (No. 2), Jesse E. Day. The Syrup Precipitate in the Direct Manufacture of White Cane Sugar, C. E. Coates and L. C. Slater. Some Notes on the Chemical Control of Petroleum Refineries, C. E. Coates and M. M. Merritt.	
Rochester Section .....	54
Sewage Disposal, C. C. Hopkins. The Photographic Microscope in Analysis, Fred Wright.	
Ames Section .....	55
The Evolution of the Elements and the Periodic System, William D. Harkins.	
Washington Section .....	55
The Action of Light on Chlorine with Special Reference to the Formation of Chloroacetic Acid, H. H. Curtis. The Isolation of Vitamines from Brewer's Yeast, A. Seidell. On the Chemical Nature of Vitamines, R. R. Williams.	

St. Louis Section .....	55
Activated Sludge, Edward Bartow.	
Cleveland Section .....	55
Glass, Alexander Silverman. The Heat Temperature of Steel, R. R. Abbott.	
Virginia Section .....	55
The Revolution in Coke Manufacture and its Relation to Our National Welfare, Charles H. Herty.	
University of Michigan Section .....	56
Glass Defects, E. C. Sullivan.	
Connecticut Section .....	55
Electrical Precipitation of Flue Dust, Mr. Egbert. Manufacture and Testing of Cold Rolled Steel, F. W. Shaefer.	
Philadelphia Section .....	55
Modern Painting Practices on Structural Material, George B. Heckel. The Chemistry of Glass Making, Alexander Silverman.	
Detroit Section .....	56
The Chemical Composition of Steel in Relation to its Industrial Uses, Jos. N. Bourg.	
Western New York Section .....	56
Manufacture of Ice Cream, Harry F. Lichtenberg. The Chemistry of Photography, F. C. Frary.	
Oregon Section .....	56
The Synthesis of Metals, A. A. Knowlton.	
New Haven Section .....	56
On the Synthesis of Pyrimidine—Rosaniline Dyes, T. B. Johnson. On the Metallic Gallium and Some Gallium Reactions, P. E. Browning. The Effect of Freezing Precipitated Inorganic Colloids, Blair Saxton. An Apparatus for Determining Freezing-Point Lowering, R. G. Van Name and F. G. Brown.	
Maryland Section .....	56
By-Product Coke Oven Operation, B. W. Winship.	
Wisconsin Section .....	56
The Electron Theory, M. Mason.	
Lexington Section .....	56
Investigations on the Abderhalden Test for Pregnancy, W. S. Anderson. The Duties of the United States Assay Commission, F. E. Tuttle. Some Queer Colloidal Precipitations, C. A. Nash.	
Maine Section .....	56
Control of Sulfite Digestion by Titration Methods, A. G. Durgin. The Purchase Heat, A. B. Andrews. The Pulp and Paper Industry, R. H. McKee.	
Deceased Members .....	56

## May.

Council .....	57
Members elected between March 15 and April 15, 1916 .....	57
Meetings of the Sections:	
Chicago Section .....	61
Practical Vapor Pressures and Distillation, M. A. Rosanoff.	
Lexington Section .....	61
Note on the Occurrence of Gallium, R. N. Maxson. A Recent Discovery with Reference to the Bang Bacillus, E. S. Good. The Separation and Estimation of Polysulfids and Thiosulfate in Lime-Sulfur Solution, S. D. Averitt.	

Washington Section.....	61
A Practical Demonstration of Some of the Principles of Colloidal Chemistry, John Uri Lloyd.	
Minnesota Section.....	62
The Factors Influencing the Occurrence of HCN in Plants, J. J. Willaman. The Reimer-Tiemann Reaction, W. H. Hunter.	
Southern California Section.....	62
The Bunsen Flame in Old and New Light, Wilhelm Hirschkind.	
Rhode Island Section.....	62
The Bacterial Treatment of Textile Fibers, F. P. Gorham.	
University of Illinois Section.....	62
The Raw Material of Varnish, C. T. Bragg.	
Louisiana Section.....	62
On the Determination of Diastatic Power in Wheat Flour, M. A. Schneller. The Influence of Phosphates on Alcoholic Fermentation, Wm. L. Owen. Dis- cussion of the By-Products of Rice Milling, F. W. Liepsner.	
Puget Sound Section.....	62
Opportunities for Electrochemical Industries, C. E. Bogardus. Bleaching Powder Costs, Hainsworth. Artificial Abrasives, J. Daniels. The Produc- tion of Alkalies and Salts from Sea Water, H. L. Trumbull.	
South Carolina Section.....	62
Abstract, Report of Referee Nitrogen Determination, R. N. Brackett. Calomel Standard Cell, and the Various Thermodynamic and Thermochem- ical Relations Occurring in the Cell, C. F. Lipscomb. Gravitation, J. E. Mills. A Note upon Methods for Determining Acidity in Soils, C. J. King. The Relation of the State Laboratories to the Commercial Chemist, Boyden Nims.	
University of Missouri Section.....	63
The Methods of Radium Extraction from Carnotite Ore Used by the Na- tional Institute at Denver, Colo., Herman Schlundt.	
Oregon Section.....	63
Sulfur and Soil Acidity, Two Important Factors in the Fertility of Soils, H. V. Tartar.	
Connecticut Valley Section.....	63
Manufacture of Celluloid, Herbert E. Nims. Some Analyses of Rocks from the Islands of the Pacific, E. W. Morley. Browning of Gun Barrels, C. F. Wessell.	
University of Michigan Section.....	63
Negative Osmose, F. E. Bartell.	
Maryland Section.....	63
Coal Gas Residuals (illustrated), Frederick H. Wagner.	
Cleveland Section.....	63
The Microscope and Its Accessories, L. B. Hall.	
Cincinnati Section.....	63
The History, Characteristics and Methods of Manufacture of Modern Explosives, M. F. Lindsley.	
Iowa Section.....	63
A Plant for the Manufacture of Synthetic Phenol, Harry McCormack.	
Virginia Section.....	63
Some Chemical Classics, Garnett Ryland. Some Phenomena of Lightning and Lightning Prevention, R. E. Loving. The Relation of Research to Everyday Life, J. B. Weens.	

Rochester Section.....	64
The Character, Cost and Adulteration of Foods, A. P. Sy. Velocity of Heterogeneous Reaction with Especial Reference to Catalysis, Irving Langmuir. The Organization of Industrial Research, C. E. Kenneth Mees.	
Syracuse Section.....	64
Some Problems in Agricultural Chemistry, G. W. Cavanaugh. The Decennial of Electric Steel in America, G. M. Berry.	
Pittsburgh Section.....	64
Thermal Reactions among Hydrocarbons at High Temperatures, W. F. Rittman. The Corrosion Resistance of Copper Steel, D. M. Buck and J. O. Handy.	
Joseph Priestly, F. C. Phillips. The Extraction of Radium from its Ores, Charles Parsons.	
California Section.....	64
Some General System of Acids and Bases, Merle Randall.	
Deceased Members.....	64

## June.

General Meeting.....	65
Directors' Meeting.....	68
Council.....	69
Minutes of the Council Meeting.....	69
Report of the Committee on the Western Campaign and Mr. Lewis B. Allyn's Connection Therewith.....	72
Members elected between April 15 and May 15, 1916.....	80
Meetings of the Sections:	
Alabama Section.....	82
The Role of the Chemist in the Cement Industry, Clarence N. Wiley. Isotopic Elements, Stewart J. Lloyd.	
South Dakota Section.....	82
The Free Energy of Dilution of Sulfuric Acid, Orville E. Cushman and Merle Randall. A Study of Canned Salmon (a preliminary note), Cecil Clemens and Sylvanna Elliott. A Modified Scheme for Qualitative Analysis, O. R. Overman. The Nitro Phenyl Ethers, Hilton Ira Jones and Alfred N. Cook. Some Subjects under Investigation in the Chemical Laboratories of the University of South Dakota, Alfred N. Cook.	
Milwaukee Section.....	83
Metallography of Iron and Steel (illustrated), C. J. Atkinson. Through the Furnace to the Farm, H. E. Horton.	
Northern Intermountain Section.....	83
Two Methods for the Separation of the Alkaline Earth Group, Alice G. Paterson. Recent Advances in Ore-Dressing, R. R. Goodrich. Composition and Baking Value of Dry Farmed and Irrigated Wheat, J. S. Jones. Electric Laboratory Heating Device, Harry Redekey Rupert.	
Indiana Section.....	83
Chemistry as an Aid to the Efficiency of Democracy, Chas. H. Herty. Detection of Nickel and Cobalt Salts, A. R. Middleton. Nonprotein Forms of Nitrogen in Alfalfa, R. H. Carr. Electromotive-Force Measurements with Tenth Normal Hydrochloric Acid and Calomel Electrodes, N. E. Loomis.	

Columbus Section.....	83
Rate of Absorption of $\text{CO}_2$ by Soda-lime, C. W. Foulk. Determination of Transition Points by Difference of Potential Methods, I. M. Geiger.	
California Section.....	84
Borax and its Uses, T. M. Cramer. The Chemistry of Copper Ore Enrichment, S. W. Young. Methods by which the Civilian Engineers Can Prepare Themselves to Assist the Engineer Corps of the U. S. Army in Case of War, Richard Park. The Work at the Military Training Camps, John Murphy. An Outline of the Work of the Organization for Industrial Preparedness of the Naval Consulting Board, A. H. Babcock.	
Pittsburgh Section.....	84
Constitution of Porcelains, A. A. Klein.	
St. Louis Section.....	84
Modern Methods in the Manufacture of Steel Castings, W. C. Hamilton. The Biological Chemistry of the Colon Group, Frederick A. Baldwin.	
North Carolina Section.....	84
The Action of Ammonia on Arsenic Iodide, Chas. H. Herty and C. B. Carter. Some Properties of the Solutions of Substantive Cotton Dyes, F. E. Carruth. Electrolysis of Certain Inorganic Salts in Liquid Ammonia Solution, C. F. Miller. The Chemistry of Gossypol, W. A. Withers and F. E. Carruth.	
Iowa Section.....	85
Electromotive Forces and Electrode Potentials in Pure and Mixed Solvents, II, F. S. Mortimore and J. N. Pearce. Barium in Tobacco, Nicholas Knight. Pure Sodium Chloride, Nicholas Knight. Acid Potassium and Sodium Phthalates as Standards in Acidimetry and Alkalimetry (Second Paper), W. S. Hendrixson. Auxamylases, E. W. Rockwood. Conditions Existing in Solutions near the Critical Temperature (a preliminary paper), P. A. Bond. A Comparison of Barbituric Acid, Thiobarbituric Acid and Malonylguanidine as Qualitative Precipitants for Furfural, A. W. Dox and G. P. Plaisance. An Aeration Method for Determining Alcohol in Fermentation Mixtures, A. W. Dox and A. R. Lamb. Relative Influence of Bacteria and Enzymes on Silage Fermentation (preliminary report), A. R. Lamb. Estimation of Calcium in Ash of Forage Plants and Animal Carcasses, S. B. Kuzirian.	
Wisconsin Section.....	85
Some Characteristics of Base Metal Thermocouples, O. L. Kowalke. The Theory of Distillation, M. A. Rosanoff.	
Rochester Section.....	85
The Development of Calorimetry, W. R. White. The Mercurial Thermometer and its Adaption to Industrial Arts, H. Y. Norwood.	
Louisiana Section.....	85
A Preliminary Report on Raw Materials Available for Certain Louisiana Chemical Industries, by the Committee on Resources, Chas. E. Coates.	
University of Michigan Section.....	86
Some Relationships between Ionization and Structure in Unsaturated Acids, Oliver Kamm.	
New Haven Section.....	86
The Experimental Methods of the Badische Anilin and Soda Fabrik, B. C. Hesse.	
Detroit Section.....	86

The Rare Gases, H. P. Talbot. Modern Facts on Cider Vinegar, Floyd W. Robison.	
Syracuse Section.....	86
The Flow of Heat through Furnace Walls. Radiation of Heat from Furnaces. Proper Materials to be Used in the Making of Mortar for Use in Furnaces, J. W. Richard.	
Chicago Section.....	86
New York Section.....	86
University and Industry, William H. Nichols.	
Eastern New York Section.....	86
The Mendelian Theory of Heredity and the Determination of Sex (illustrated), H. B. Goodrich. Calorimetry: The Development of Calorimetry, W. P. White.	
Western New York Section.....	87
Hydrofluoric Acid and Fluorides, K. F. Stahl. The Common Refractory Oxides, Robert B. Sosman.	
Philadelphia Section.....	87
The Manufacture of Vaccines and Serums, C. W. Brown.	
Lexington Section.....	87
Note on the Occurrence of Gallium, R. N. Maxson. The Growth of Isolated Plant Embryos, G. D. Buckner. On the Reaction between Iodine and Tetrathionate, P. L. Blumenthal.	
Cleveland Section.....	87
The Relations in Origin and Composition of Coal, Petroleum and the Natural Asphalts, C. F. Mabery.	
Washington Section.....	87
The Preparation of Heavy Metal Salts of Certain Organic Acids, C. N. Myers. Some Observations upon the Toxicity and Chemotherapy of the Heavy Metals, G. C. Lake. The Separation and Determination of Small Amounts of Antimony, Elias Elvove.	
Oregon Section.....	87

## GENERAL SOCIETY MINUTES AND REPORTS.

On November 1st, a nominating ballot was sent to all members of the Society as required by the Constitution, the following being the nominees of the membership sent to the Council for election:

For President: C. H. Herty, Julius Stieglitz, Louis Kahlenberg and L. H. Baekeland.

For Councilors-at-Large: W. D. Bigelow G. N. Lewis, F. N. Smalley, Geo. D. Rosengarten, Edward Bartow, L. W. Jones, Wm. Brady, B. C. Hesse.

The ballot was counted by a committee consisting of C. L. Parsons, J. A. LeClerc, and John Johnston, assisted by seven other members of the Society.

The result of the election by the Council will be found in the Council minutes.

### Report of the Secretary of the American Chemical Society for the Year 1915.

The growth of the American Chemical Society during the year 1915 was greatly affected by the foreign war. However, our membership has increased over that of 1914. The Society has made a net gain of 247 members during the year. The membership of the Society at the end of 1914 was 7170. It is now 7417. Statistics follow:

Honorary members	15
Life members.	13
Corporation members	57
Members	7,332
Total	7,417

During the year the deaths of the following members were reported to the Secretary: R. E. Berger, Cleveland, Ohio; R. K. Birley, East Orange, N. J.; John M. Davison, Santa Barbara, Calif.; Dr. F. Eckhardt, Grasselli, N. J.; J. S. Wm Greth, Pittsburgh, Pa.; Chas. M. Hall, Niagara Falls, N. Y.; S. H. Hartig, Pittsburgh, Pa.; John K. Hamilton, Pittsburgh, Pa.; J. Langeloth, N. Y. City; D. W. Lewis, Cleveland, O.; Robt. L. Maury, Saranac Lake, N. Y.; N. Frederick Merrill, Burlington, Vermont; Gail Mersereau, Brooklyn, N. Y.; Hugh Allan Murta, Man., Canada; H. H. McGregor, Cleveland, Ohio; J. U. Nef, Chicago, Ill.; J. H. Pettit, Urbana, Ill.; Albert Plaut, N. Y. City; Howard E. Reid, Siegfried, Pa.; J. Roemer, White Plains, N. Y.; Elwood D. Rood, Enid, Oklahoma; David Stern, Cincinnati, Ohio; W. M. Stiles, Long Island

City, N. Y.; Richard Sommer, Milwaukee, Wis.; F. W. Spanutius, Hastings-on-Hudson, N. Y.; T. B. Stillman, Jersey City, N. J.; Wirt Tassin, Washington, D. C.; Henry L. Wheeler, Hartford, Conn.; Chas. N. White, Wilmington, Del.; James G. Woolworth, Providence, R. I.; C. W. Wright, Rock Island, Ill.

The number of members not in arrears registered in the Local Sections on November 30, 1914, was 5,414; the number on November 30, 1915, was 5,527. The number in each Section for 1914 and 1915 is noted below:

Local section.	Number of paid mem- bers, 1914.	Number of paid mem- bers, 1915.	Cash retained from balance, 1914.	Total Dr. account, 1915.

	5,419	5,527	\$544.48	\$4,511.51

The table gives a summary of the sectional accounts for the year, shows the number of members in each Section for the present year and during 1914, the funds held over from 1914 account, and the total funds (which include the balances) charged to the 1915 account.

During the past two fiscal years, December 1, 1913, to November 30, 1915, the Secretary has made collections to the amount of \$76,805.97 in 1914 and \$80,189.22 in 1915, as follows:

	1914.	1915.
Membership dues.....	\$65,953.00	\$67,846.00
Subscriptions.....	5,761.59	6,676.32
Back numbers.....	2,514.07	2,548.63
Postage.....	1,054.13	1,084.07
Reprints.....	930.10	1,541.57
Exchange.....	19.44	17.36
Interest.....	373.64	475.27
Life membership.....	200.00	...
	<hr/> \$76,805.97	<hr/> \$80,189.22

These amounts were duly transmitted to the Treasurer of the Society.

Subscription and the sale of back numbers during the past year have again increased.

Several complete sets of our Journal have been sold to foreign and domestic libraries and several incomplete sets have been completed by the purchase of odd volumes where they could not be furnished from stock. The stock has been kept in good condition by the purchase of numbers needed to complete full volumes and by reprinting two small numbers issued in the early years of the Society. A few complete sets are still available for sale.

Back numbers are mailed direct from Easton, Pennsylvania, on orders sent out through the Secretary's Office. The following is a summary of the back numbers sent out by the Secretary during the year, together with the present stock of Journals and the condition of the Society's mailing lists:

Copies of the Society's publications sent out from December 1, 1914, to November 30, 1915, aside from mailing lists.....		28,721
Copies of the <i>Jour. Amer. Chem. Soc.</i> in stock.....		27,849
Copies of the <i>Chemical Abstracts</i> in stock.....		27,200
Copies of the <i>Jour. Ind. &amp; Eng. Chem.</i> in stock.....		8,976
Copies of the General Index, Vols. 1-20, <i>J. A. C. S.</i> in stock....		444
Copies of the Anniversary Number in stock.....		276
Mailing list for both Journals and <i>Chemical Abstracts</i> .....		6,779
Mailing list for <i>Chemical Abstracts</i> only.....		245
Mailing list for <i>Jour. Amer. Chem. Soc.</i> only.....		487
Mailing list for <i>Jour. Ind. &amp; Eng. Chem.</i> only.....		550

The Secretary wishes again to express to the members of the Society his appreciation for their continued assistance and loyal support of his efforts to administer the duties of his office. Without this aid little could have been accomplished. Respectfully submitted,

CHARLES L. PARSONS, *Secretary.*

### Report of the Editor of the Journal of the American Chemical Society for the Year 1915.

During the past three years papers and book reviews have been published as follows:

	Pages.			Number of papers.		
	1913.	1914.	1915.	1913.	1914.	1915.
Proceedings.....	114	112	96	...	...	...
Physical and Inorganic.....	1029	1154	1512	107	115	169
Organic and Biological.....	918	1320	1233	111	136	147
Book Reviews.....	75	80	43	85	83	52

Six papers have been referred to the Editor of the *Journal of Industrial and Engineering Chemistry* as more suitable for publication in that Journal than in the JOURNAL OF THE AMERICAN CHEMICAL SOCIETY, forty-two papers have been returned to the authors for revision, or because they were not considered suitable for publication, thirty-nine papers have been published after revision made at the suggestion of the Board of Editors.

The increase in the numbers of papers published has been greater than the increase of the previous year, but the increase in the number of pages has been considerably less. This is because the Board of Editors have found it necessary to insist upon a concise form for papers which are to be published.

The circulation of the JOURNAL for December, 1915, was 7270 copies. With the exception of our own *Journal of Industrial and Engineering Chemistry* we know of no other journal in the world, publishing original articles in chemistry, that has a circulation over 5000 and, so far as we are informed, no other journal which publishes such articles in America has one-tenth of the circulation of our journals. In the light of these facts it is evident that our journals furnish the only means by which an

author can reach any large proportion of the chemists of the country. It has always been our policy to publish all suitable articles which are submitted to us. The relation which our journals has to the chemists of the country lays upon us a strong obligation to do this.

It is evident that we can continue this policy, however, only by the most careful scrutiny of all papers with a view to possible abbreviation. We wish to urge authors, most earnestly, to keep this in mind in preparing their papers. Unless it is necessary for the purpose of securing priority, no paper should be published until the experimental work of which it treats is brought as nearly as possible to a satisfactory conclusion. We cannot well afford space for half-finished or inaccurate work. Historical references should be very brief and should consist largely of references to the literature. All tables should be put into a form which will occupy the least possible space in printing. Authors should also consider carefully just how much of their original data is really essential for the information of future workers in the same field. In many cases averages are better than the complete data, and constants which result from a series of observations may be given without complete data, if they are accompanied by a careful statement of the degree of concordance which has been obtained.

In many cases members of our Board of Editors, who, it will be remembered, serve without any compensation, spend a good deal of time in preparing careful, detailed criticisms of papers with a view to their improvement before publication. We wish here to express our appreciation of the kindly way in which most authors receive these criticisms. As one member of the Board has put it, "we would much rather accept a paper than to reject it, and we would also much rather publish a paper as it is received than insist on its abbreviation or revision."

WILLIAM A. NOYES, *Editor*.

### Report of the Editor of Chemical Abstracts for the Year 1915.

As was to be expected, the war in Europe has had a marked effect on *Chemical Abstracts* during the past year. Although the field has been covered as completely as in normal times, the number of abstracts published during 1915 (18,449) is only 75.8% of the average for the three preceding years (24,339), when claim was properly made that the journal closely approached completeness. In some cases delays in the appearance of abstracts have been necessary, due to difficulties in obtaining journals from the countries involved in the war.

The average length of the abstracts in the 1915 volume, as compared with those of previous years, is shown in the following table:

Year.		1907.	1908.	1909.	1910.	1911.	1912.	1913.	1914.	1915.
Page	Journal article ab-									
	stracts.....	0.324	0.270	0.224	0.223	0.205	0.183	0.173	0.180	0.207
	Patent abstracts..	not detd.		0.096	0.103	0.108	0.077	0.083	0.084	0.093

The need of fuller abstracts in many cases has long been felt; with the available space no longer inadequate this has been brought about, especially in the case of abstracts of papers appearing in the rarer journals and in the less generally read languages. Except in the few cases in which titles are obviously sufficient for all that is suited to *Chemical Abstracts*, the publication of title abstracts has been discontinued. A considerable increase has been made in the number of cuts used with abstracts, especially with patent abstracts. Descriptions of apparatus are often far from satisfactory without drawings.

Italian patents have been abstracted in 1915 for the first time. Italy is the only country of consequence not previously on the list of those whose patents are reviewed in *Chemical Abstracts*.

No. 24 of the 1915 volume contains, in addition to the title pages and author and subject indexes, a list of official abbreviations and a revised list of periodicals abstracted. The latter contains data concerning 671 periodicals, 17 having been added to the 1914 list. Special attention is called to this list as it has been demonstrated that many consider such a list very valuable. No numerical patent index was published in 1915. Suspicion that this index has been little used and that its publication at considerable cost is therefore not justified has been verified by a large amount of evidence gathered. Through the ready coöperation of the assistant editors and abstractors it has been possible to get into the 1915 volume the maximum number of abstracts of available papers, thus making the index very nearly a complete record of the period covered. In the case of joint author patents second and third authors have for the first time been entered as cross-references in the author index.

Preliminary measures have been taken, which it is hoped will lead to the publication of a ten-year index after the completion of the 1916 volume. The success of this project will have a decided influence on the future of the journal. It merits the support of every member of the Society.

The editor can have no words of commendation too cordial for the large amount of excellent work so unselfishly done by the assistant editors and abstractors. The success of the journal depends largely on the assistance rendered by these men. Much credit is due to the office force and the printers for their faithful work all through the year and particularly on the index, the preparation, checking and printing of which is a strenuous task for all. Miss Mary E. Kline, who has had considerable graduate training in chemistry, has taken up the indexing work formerly done by Miss Laura G. Collison. Circumstances have taken Miss Collison from us after five years of creditable service.

Statistics for the separate departments for 1915 are:

	No. pages.	No. abstracts.

### Report of the Editor of the Journal of Industrial and Engineering Chemistry for the Year 1915.

We have produced during the past year 94,900 copies of the *Industrial Journal*. The printing has been divided as follows: 1112 pages of editorial matter equivalent to  $92\frac{2}{3}$  pages per month, and 712 pages of advertising matter, equivalent to  $59\frac{1}{3}$  pages per month. The editorial matter, together with a comparison of this work in previous years, may be summarized as follows:

	1911.	1912.	1913.	1914.	1915.
Pages in editorial section:.....	970	946	1052	1066	1112

The additional material for the 1915 volume is made up of Scientific Society reports, Notes and Correspondence, abstracts from Government reports, Personals and general matter.

Respectfully submitted,

M. C. WHITAKER.

## MINUTES OF THE DIRECTORS MEETING.

December 11, 1915.

The Directors of the American Chemical Society met at the Chemists' Club, New York City, on Saturday, December 11, 1915, with President Herty in the chair and all Directors present.

A communication having been received from Congressman Albert Johnson regarding the use of the centigrade scale of temperature measurement in the United States Government publications, the following resolution was passed:

"Resolved, that the Directors of the American Chemical Society are unanimously in favor of the bill presented by Hon. Albert Johnson for the adoption of the centigrade scale of temperature measurement in the United States Government publications, with the understanding that for such time as may be deemed necessary the equivalent temperature in the Fahrenheit scale may follow in parenthesis where the various bureaus concerned deem such inclusion wise."

The Directors voted to sell a microscope and accessories belonging to the Society for the sum of \$15.00, offered by Mr. Buswell through Professor Alexander Smith.

It was voted that \$11.62 be appropriated to the Ames Section, recently authorized by the Council, for their 1915 expenses.

It was voted that \$176.43 be transferred from such funds already appropriated as are still available to cover deficit in the budget of the *Journal of the American Chemical Society*.

It was voted to transfer \$241.10 from the *Chemical Abstracts* budget to cover a deficit of like amount in the *Journal of Industrial and Engineering Chemistry*.

It was voted that in the future the Finance Committee be authorized

to approve all bills in excess of the budget where the bill is a matter of contractual obligation.

It was voted that the Finance Committee, acting with the consent of the President, be authorized to make temporary loans of the general funds of the Society to such fiduciary institutions as may be approved by them.

It was voted that the action of the Finance Committee and the President in reinvesting \$2,000.00 of the Society's funds in New York City bonds 4 $\frac{1}{2}$ %—1965—be approved. The question of reinvesting funds of the Society now invested in Brooklyn Rapid Transit was left to the Finance Committee and President with power.

It was voted that the Finance Committee and President be authorized and instructed to invest \$5,000 from the general funds of the Society in interest-bearing securities approved by them.

The Treasurer's report was received and approved subject to audit.

It was unanimously voted (Dr. Love not voting) to pay \$500 per year salary to the Chairman of the Finance Committee.

In reply to a communication from the Editor of the *Journal of Industrial and Engineering Chemistry* regarding the editorial policy of that Journal, it was voted that the Secretary be instructed to inform the Editor of the *Journal of Industrial and Engineering Chemistry* that the Directors would be glad if he and his board of editors would consider the whole matter of editorial policy at the next general meeting of the American Chemical Society and recommend such action to the Board of Directors as they deem wise.

It was voted that hereafter railroad transportation, sleeper, and meals en route of Directors attending Board of Directors' meetings, other than those held at general meetings of the Society, be paid from Society funds.

It was voted that \$250.00 be appropriated from the general funds of the Society for the expenses of the Committee on coöperation with the United States Government regarding the collating of statistics of foreign commerce in chemicals.

It was voted that the Secretary be directed to request from the Board of Trustees of The Chemists' Club information regarding the expenditure of the income from the Morris Loeb fund already paid to them, and to request a statement regarding their future plans for the Morris Loeb Chemical Type Museum.

By motion of Director Brady it was voted to lay upon the table the proposition of Mr. A. V. Main, which had been presented to the Directors through him.

The following budget for 1916 was then adopted:

## ESTIMATED RECEIPTS.

	1915.	1916.
Secretary's office.....	\$ 76,000	\$ 80,000
Advertisements.....	24,000	26,000
Interest.....	1,200	1,700
	<hr/> \$101,200	<hr/> \$107,700

## ESTIMATED EXPENDITURES.

*Journal of the American Chemical Society:*

	1915.	1916.
Editor's salary.....	\$ 1,000	\$ 1,000
Expenses, including reviews.....	600	560
Printing, including reprints.....	15,400	17,600
Total.....	<hr/> \$ 17,000	<hr/> \$ 19,160

*Chemical Abstracts:*

Editor's salary.....	\$ 1,800	\$ 2,000
Associate editors' salary.....	1,200	1,400
Clerical assistance.....	3,000	2,750
Expenses.....	600	700
Abstractors and department heads.....	8,720	7,550
Printing, including index.....	24,800	21,500
Total.....	<hr/> \$ 40,120	<hr/> \$ 35,900

*Journal of Industrial and Engineering Chemistry:*

Editor's salary.....	\$ 1,000	\$ 1,000
Assistant editors' salaries.....	2,590	2,900
Clerical and office expenses.....	2,100	3,100
Printing, editorial.....	12,400	15,750
Printing, advertisements.....	6,000	7,000
Total.....	<hr/> \$ 24,090	<hr/> \$ 29,750

Advertising manager..... 6,000 6,500

Finance committee, chairman..... 500

*Secretary's office:*

Collection commissions.....	\$ 3,500	\$ 3,500
Expense.....	1,700	1,700
Clerical.....	2,700	2,900

*President's office:*..... 100 .....

*Treasurer's office:*

Salary.....	300	500
Expense.....	400	400
Local sections.....	3,800	4,000
General meetings.....	1,200	1,000
Incidentals.....	800	1,200
Back numbers.....	800	850
Life membership.....	130	.....
Directory.....	.....	500

Total..... \$ 21,430 \$ 23,550

Grand total..... \$102,640 \$108,360

CHARLES L. PARSONS, *Secretary.*

## COUNCIL.

On November 1, a nominating ballot for Directors was sent to the Council, the following being the four leading nominees, which, according to the Constitution, were sent to the Council again for the selection of two:

W. D. Bigelow, W. R. Whitney, Geo. B. Frankforter, A. L. Day.

This ballot was counted by a committee consisting of C. L. Parsons, J. A. LeClerc, and John Johnston.

On November 30 these nominees were sent to the Council, and also the nominees for President and Councilors-at-Large as selected by the membership. (See Proceedings, page 1.) As a result of this ballot, the following officers were elected:

*President:* Charles H. Herty, for the term January 1, 1916, to December 31, 1917.

*Directors:* W. R. Whitney and W. D. Bigelow, for the term January 1, 1916, to December 31, 1918.

*Councilors-at-Large:* George D. Rosengarten, W. D. Bigelow, B. C. Hesse and G. N. Lewis, for the term January 1, 1916, to December 31, 1918. This ballot was counted by a committee consisting of A. L. Day, John Johnston and Charles L. Parsons. CHARLES L. PARSONS, *Secretary*.

### MEMBERS ELECTED BETWEEN NOVEMBER 15 AND DECEMBER 15, 1915.

- Abbott, J. T., 1408 Emerson St., N. W., Washington, D. C.
- Abramovitz, H. L., 450 S. Rebecca St., Pittsburgh, Pa.
- Adams, C. M., c/o Imperial Sugar Co., Sugar Land, Texas.
- Adelson, Louis S., 53 Clarke Ave., Far Rockaway. L. I., N. Y.
- Apmann, Arthur M., 68 Wayne St., Jersey City, N. J.
- Atwood, F. Clarke, 316 Huntington Ave., Boston, Mass.
- Bakke, Oliver Mathias, 209 $\frac{1}{2}$  Lane St., Dallas, Texas.
- Bakken, H. E., 301 Third St., N. E., Little Falls, Minn.
- Banbury, F. H., 577 Central Ave., Orange, N. J.
- Bardorf, Charles F., St. Lawrence Sugar Refineries, Ltd., Maisonneuve, P. Q., Canada.
- Beaver, David J., 310 Victory Ave., Schenectady, N. Y.
- Beecher, Ward, R. F. D. No. 2, Youngstown, Ohio.
- Behr, Alexander W., c/o Russian American Chamber of Commerce, Mjasnitsky Proesd 2, Moscow, Russia.
- Beneker, J. C., Pacific Coast Steel Co., Youngstown Station, Seattle, Wash.
- Bnags, Arvid H., 206 W. Green St., Smethport, Pa.
- Bennett, Charles S., 607 S. Hill St., Los Angeles, Calif.
- Bertolet, Elmer C., 633 Belgrade St., Philadelphia, Pa.
- Bigelow, Charles A., c/o Aetna Explosives Co. Inc., 2 Rector St., New York City.
- Bird, Jr., Charles S., East Walpole, Mass.
- Boehringer, Dr. Rudolph, 112 Second Ave., Newark, N. J.
- Brandon, Harry M., 5 Elizabeth St., Dover, N. J.
- Brewster, G. A., Parkview, Edgemont St., East St. Louis, Ill.
- Brown, Eugene P., 1009 Wertland St., University, Va.
- Brown, Philip, 615 W. Onondaga St., Syracuse, N. Y.

- Brown, Walter J., 290 Rutland Road, Brooklyn, N. Y.  
 Bryan, C. L., Virginia-Carolina Chemical Co., Richmond, Va.  
 Bullens, D. K., Frankford, Philadelphia, Pa.  
 Byers, Louis L., Abrasive Material Co., Bridesburg, Philadelphia, Pa.  
 Campbell, Robert, Nairn Linoleum Co., Newark, N. J.  
 Campbell, Summer E., 670 Highland Ave., Newark, N. J.  
 Carlisle, Paul J., 213 S. Marina St., Prescott, Arizona.  
 Cathcart, Paul H., National Cannery Association, Washington, D. C.  
 Catlett, Richard H., 44 The Fenway, Boston, Mass.  
 Chebotaref, Leo P., Standard Aniline Products Co., Wappinger Falls, N. Y.  
 Clinton, Guy, College of Agriculture, Los Banos, P. I.  
 Collins, Grellet, N., 4111 Walnut St., Philadelphia, Pa.  
 Condit, Percy H., 38 Hamilton St., East Orange, N. J.  
 Coolidge, Walter H., Box 641, Georgetown, Ky.  
 Coyne, James Kitchenman, 2037 North Broad St., Philadelphia, Pa.  
 Currie, William E., 211 14th St., University, Va.  
 Davies, Earle L., 35 Adams St., Akron, Ohio.  
 Davis, R. F., El Segundo, Calif.  
 Davis, Ralph W., 320 Seventeenth Ave., Homestead, Pa.  
 Deterding, Henry C., Crampton Hall, Illinois College, Jacksonville, Ill.  
 Dinsmore, Ray P., 22 So. Maple St., Akron, Ohio.  
 Dixon, Frederick W., 409 Pine St., Jamestown, N. Y.  
 Dodds, Eugene H., 311 So. Ridgeland Ave., Oak Park, Ill.  
 Downing, George Valentine, Elsmere, Del.  
 Downing, R. C., 30 W. 70th Place, Chicago, Ill.  
 Dubbs, C. P., 1743 Wesley Ave., Evanston, Ill.  
 Dunphy, Raymond A., Mellon Institute, Pittsburgh, Pa.  
 Durham, Charles, 2912 Prairie Ave., Chicago, Ill.  
 Ellinger, Louis J., 11 East 68th St., New York City.  
 Engles, Charles Robert, 3320 W. Huntingdon St., Philadelphia, Pa.  
 Essex, Harry, Mellon Institute, Pittsburgh, Pa.  
 Fay, Thornwell, c/o Union Sulphur Company, Sulphur, La.  
 Fisher, Harry H., Ridley Park, Pa.  
 Fosgate, Neal R., 419 Pearl St., Burlington, Vt.  
 Foster, Goodwin L., Sharon, Mass.  
 Fowler, Edward J., c/o Pacific Foundry Co., 18th and Harrison Sts., San Francisco, Calif.  
 Frazier, Thos. A., 1302 Sheffield St., Pittsburgh, Pa.  
 Frusher, Tom, 60 Federal St., Boston, Mass.  
 Fry, J. M., 262 Dixon Place, Akron, Ohio.  
 Gahl, Rudolf, Inspiration Consolidated Copper Co., Globe, Ariz.  
 Gailey, Andrew J., 2112 Federal St., Philadelphia, Pa.  
 Gallagher, J. A., North Wilmington, Mass.  
 Gallup, Wm. Arthur, North Adams, Mass.  
 Geist, H. H., 604 N. 3rd St., Pottsville, Pa.  
 Githens, Frank Weeder, c/o Penn. Wire Glass Co., Dunbar, Pa.  
 Goerner, Alfred, 542 Kosciusko St., Brooklyn, N. Y.  
 Goldsmith, C. H., Orono, Maine.  
 Grantham, R. I., c/o Sharpe & Dohme, Baltimore, Md.  
 Gubelmann, Dr. Ivan, 1800 S. Second St., St. Louis, Mo.  
 Hammett, Louis P., Hollis 24, Cambridge, Mass.

## MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505, Washington, D. C.]

### LEXINGTON SECTION.

The 26th regular meeting was held November 22. Program: "The Effect of the European War on Drug Supplies," by L. A. Brown; "The Stability of Silver Fulminate under Water," by A. M. Peter.

The December meeting was held December 8. Program: "The Translocation of the Mineral Constituents of Certain Seeds during Growth," by G. D. Buckner; "A Review of the Literature on the Distribution and

Sources of Iodine in Plant and Animal Life," by P. L. Blumenthal. The officers for 1916 were elected, as follows: C. A. Nash, *Chairman*; O. M. Shedd, *1st Vice-Chairman*; Mary Sweeny, *2nd Vice-Chairman*; P. L. Blumenthal, *Secretary-Treasurer*; F. E. Tuttle, *Councilor*.

LLOYD C. DANIELS, *Secretary*.

#### CHICAGO SECTION.

The regular meeting was held December 8. Program: "The Manufacture of Gasoline and Benzole Toluene from Petroleum and other Hydrocarbons," by Walter F. Rittman.

A special-memorial meeting was held in honor of Dr. John Ulric Nef, December 17. Dr. Lauder W. Jones spoke on "The Scientific Work Developed by Dr. Nef."

D. K. FRENCH, *Secretary*.

#### AMES SECTION.

The 2nd regular meeting was held December 2. Program: "Peculiarities in the Chemistry and Physics of Silicate Industries," by Homer F. Staley.

W. G. GARSSLER, *Secretary*.

#### MARYLAND SECTION.

At the regular meeting held November 13, the following officers were elected for 1916: C. P. Van Gundy, *Chairman*; E. E. Reid, *Vice-Chairman*; F. M. Boyles, *Secretary-Treasurer*; S. T. Powell, W. W. Randall, *Executive Committee*.

The 9th regular meeting was held December 11. Program: "Partition or Neutral Solubility," by E. E. Reid and B. B. Wroth; "Methods of Toxicological Examinations," W. B. D. Penniman.

FRANK M. BOYLES, *Secretary*.

#### LOUISIANA SECTION.

The 89th regular meeting was held November 19. Program: "Some Aspects of Illuminating Gas Manufacture," C. Hartogh; "Journal Reviews," Philip Asher.

The 90th regular meeting was held December 17. Program: "The Manufacture and Usages of White Lead," and "The Crime of Carelessness" (motion pictures).

F. W. LIEPSNER, *Secretary*.

#### WISCONSIN SECTION.

The November meeting was held November 17. Professor J. H. Walton, Jr., spoke on "The Influence of Impurities on the Rate of Growth of Ice Crystals."

The December meeting was held December 8. Professor R. A. Millikan, of the Physics Department of the University of Chicago, spoke on "The Nature of Radiant Energy."

The annual meeting was held December 10. The following officers were elected for 1916: E. V. McCollum, *Chairman*; P. W. Carleton, *Vice-*

*Chairman*; L. A. Augspurger, *Secretary*; E. Truog, *Treasurer*; R. Fischer, *Councilor*.

A. E. KOENIG, *Secretary*.

#### CINCINNATI SECTION.

At the meeting held November 10 the following officers were elected for 1916: C. Bahlmann, *President*; F. O. Clements, *1st Vice-President*; H. S. Fry, *2nd Vice-President*; E. K. Files, *Secretary-Treasurer*; L. W. Jones, *A. Campbell, Councilors*.

STEPHEN J. HAUSER, *Secretary*.

#### UNIVERSITY OF MICHIGAN SECTION.

The November meeting was held November 23. Program: "A Study of the Hydrochloric Acid Concentration Cell with Respect to Activity and Concentration, Boundary Potential and Transparent Members," by A. L. Ferguson. The following officers were elected to serve for 1916: D. M. Lichty, *Chairman*; H. H. Willard, *Secretary-Treasurer*; W. J. Hale, *Councilor*; W. B. Peet, M. Gornberg, W. G. Smeaton, *Executive Committee*.

The December meeting was held December 9. Program: "Ferrotungsten as an Industry," by R. L. Sessions.

H. H. WILLARD, *Secretary*.

#### NEW YORK SECTION.

The regular meeting was held December 10, in conjunction with the American Electrochemical Society. Program: "University and Industry," Richard C. Maclaurin, Henry P. Talbot, William H. Walker, Arthur D. Little, all representing Massachusetts Institute of Technology; "The Naval Consulting Board of the United States," by L. H. Baekeland and W. R. Whitney. The following councilors were elected for 1916: Charles Baskerville, S. R. Church, B. C. Hesse, C. M. Joyce, T. B. Wagner, A. C. Langmuir, K. G. Mackenzie, J. M. Matthews, T. J. Parker, I. F. Stone, J. E. Teeple.

C. M. JOYCE, *Secretary*.

#### PUGET SOUND SECTION.

The following officers for 1916 were elected at the meeting held November 20: E. A. Dieterle, *Chairman*; Rex Smith, *Vice-Chairman*; H. L. Trumbull, *Secretary*; J. E. Bell, *Treasurer*; H. K. Benson, *Councilor*.

H. L. TRUMBULL, *Secretary*.

#### UNIVERSITY OF ILLINOIS SECTION.

The following officers for 1916 were elected at the meeting held November 15: W. A. Noyes, *Chairman*; John C. Hessler, *Vice-Chairman*; G. D. Beal, *Secretary*; B. S. Hopkins, *Treasurer*; E. W. Washburn, S. W. Parr, *Councilors*.

G. D. BEAL, *Secretary*.

#### NORTHEASTERN SECTION.

The regular meeting was held December 10. Program: "The Chemistry of Amorphous Solids," by Warren K. Lewis. The following officers were

elected for 1916: F. H. Thorp, *President*; C. L. Gagnebin, *Vice-President*; E. B. Spear, *Secretary*; H. C. Lythgoe, *Treasurer*; Roger Adams, F. Bonnet, Jr., G. J. Esselen, Jr., R. B. Earle, G. W. Harris, *Executive Committee*; Henry Fay, W. L. Jennings, Grinnell Jones, W. K. Robbins, H. P. Talbot, *Councilors*.

GRINNELL JONES, *Secretary*.

#### WESTERN NEW YORK SECTION.

A meeting was held December 8 in conjunction with the American Electrochemical Society. Program: "Electrons, Atoms, and Energy Quanta," by Dr. Saul Dushman.

RAY H. WHITE, *Secretary*.

#### CALIFORNIA SECTION.

The eighty-seventh regular meeting was held November 23. Program: "The Equilibrium of Oxidation Reactions," by Prof. Arthur A. Noyes; "Hydrocarbon Reactions at High Temperature," by Dr. Walter F. Rittman.

BRYANT S. DRAKE, *Secretary*.

#### OREGON SECTION.

The annual meeting was held November 27. Program: "Some Modern Views of Matter," by W. C. Morgan.

F. A. OLMSTEAD, *Secretary*.

#### DETROIT SECTION.

The regular meeting was held December 16. The program consisted of three papers as follows:

Wilbur L. Scoville, "Formaldehydized Capsules." Discussion led by C. H. Briggs, F. O. Taylor and L. B. Hayward.

Dr. Charles H. Oakman, "Dental Surgery." Discussions by Drs. Stephenson, Hayward and Clark.

John W. M. Bunker, "A Piece of Cheese." Discussions by Dr. Diack, F. O. Robison and H. C. Hamilton.

EDW. J. GUTSCH, *Secretary*.

#### MINNESOTA SECTION.

The Section met Nov. 19. Program: "The Nature of the Proteins Extracted from Wheat Flour by Various Processes," by Prof. C. H. Bailey; "Recent Advances in Chemo-therapy," by Dr. A. D. Hirschfelder.

The Section met December 17. Program: "Flavoring Extracts and Baking Powders," by Wm. Kennedy; "The Polymerization of China Wood Oil," by Carl Schuman; "The Swelling of Rubber in Organic Liquids," by I. H. Derby.

STERLING TEMPLE, *Secretary*.

#### SOUTHERN CALIFORNIA SECTION.

The regular meeting was held November 18. The paper of the evening was presented by Mr. L. H. Buck, Chemist for the City Dye Works, entitled, "Carbon Tetra-chlorid."

H. L. PAYNE, *Secretary*.

## NEW HAVEN SECTION.

The regular meeting was held December 10. Professor C. E.-A. Winslow, Anna M. R. Lauder Professor of Public Health in the Yale Medical School, delivered a lecture on the subject, "The Disposal of City Sewage."

GEORGE S. JAMIESON, *Secretary*.

## ROCHESTER SECTION.

The regular meeting was held December 6. Dr. Frank K. Cameron, Bureau of Soils, Dept. of Agriculture, Washington, D. C., gave a talk on "American Resources in Fertilizer Materials."

H. H. TOZIER, *Secretary*.

## WASHINGTON SECTION.

The Section held a special meeting December 8. The meeting was held through the courtesy of the National Rivers and Harbors Congress.

The 254th meeting of the Society was held December 16. Program: G. K. Burgess, of the Bureau of Standards, "Some Examples of Metal Failures" (illustrated); B. McCollum, of the Bureau of Standards, "Chemical Factors Affecting Electrolytic Corrosion in Soils and Reinforced Concrete;" R. B. Dole, of the Geological Survey, "The Action of Natural Waters on Boilers."

E. C. McKEEVER, *Secretary*.

## MILWAUKEE SECTION.

There was an extra meeting of the Engineers Society of Milwaukee held under the auspices of the Milwaukee Section of the American Chemical Society, December 3. Professor S. W. Parr, of the University of Illinois, delivered an illustrated talk on, "Development in the Marketing of Coal--Specifications, Storage, etc."

BEN L. SALOMON, *Secretary*.

## CLEVELAND SECTION.

The Section held its regular December meeting December 13. Dr. A. G. Worthing, of the Nela Research Laboratory of the General Electric Co., addressed the Society on, "The Electron Theory and Some of Its Applications."

A. F. O. GRIMMANN, *Secretary*.

## NEBRASKA SECTION.

The December meeting was held December 11. Chancellor Samuel Avery, of the University of Nebraska, gave an address on "Our National Chemical Industries." The following officers for 1916 were elected: F. W. Upson, *President*; J. S. Cutter, *Vice-President*; H. M. Plum, *Secretary-Treasurer*; Samuel Avery, *Councilor*; H. H. Hosford, Geo. Borrowman, C. A. Morrow, *Executive Committee*.

H. M. PLUM, *Secretary*.

## COLUMBUS SECTION.

The November meeting was held November 23. Professor W. L. Evans lectured on "The Life and Work of John Ulric Nef."

W. J. McCAUGHY, *Secretary*.

## PHILADELPHIA SECTION.

The regular meeting was held December 16. Program: "The Decomposition of Hydrocarbon Oils under High Temperatures and Pressures, and the Industrial Applications of the Process," by Dr. Walter F. Rittman.

C. S. BRINTON, *Secretary*.

## VIRGINIA SECTION.

The December meeting was held December 10. Through the courtesy of the faculty of Richmond College, the Section heard Prof. W. S. Franklin, of Columbia University, lecture on "Some Mechanical Analogies in Electricity and Magnetism."

W. A. BURROWS, *Secretary*.

## PITTSBURGH SECTION.

The 21st regular meeting was held November 18. Program: "Demonstration of a Portable Gas Detector," by G. A. Burrell; "The Mechanism of Corrosion," by James Aston; "The Manufacture of Refractories," by R. H. H. Pierce.

The 122nd regular meeting was held December 16. Program: "Hydrometallurgy of Copper," by Raymond F. Bacon; "The Removal of Iron from a Municipal Water Supply," by S. Buka.

W. C. COPE, *Secretary*.

## CONNECTICUT VALLEY SECTION.

The 36th regular meeting was held December 11. Program: "Smoking Opium in the United States," by H. L. Thompson; "The Rittman Gasoline Process," by E. C. Stone.

R. J. MARSH, *Secretary*.

## DECEASED MEMBERS.

Richard E. Berger, Cleveland, O. Died November 25, 1915.

Siegfried H. Hartig, Pittsburgh, Pa. Died November 15, 1915.

David W. Lewis, Cleveland, O. Died November 24, 1915.

James H. Pettit, Urbana, Ill. Died November, 1915.

Anton Vorisek, New York City. Died December 3, 1915.

# Proceedings.

## COUNCIL.

President Herty appointed Dr. Charles Baskerville to represent the A. C. S. on the Joseph H. Holmes Memorial Committee with Dr. S. S. Voorhees as alternate.

#### CORPORATION MEMBER.

Stresen-Reuter & Hancock, Inc., 1501 So. Peoria St., Chicago, Ill.

### MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505, Washington, D. C.]

#### EASTERN NEW YORK SECTION.

The 61st meeting was held December 30th. The subject for the meeting was "Disposal of Municipal Waste in Schenectady." Papers were presented, as follows: "Garbage Reduction," by Mr. W. W. Chadsey, Deputy Commissioner of Public Works; "Treatment of Sewage," by Mr. W. E. Weller, Deputy City Engineer. The following officers were elected for the ensuing year: *President*, W. C. Arsem; *Vice-President*, M. A. Hunter; *Secretary-Treasurer*, A. J. Salathe; *Councilor*, W. D. Coolidge; *Advisory Committee*, Dr. E. Ellery, Dr. G. R. Fonda, Dr. S. Dushman.

W. E. RUDER, *Secretary*.

#### CINCINNATI SECTION.

The Cincinnati Section of the American Chemical Society celebrated its Twenty-Fifth Anniversary on the evenings of December the twentieth and twenty-first. Dr. Thomas H. Norton gave an illustrated lecture on "The Trend of American Technical Chemistry."

The 202nd regular meeting was held January 12th. Dr. W. H. Frost gave an illustrated lecture entitled: "An Outline of Studies by the U. S. Public Health Service on the Pollution of the Ohio River."

E. K. FLEIS, *Secretary*.

#### INDIANA SECTION.

The regular meeting was held January 14th. Program: "Commercial Applications of Oxygen," by Mr. Philip J. Kroll.

H. W. RHODEMANTEL, *Secretary*.

#### WASHINGTON SECTION.

The Annual Meeting was held January 13th. Program: Address of President Alsberg, on "The Chemical Analysis of Animal Nutri-

tion." The following were elected officers of the local Section of the American Chemical Society for the year 1916: *President*, R. B. Sosman, of the Geophysical Laboratory; *First Vice-President*, H. M. Loomis, of the Bureau of Chemistry; *Second Vice-President*, A. Seidell, of the Hygienic Laboratory; *Secretary*, E. C. McKelvy, of the Bureau of Standards; *Treasurer*, F. P. Dewey, of the Bureau of Mint; *Councilors*, J. Johnston, of the Geophysical Laboratory; R. C. Wells, of the Geological Survey; C. S. Hudson, of the Bureau of Chemistry; *Executive Committee*, J. C. Hostetter, of the Geophysical Laboratory; E. C. Schorey, of the Bureau of Soils; A. N. Finn, of the Bureau of Standards; M. J. Ingle, of the Bureau of Chemistry.

E. C. MCKELVY, *Secretary*.

#### ROCHESTER SECTION.

The regular meeting was held December 20th. Dr. W. F. Rittman from the Bureau of Mines of the Dept. of the Interior, Pittsburgh, Pa., gave a talk on "Thermal Reactions among Hydrocarbons in a Single Phase System."

A meeting was held January 3rd. Mr. F. R. Baxter gave a talk on "Oils."

The regular meeting was held January 17th. Mr. M. H. Eisenhart gave a talk on "The Manufacture of Acids."

H. H. TOZIER, *Secretary*.

#### CONNECTICUT VALLEY SECTION.

The 37th regular meeting was held January 8th. Program: "Our Experience with Nickel Anodes," by C. H. Corbin; "Some Experiments in Making Electrolytic Copper Pipe," by C. F. Wessell; "Mechanical Plating and Polishing," by G. B. Hoogaboom.

R. J. MARSH, *Secretary*.

#### PHILADELPHIA SECTION.

At a meeting held December 16th, the following officers were elected and installed for the coming year: *Chairman*, Mr. C. S. Brinton; *Vice-Chairman*, Mr. J. A. Branegan; *Secretary-Treasurer*, Mr. J. H. Graham; *Members of the Executive Committee*, Dr. G. D. Rosengarten, Mr. W. G. Bower, Mr. C. C. Tutweiler; *Councilors*, Dr. W. T. Taggart, Mr. J. S. Goldbaum, Mr. G. E. Barton, Mr. E. F. Hicks.

C. S. BRINTON, *Secretary*.

#### PITTSBURGH SECTION.

The 122nd regular meeting was held December 16th. The following officers were elected for the year 1916: *Chairman*, K. F. Stahl; *Vice-Chairman*, C. H. Viol; *Secretary*, W. C. Cope; *Treasurer*, C. E. Nesbitt; *Councilors*, F. C. Phillips, R. F. Bacon, and A. C. Fieldner. Program: "The Hydrometallurgy of Copper," by Raymond F. Bacon; "The Removal of Iron from a Municipal Water Supply," by S. Buka.

W. C. COPE, *Secretary*.

## UNIVERSITY OF MISSOURI SECTION.

The 63rd meeting and annual election of officers was held December 16th. The following officers were elected: *President*, J. W. Marden; *Vice-President*, Miss L. Stanley; *Treasurer*, E. E. Vanatta; *Secretary*, H. L. Dahm; *Councilor*, H. Schlundt.

H. L. DAHM, *Secretary*.

## SOUTHERN CALIFORNIA SECTION.

The annual meeting was held December 16th. The following officers were elected for 1916: *President*, Erwin H. Miller; *Vice-President*, Elbert E. Chandler; *Secretary*, Henry L. Payne; *Treasurer*, John S. Carman; *Councilor*, Edgar S. Baruch. Program: "The Manufacture of the Illuminating Mantle," by M. N. Lando.

H. L. PAYNE, *Secretary*.

## AMES SECTION.

The third regular meeting was held January 20th. Program: "Compounds of Ammonia and Certain Metallic Salts," by Dr. G. J. Fink; "Is the Hydrochloric Acid of the Gastric Juice Efficient as a Germicide?" by Dr. C. C. Fowler.

W. G. GAEBLER, *Secretary*.

## COLUMBUS SECTION:

A joint meeting of the Columbus Section of the American Chemical Society and Section "C" of the American Association for the Advancement of Science was held December 31st. Program: "Some Interesting Physical and Chemical Properties of Clays" (illustrated by experiments), by Arthur S. Watts; "The Contributions of Chemistry to the Production and Preparation of Human Food," by John F. Lyman; "The American Chemist and the War's Problems," by James R. Withrow; "The Fertilizer Resources of the United States," by Frank K. Cameron, Washington, D. C.

WM. J. McCAGHEY, *Secretary*.

## ST. LOUIS SECTION.

A special meeting of the section was held on Monday evening, December 6th. Dr. Walter F. Rittman, of the United States Bureau of Mines, addressed the section on "The Gasoline Situation in America."

The annual meeting was held December 13th, at the American Hotel. The officers for 1916 were elected as follows: *Chairman*, Mr. A. C. Boylston; *Vice-Chairman*, Mr. Gaston DuBois; *Secretary*, Geo. Lang, Jr.; *Treasurer*, Mr. J. D. Robertson; *Councilor*, Dr. L. McMaster. Mr. Boylston presented a paper on "Some Relations Between Chemical Constitution and Physiological Action."

A meeting was held Monday, January 10th. Program: Dr. F. O. Anderegg, of the Mallinckrodt Chemical Works, presented a paper on "The Silver Coulometer."

GEO. LANG, JR., *Secretary*.

## VIRGINIA SECTION.

The annual meeting of the section was held Friday, January 14th. Program: Dr. Frank R. Elder read a paper on "Tannin." Dr. F. B. Carpenter reviewed the potash situation. Mr. A. M. Förrester discussed the sulfuric acid situation.

W. A. BURROWS, *Secretary*.

## NASHVILLE SECTION.

The 37th meeting was held January 21st. Program: "The Simultaneous Developing and Fixing of Photographic Plates," by Dr. James F. Norris.

VICTOR P. LEE, *Secretary*.

## CLEVELAND SECTION.

The January meeting was held January 10th. Professor M. F. Coolbaugh spoke on "Experiments on the Electrolysis of Cyanide Solutions."

A. F. O. GERMANN, *Secretary*.

## LEXINGTON SECTION.

The 29th regular meeting was held January 13th. Program: "Report on the Annual Convention of the Association of Official Agricultural Chemists, for 1915," by Wm. Rodes, Jr.; "Note on a Specimen of Ferric Phosphate from Laurel County, Kentucky," by Dr. A. M. Peter; "Chemical Changes Occurring during the Ripening of the Wild Goose Plum," by J. S. McHargue.

P. L. BLUMENTHAL, *Secretary*.

## WISCONSIN SECTION.

The January meeting was held January 12th. Professor A. S. Loevenhart spoke on "Some Experiments on Animal Oxidations."

L. F. AUGSPURGER, *Secretary*.

## NEW YORK SECTION.

In the January Proceedings (p. 17, under this section) it should have read, "in conjunction with the New York Sections of the Society of Chemical Industry and the American Electrochemical Society."

## MILWAUKEE SECTION.

At the meeting of the section on December 24th, the following officers were elected for the ensuing year: *Chairman*, R. N. Bauer; *Vice-Chairman*, C. B. Rickey; *Secretary*, H. T. McAllister; *Treasurer*, F. L. Theurer; *Councilor*, A. J. Schedler.

GEORGE N. PRENTISS, *Chairman*.

## KANSAS CITY SECTION.

Officers elected at the December 11th meeting: *President (Chairman)*, Dr. W. A. Whitaker; *Vice-President*, C. S. Curtis; *Councilor*, E. H. S.

Bailey; *Secretary-Treasurer*, W. B. Smith; *Assistant Secretary*, G. W. Stratton.

W. B. SMITH *Secretary*.

DECEASED.

Robert J. Davidson, Blacksburg, Va., December 19, 1915.

Loran O. Potterf, Urbana, Ill., December, 1915.

# Proceedings.

## COUNCIL.

The Committee appointed in accordance with the resolution passed at the Seattle meeting to investigate the so-called "Westfield Campaign" and Lewis B. Allyn's connection therewith, as announced in the October, 1915, Proceedings, has been modified to consist of the following: Julius Stieglitz, *Chairman*; E. H. S. Bailey, A. D. Thorburn, L. P. Brown, L. W. Jones.

On January 12th the following communication was sent to the Council:  
COUNCILORS OF THE AMERICAN CHEMICAL SOCIETY.

GENTLEMEN:

At the Cincinnati meeting of the Council of the American Chemical Society the following paragraph was spread on the minutes:

"A communication was presented to the Council from the Secretary of the Committee on Organization and Membership of the American Association for the Advancement of Science, stating that the American Association had arranged to have, every four years, a meeting in one of our larger cities in the hopes that the American Chemical Society and other societies not now regularly affiliated with the Association might be induced to meet with them at these four-year periods. It was voted that the Secretary be instructed to reply that the sentiment of the Council was entirely favorable to the proposed plan, and to state that it is the opinion of the Council that the American Chemical Society will hold its annual meeting in 1916 with the American Association for the Advancement of Science at the place selected, convocation week, December-January, 1916-1917."

At the Seattle meeting of the Council the following paragraph was spread on the minutes:

"The Council voted that time and place of the Fall meeting for 1916 be left to the President and Secretary with the understanding that as soon as the constitutional limit of one year previous to the date of the meeting had been reached, the President and Secretary would announce New York as the place of the meeting as per previous understanding that the meeting should be held in affiliation with the American Association for the Advancement of Science."

When the vote was passed at Seattle it was understood that the second National Exposition of Chemical Industries would be held in New York City during the last week of December, 1916. Since that time, however, the Exposition authorities have found it impossible to do so, owing to the fact that the Grand Central Palace has been engaged for the 1916-1917

automobile show at that time. They were, accordingly, obliged, such to their regret, to change the date of their Exposition to the week beginning Monday, September 25, 1916.

The success of the first National Exposition of Chemical Industries is well known to the Council. It seems certain that there will be a large gathering of chemists on account of this Exposition in New York City in the week beginning September 25, 1916, and that many of our members would not wish to come twice to New York during the Fall of this year. The second National Exposition of Chemical Industries promises to be one of the most successful expositions ever held in this country having any bearing on our chemical activities. This seems doubly certain on account of the great opportunities for our chemical industries arising from commercial conditions depending on the foreign situation.

I have just received from President Herty the invitation of the New York Section inviting the American Chemical Society to hold its annual meeting in the City of New York during the week beginning September 25, 1916, on account of the fact that the second National Exposition of Chemical Industries is to be held at that time. I have no doubt that, if the Council deem it advisable, the New York Section will amend this invitation to make their date coincide with that of the meeting of the Association for the Advancement of Science.

For your information, I would state that rooms for the meeting of the Society are available either in September or December.

Under the above conditions, the President and Secretary do not feel that the decision should lie with them, and this communication is therefore sent to you in the form of a letter ballot. Kindly indicate your preference below.

Yours very truly,

CHARLES L. PARSONS,  
*Secretary.*

Mark your choice with an X.

1. In favor of having the annual meeting for 1916 in New York City in the week beginning September 25, 1916.

2. In favor of having the annual meeting of the American Chemical Society in New York City in the week beginning December 25, 1916.

On February 3rd the vote was counted by Messrs. F. G. Cottrell, Chas. L. Parsons and J. D. Davis, Committee, and the result was as follows; in favor of September 25th date, 54; in favor of December 25th date, 30; illegal ballots 4. Accordingly, the invitation of the New York Section to hold the Fall meeting of 1916 in New York City on September 25th was accepted and a communication to this effect was transmitted to the chairman of the Section.

## MEMBERS ELECTED BETWEEN JANUARY 15 AND FEBRUARY 15, 1916.

- Baeza, Walter J., 839 West End Ave., New York City.  
 Bailey, R. K., Cliffside, Texas.

## MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505,  
 Washington, D. C.]

### CALIFORNIA SECTION.

The eighty-eighth regular meeting was held January 22nd. Program:  
 "Electrochemical Possibilities of California as Compared with those of  
 Sweden and Norway," by J. W. Beckman. "Solutions of Metals in  
 Liquid Ammonia," by W. L. Argo.

BRYANT S. DRAKE, *Secretary*.

### NORTHERN INTERMOUNTAIN SECTION.

The Section held a meeting at Pullman, Washington, December 11th.  
 Program: "Notes on the Homedale Nitrate and Potash Deposits," by  
 Professor C. C. Todd. "The Effect of Dihydroxystearic Acid and  
 Uvitonic Acid in Soil and in Water Solution," by Professor P. P. Peterson.  
 "Gluten Formation in Wheat Kernel," by Professor George A. Olson.

GEO. A. OLSON, *Secretary*.

### LEXINGTON SECTION.

The Section held its 30th regular meeting February 10th. Program:  
 Review of Soil Nitrogen as a Measure of the Organic Matter in Soils,"  
 by S. D. [unclear]. Paper—"Variations in the Mineral Composition of the

Sap, Leaves and Stems of the Wild Grape Vine and the Sugar Maple Tree," by O. M. Shedd.

PHILIP L. BLUMENTHAL, *Secretary*.

#### INDIANA SECTION.

The January meeting was held January 14th. Mr. Philip J. Kroll gave an illustrated talk on the "Technical Application of Oxygen."

The February meeting was held February 11th. Program: "An Ex-Official's View of Food Control Work," by T. J. Bryan.

H. W. RHODENHAMEL, *Secretary*.

#### ST. LOUIS SECTION.

The Section met February 7th. Program: "The Practical Sterilization of Water as Affected by the War," by W. F. Monfort.

GEO. LANG, JR., *Secretary*.

#### PITTSBURGH SECTION.

The 123rd regular meeting was held January 20th. The paper of the evening was presented by Mr. Joseph E. Babb, Supt. Fort Pitt Oil & Paint Co. "Lubricating Greases: their Composition, and Methods of Analysis."

The 124th regular meeting was held February 17th. Program: "Thermal Reactions Among Hydrocarbons at High Temperatures," by W. F. Rittman, U. S. Bureau of Mines. "The Corrosive Resistance of Copper Steel," by D. M. Buck, Chemist American Sheet & Tin Plate Co., and J. O. Handy, Director Pittsburgh Testing Laboratories.

W. C. COPE, *Secretary*.

#### DETROIT SECTION.

The January meeting was held January 20th. Program: "Formaldehyzed Capsules," by Wilbur L. Scoville. "The Theory and Practice of Case Hardening," by Herman G. Kiefer.

EDWARD J. GUTSCH, *Secretary*.

#### VIRGINIA SECTION.

The February meeting was held February 11th. The following papers were read: "Some Research Problems," by Dr. J. B. Weems. "Sulfides in Flowers of Sulfur," by Mr. R. F. McCrackan, Mr. O. L. Barden and Mr. R. C. Courtney. "Chemical Methods for Differentiating Cotton, Wool and Silk," by Dr. E. C. L. Miller and Mr. J. C. Ford.

At the January meeting the following officers were elected: *President*, R. B. Arnold; *Vice-President*, Dr. E. C. L. Miller; *Secretary-Treasurer*, W. A. Burrows; *Councilor*, Dr. E. W. Magruder.

W. A. BURROWS, *Secretary*.

#### NEW HAVEN SECTION.

At the annual meeting on January 14th, the following officers were elected for 1916: Ralph G. Van Name, *President*; C. H. Matthewson, *Vice-President*; Wm. Druschel, *Treasurer*; T. B. Johnson, *Councilor*; G. S. Jamieson, *Secretary*.

G. S. JAMIESON, *Secretary*.

## OREGON SECTION.

The annual meeting of the Section was held November 27, 1916. The paper of the evening was by Wm. Conger Morgan on "Some Modern Views of Matter." The following were elected to serve as officers for 1916: Wm. Conger Morgan, *President*; O. F. Stafford, *Vice-President*; Norman C. Thorne, *Secretary*; H. V. Tartar, *Councilor*.

The 26th regular meeting was held February 5th. The paper of the evening, "The Synthesis of Metals," by A. A. Knowlton.

NORMAN C. THORNE, *Secretary*.

## GEORGIA SECTION.

The following have been elected to serve as officers of the Section for 1916: V. H. Bassett, *President*; T. C. Law, *Vice-President*; J. S. Brogdon, *Secretary*; F. N. Smalley, *Councilor*.

J. S. BROGDON, *Secretary*.

## RHODE ISLAND SECTION.

The regular meeting was held January 21st. Program: "Green Gills in Oysters," by Prof. P. H. Mitchell.

The February meeting was held February 18th. Program: "Sympathetic on Induced Reactions," by A. B. Lamb.

ROBT. F. CHAMBERS, *Secretary*.

## CHICAGO SECTION.

The regular meeting was held January 21st. Program: "The Chemistry of Glass Making," by Dr. Alexander Silverman.

D. K. FRENCH, *Secretary*.

## PHILADELPHIA SECTION.

The regular meeting was held January 20th. Program: An address on "The Extraction and Recovery of Radium, Uranium and Vanadium from Carnotite," by Charles L. Parsons.

J. HOWARD GRAHAM, *Secretary*.

## MINNESOTA SECTION.

The Section met January 21st. Dr. Ross A. Gortner spoke on "Animal Pigments," and Dr. J. F. McClendon spoke on "The Physiological and Biochemical Significance of Hydrogen Ion Concentration."

The Section met February 18th. F. W. Emmons spoke on "The Chemist and the Flour Industry," and E. K. Strachan spoke on "Nonideal Solutions."

STERLING TEMPLE, *Secretary*.

## PUGET SOUND SECTION.

The regular meeting was held January 29th. A paper on "Plasticity of Clays," illustrated by data, was presented by R. F. McMichael.

H. L. TRUMBULL, *Secretary*.

## UNIVERSITY OF MICHIGAN SECTION.

The January meeting was held Tuesday, January 25th. Mr. R. J. Carney gave a paper on "The Determination of Thorium in Monazite Sand."

H. H. WILLARD, *Secretary*.

#### CORNELL SECTION.

A research meeting was held January 25th. The following papers were presented: "The Electrolytic Production of Perchlorates," by E. L. Mack. "The Nitration Products of Phenoltetrachlorophthalein and Some of Its Derivatives," by J. J. Kennedy. "The Electrolysis of Solutions of the Rare Earths," by A. B. Ray. J. A. BRIDGMAN, *Secretary*.

#### UNIVERSITY OF ILLINOIS SECTION.

The regular meeting was held January 18th. Program: "Syntheses in the Naphthalene Series," by Mr. H. B. McCluggage and Dr. Oliver Kamm. "Triphenylmethyl," by Dr. Laurence C. Johnson.

The regular February meeting was held February 15th. Program: "Qualitative Tests for Drugs Containing Emodin," by Ruth E. Okey and G. D. Beal. "Preparation and Characterization of Trimethylene-oxide," by C. G. Derick and D. W. Bissell. "The Preparation of Conductivity Water," by E. W. Washburn and H. J. Weiland.

G. D. BEAL, *Secretary*.

#### KANSAS CITY SECTION.

The 114th regular meeting was held January 22nd. Program: "Vanadium." "The Metallurgy of Vanadium," by Mr. R. L. Grider. "The Chemistry of Vanadium," by Dr. P. V. Faragher. "Vanadium Steels," by Mr. Clarence Estes.

W. B. SMITH, *Secretary*.

#### ROCHESTER SECTION.

The regular meeting was held February 7th. Prof. Alexander Smith, of Columbia University, gave a talk on "Sulfur."

H. H. TOZIER, *Secretary*.

#### WISCONSIN SECTION.

The February meeting was held February 16th. Professor L. Kahlenberg spoke on "A Neglected Principle of Chemistry."

L. F. AUGSPURGER, *Secretary*.

#### CONNECTICUT VALLEY SECTION.

The 38th regular meeting was held February 12th. Program: "The Chemistry of Synthetic Caoutchouc," by Prof. Joseph S. Chamberlain. "The Color Problem in the Paper Industry," by Mr. R. F. Hatch.

R. J. MARSH, *Secretary*.

#### MARYLAND SECTION.

The 11th regular meeting was held February 12th. Program: "The Estimation of Sugar in the Blood," by Dr. Geo. Peirce of Johns Hopkins Hospital.

FRANK M. BOYLES, *Secretary*.

#### CLEVELAND SECTION.

Dr. Chas. H. Viol, Director of the Radium Research Laboratory of the Standard Chemical Company, Pittsburgh, addressed the Section February 14th on the subject: "Radium and Radio-Activity."

A. F. O. GERMANN, *Secretary*.

#### COLUMBUS SECTION.

The February meeting was held February 11th. Program: "Some Problems in Municipal Chemistry," by Mr. C. B. Hoover, Chemist in charge of Sewage Disposal, Columbus, Ohio. "The Present Chemical Situation as Related to Problems in Water Purification," by Mr. Charles P. Hoover, Chemist at The Municipal Filtration Plant, Columbus, Ohio.

W. J. McCaughey, *Secretary*.

#### WESTERN NEW YORK SECTION.

The regular meeting was held February 17th. "Manufacture and Bacteriology of Ice Cream," by H. F. Lichtenberg. R. H. White, *Secretary*.

#### DECEASED.

Stanley Feather Hodgson, Mellon Institute, Pittsburgh, died Jan. 7th.  
W. A. Langdon, 225 N. 4th St., Allentown, Pa., died Jan. 20th.

J. H. Payne, 4004 Dalrymple Ave., Baltimore, died Jan. 28th.

#### Sir Henry Roscoe.

The name of Roscoe has long been a household word among chemists. True, his activity in chemical lines came practically to an end about thirty years ago when he resigned his professorship and entered Parliament, but his text-books continued in extensive use and either "little Roscoe" or "Roscoe and Schorlemmer," or both, are known wherever the science of chemistry is cultivated.

The Rt. Hon. Sir Henry Enfield Roscoe died suddenly at his residence near London on December 18th. He had nearly completed his 83rd year, having been born January 7, 1833. He had always enjoyed good health except for occasional attacks of gout, and up to within an hour of his death he was well and happy. "Heart failure" is given as the cause of his ideal end.

Roscoe's grandfather, William Roscoe, rose to distinction, having represented Liverpool in Parliament in 1806. His "Lives of Lorenzo di Medici and Leo X" is well known and is his chief claim to fame. His son, Henry Roscoe, the father of Sir Henry, was a barrister who became a judge in Liverpool. He died at an early age and left his widow in straitened circumstances. She gave lessons in painting to help her to support her family. Later she published a "Life of Vittoria Colonna." She was a woman of unusual ability and force of character.

Roscoe's early education was obtained at the High School of Liverpool. His teacher in science was Balmain, the discoverer of luminous paint, and from him he acquired a taste for scientific studies. In his interesting "Life and Experiences," published in 1906, he tells us that at this early period of his life he attended a lecture by Mr. Pepper (of ghost fame). He says the thought passed through his mind: "Shall I ever attain to the

position of a scientific lecturer and burn phosphorus in oxygen on a large scale before an admiring audience?"

He was sent to University College, London, in 1848. Graham was then the professor of chemistry there, and he was succeeded by Williamson during Roscoe's student years, so that he had the good fortune to come under the influence of both of these able men. He received the degree of B.A. from the University of London. He then went to Heidelberg to continue his studies under Bunsen. Here he took part in the well-known researches on the chemical action of light. He continued work in this field for some years after receiving the degree of Doctor of Philosophy from Heidelberg in 1854, returning to Heidelberg in the summer vacations for this purpose. The results of the investigations were published in the *Philosophical Transactions* and in Poggendorff's *Annalen*. In Ostwald's reprint in his *Collection of Scientific Classics*, he says: "The Photo-Chemical researches of Bunsen and Roscoe deserve the name of a classical investigation as they not only have gathered together all points known hitherto on the subject, but by their wide and thorough experiments have laid the foundation for all further work on the subject. It cannot be doubted that these researches not only serve as a classical, but as *the* classical type for all future experiments on the subject of physical chemistry."

Roscoe's residence in Heidelberg and his association with Bunsen and with Kirchhoff naturally led him to take special interest in spectrum analysis. He translated the book of Bunsen and Kirchhoff and also lectured extensively on this subject.

In 1857 he was elected professor of chemistry in Owens College, Manchester, succeeding Frankland. The College had then been in existence only six years, and it was in a low state financially. In his "Life and Experiences" he says: "The institution was at that time nearly in a state of collapse, and this fact had impressed itself even on the professors. I was standing one evening, preparing myself for my lecture by smoking a cigar at the back gate of the building, when a tramp accosted me and asked me if this was the Manchester Night Asylum. I replied that it was not, but that if he would call again in six months he might find lodging there! That this opinion as to the future of the college was also generally prevalent is shown by the fact that the tenancy of a house in Dover Street was actually refused to me when the landlord learned that I was a professor in that institution."

His principal work was done while holding the professorship in Owens College, which he resigned in 1885 to enter Parliament, after a continuous service of 28 years. During this period the college became completely transformed and in 1880 a Royal Charter constituting the Victoria University was granted. Of this new university Owens College was a part,

the other parts being the University College of Liverpool and the Yorkshire College of Leeds.

There can be no doubt that Roscoe rendered his country a great service in improving the methods of teaching chemistry. In this work he was ably seconded by Carl Schorlemmer, a German who was thoroughly imbued with the spirit of the German universities. He held the chair of Organic Chemistry and distinguished himself by his researches and by his literary work. Roscoe had great admiration for the German methods and he did what he could to give his laboratory the advantage of these methods.

Roscoe's contributions to chemistry are not numerous. Probably the most important is that on vanadium. He says: "This is certainly the best piece of work I ever did and I do not know that I ever enjoyed anything of an intellectual kind more thoroughly." \* \* \* "The subject aroused very general attention throughout the scientific world, and my view concerning the relationships of the metal was universally adopted. Those who wish to understand this matter more fully can read the papers in the *Philosophical Transactions* (Bakerian Lecture, 1868), and also several lectures on the subject which I gave at the Royal Institution." \* \* \* "The explanation of the close resemblance between vanadium on the one hand, and phosphorus and arsenic on the other, is the chief outcome of this work."

His "Lessons in Elementary Chemistry" was published in 1866. Up to 1906 the number of copies sold was 211,000. Translations appeared in German, Russian, Italian, Hungarian, Polish, Swedish, Japanese, and even in one of the Indian vernaculars, Urdu. His *Primer* had also a wide, in fact, a still wider circulation. Up to 1906, 355,000 copies were sold. It was translated into Icelandic, Polish, German, Italian, Japanese, Bengali, Turkish, Malayalam, and Tamil!

The well-known "Treatise on Chemistry" by Roscoe and Schorlemmer is unquestionably the best English treatise in chemistry and certainly one of the best in any language. It was translated into German by Schorlemmer and published in 1880 by Vieweg.

As has already been stated Roscoe was elected to Parliament in 1885, and then resigned the professorship. Since that time his activities have not been displayed especially in the field of chemistry. He, however, continued to exert a strong influence upon educational matters. After his retirement from Parliament he and his wife lived in what he called "the most beautiful and healthy spot in the whole of Surrey, namely, at Woodcote Lodge." This is only twenty-six miles from Hyde Park Corner, but "as far from the madding crowd" as if it "were ten times that distance." It was here that Roscoe's useful life ended suddenly and ideally.

IRA REMSEN.

# Proceedings.

## COUNCIL.

March 2, 1916.

### COUNCIL OF THE AMERICAN CHEMICAL SOCIETY.

*Gentlemen:*

On February 14th a letter was received from Prof. W. A. Noyes moving reconsideration of the recent vote selecting the date of September 25, 1916, for the time of our Annual Meeting rather than Convocation Week in December. Under vote of the Council (*Proc.*, 1912, p. 43), it is necessary that the President certify to the urgency of this vote before it can be sent to the Council. After some correspondence between Professor Noyes and President Herty, I am this morning in receipt of a letter from President Herty certifying to the urgency of the matter, and Professor Noyes' motion to reconsider is accordingly submitted to you for your opinion. Professor Noyes' motion and President Herty's letter to me regarding the matter follow:

"February 10, 1916.

PROFESSOR C. L. PARSONS,

Washington, D. C.

*Dear Professor Parsons:*

In the recent vote of the Council on the date of the fall or winter meeting of the American Chemical Society I voted in favor of the September date in order that I might move a reconsideration of the question. I can not believe that the members of the Council, in voting as they have, gave due consideration to the following points which favor the December date:

1. A plan has been carefully formed to bring all of the scientific interests of the country together in one city once in five years. The December date was set in order to carry out this plan for the first time. It seems only fair that the chemists of the country should coöperate in carrying out this important scheme.

2. The date in September which is proposed is at a time when practically all of the professors and teachers in our colleges and universities are busy with the opening of the year's work and very few of this class of our members would find it possible to attend the meeting.

I move, therefore, that the motion fixing the date of the meeting in September be reconsidered.

I also move that in case the motion to reconsider carries the fixing of the date of the meeting be left to the Directors, or, if they prefer, postponed till the April meeting of the Council.

Very respectfully,

W. A. NOYES."

"February 29, 1916.

DR. CHARLES L. PARSONS, *Secretary*,  
American Chemical Society,  
Box 505, Washington, D. C.

*My Dear Dr. Parsons:*

In the recent letter ballot of the Council, held for the purpose of advising the President and Secretary as to the wishes of the Council regarding the time for holding the 1916 annual meeting, Dr. W. A. Noyes voted in favor of the September date in order to move a reconsideration. He now so moves, with the addition that in case of reconsideration the matter be left to the decision of the Directors.

Under the action of the Council at the 1911 Washington meeting it becomes my duty to pass upon the urgency of this motion.

While simultaneous action on the two motions is somewhat unparliamentary, nevertheless in view of the desirability of settling this matter as promptly as possible, I beg to certify to the urgency of Dr. Noyes' motion for reconsideration, and request that you will submit the matter to the Council immediately for letter ballot.

I regret that I cannot agree with the author of the motion in his desire that the annual meeting this year should be held in December, rather than in September as has been decided by the votes of so large a proportion of the Council.

Under normal conditions I would favor most heartily the policy of meeting quadrennially with the American Association for the Advancement of Science. At the Cincinnati meeting I spoke most earnestly in behalf of this policy, but this is an entirely different world from what it was at that time.

As a result of the European war chemistry has received a tremendous impulse in this country; the general public has been aroused to its importance to the welfare of the country; and this year of all others it is extremely desirable that we should have at our annual meeting the largest gathering of chemists that this country has ever known, for there are many problems, the solution of which demands personal conferences by men from every section of the country. There is need for the presence of both the men from the universities and the men of the industries at such conferences, and there is need of the greatest legitimate publicity of our work and aims.

I deeply regret that it was found absolutely impossible to hold the Second National Exposition of Chemical Industries during Convocation Week. Every effort was made to do so, but all of these efforts failed through inability to secure a suitable building during that week. The exposition must be held in September. If, therefore, we should decide to hold our annual meeting in December, I am confident that it would re-

sult in a large portion of our membership attending the Exposition and failing to attend the meeting of the Society. This would mean a very great loss in this particular year to the prestige and usefulness of the Society. The opportunity of a lifetime is in our hands. It seems to me that we would be very unwise to divide our strength just at the time when we have so wonderful an opportunity for increasing it.

Should the Council vote against reconsideration, members of the Society connected with universities would not be thereby necessarily prevented from attending the annual meeting. It seems reasonable that university authorities would gladly give leave-of-absence to members of chemistry staffs in those institutions which open on or before September 25th, and certainly the departments of chemistry in all of our universities would have much to gain from a meeting held in conjunction with the Second National Exposition of Chemical Industries.

Sincerely yours,

CHAS. H. HERTY, *President.*"

CHH :TAJ

Kindly signify your wishes by means of a cross, tear off ballot, and mail in inclosed envelopes to this office. Ballot is void unless it reaches me on or before March 23rd.

Yours very truly,

CHARLES L. PARSONS,  
*Secretary.*

1. ———In favor of reconsideration.

———Opposed to reconsideration.

2 If in favor of reconsideration.

———In favor of Dr. Noyes' request for immediate decision by the Directors.

———Opposed.

The above ballot was counted by a committee consisting of F. G. Cottrell, J. D. Davis, and Chas. L. Parsons. Ninety-seven ballots were cast, of which 31 were in favor of reconsideration, 61 opposed to reconsideration, and 5 illegal.

MEMBERS ELECTED BETWEEN FEBRUARY 15 AND MARCH 15, 1916.

Abbe, Paul O., 30 Broad St., New York City.

Alvord, Arthur L., 332 W. College Ave., State College, Pa.

Andrews, Joseph, 172 Church St., West Haven, Conn.

Bailey, Richard O., Oneida Community, Ltd., Oneida, N. Y.

Baker, Chas. F., Linden St., Meadville, Pa.

Ball, Albert E., 205 North Fourth St., McDonald, Pa.

Bateman, G. Alan, 503 N. Walnut St., West Chester, Pa.

Beckman, John Woods, 2215 Marin Ave., Berkeley, Calif.  
 Benjamin, Hugo S., Box 36, Big Stone Gap, Va.  
 Bentzen, F. W., 619 Ash St., Baraboo, Wisc.  
 Bernstrom, Harry O., 732 Comstock Ave., Syracuse, N. Y.  
 Bolte, C. Lawrence, 3757 Ellis Ave., Chicago, Ill.  
 Boyden, Sidney D., Battle Creek, Mich.  
 Brown, Henry C., c/o International Lead Ref. Co., East Chicago, Ind.  
 Buckley, Byron G., 112 W. Wood's Rd., Solvay, N. Y.  
 Bukacek, Adolph, North Dighton, Mass.  
 Bull, Hans, 4642 Penn St., Frankford, Philadelphia, Pa.  
 Burdett, Harold W., 25 Grove Ave., Leominster, Mass.  
 Bush, Burton T., 18 Platt St., New York City.  
 Camillus, Sister Mary, St. Xavier Academy, 4928 Cottage Grove Ave., Chicago, Ill.  
 Campbell, John Hayes, 2200 Insurance Exchange, Chicago, Ill.  
 Chambers, Alfred A., U. S. Geological Survey, Washington, D. C.  
 Clark, Paul W., 2235 Rose St., Berkeley, Calif.  
 Compton, J. N., 48 Y. M. C. A., Indianapolis, Ind.  
 Cooper, Hewitt W., Louisville Lead & Color Co., 223 N. 15th St., Louisville, Ky.  
 Crampton, Theo. H. M., Good Springs, Nevada.  
 Cronquist, G. Wson, Helsingborg, Sweden.  
 Dickson, J. V., 18 Callendar St., Toronto, Canada.  
 Doubleday, Arthur W., 220 Marlborough St., Boston, Mass.  
 Dure, Henry F., 103 McGraw Pl., Ithaca, N. Y.  
 Dyson, Robert E., 129 Bank St., St. Marys, Pa.  
 Edelstein, Oscar, 6 W. 116th St., New York City.  
 Elliott, Bruce S., 614 Bank of Commerce Bldg., St. Louis, Mo.  
 Elliott, Wesley A., Riverside Club, Pennsgrove, N. J.  
 Esten, Paul A., c/o Winslow Bros. & Smith Co., Norwood, Mass.

### MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505, Washington, D. C.]

#### EASTERN NEW YORK SECTION.

The 64th meeting of the Section was held March 9th. The subject was, "The Electrolytic Refining of Copper," and the speaker, F. D. Easterbrooks, of Albany. Slides and pure chemical by-products were shown. The Society of Engineers of Eastern New York met with the Section.

ALBERT J. SALATHÉ, *Secretary*.

#### NEW YORK SECTION.

The fourth regular meeting was held in conjunction with the New York Section of the American Electrochemical Society and the Society of Chemical Industry, under the auspices of the American Electrochemical Society, February 11th.

The following papers were read: "Electrochemical War Supplies," by Lawrence Addicks (read by title); "Air Saltpeter," by W. S. Landis; "Hydrogen for Military Purposes," by E. D. Ardrey; "New War Products," by A. H. Hooker; "Magnesium," by W. M. Grosvenor; "Liquid Chlorine," by G. Ornstein; "Electrolytic Zinc," by W. R. Ingalls.

The fifth regular meeting was held March 10th. Program: Presentation of the William H. Nichols Medal to C. S. Hudson; "The Acetyl Derivatives of the Sugars," by C. S. Hudson; "Development of the Bureau of Chemistry," by Carl L. Alsberg.

The following officers were elected to serve the Section for 1916-1917, beginning July 1, 1916: J. M. Matthews, *Chairman*; F. J. Metzger, *Vice-Chairman*; C. F. Roth, *Secretary-Treasurer*; T. B. Wagner, Allen Rogers, C. M. Joyce, A. E. Hill, *Executive Committee*.

C. M. JOYCE, *Secretary*.

#### MILWAUKEE SECTION.

A meeting was held February 18th. Mr. F. W. Kressmann of the Forest Products Laboratory, Madison, Wis., gave an illustrated talk on, "The Uses of Wood Flour, Especially the Manufacture of Linoleum."

H. T. McALLISTER, *Secretary*.

#### CALIFORNIA SECTION.

The Section held its eighty-ninth regular meeting on February 15th in conjunction with the local Section of the American Institute of Mining Engineers.

The paper of the evening was given by Dr. Joel H. Hildebrand on, "The Fundamental Principles Underlying Flotation."

BRYANT S. DRAKE, *Secretary*.

#### EASTERN NEW YORK SECTION.

The 62nd meeting was held February 10th in conjunction with the Schenectady Section of the American Institute of Electrical Engineers and other scientific bodies. The address was given by Dr. John A. Brashear, Past President of the American Society of Mechanical Engineers, who took for his subject: "The Great Telescopes of the World and the Discoveries Made by Their Use."

The 63rd meeting was held jointly with the Theta Chapter of the Sigma Xi, February 11th. The speaker was Professor R. D. Kleeman, and the subject, "Ultra-Violet Light."

The 64th meeting was held March 9th. Program: "The Electrolytic Refining of Copper," by F. D. Easterbrook.

A. J. SALATHÉ, *Secretary*.

#### UNIVERSITY OF MISSOURI SECTION.

The 64th meeting of the Section was held February 18th. Dr. C. W. Greene addressed the Section on, "Some New Physiological Aspects of Fat Metabolism."

HENRY L. DAHM, *Secretary*.

#### KANSAS CITY SECTION.

The 112th meeting was held November 13th. Program: "The Fate of Food Protein in the Animal Body," by Dr. P. A. Shaffer.

The 113th meeting was held December 11th. Program: "High Alloy Steels for Long Span Bridges," by Dr. J. A. L. Waddell.

The 115th meeting was held February 19th. Program: "A Picric-Phosphotungstic Acid Clarifier for Sugar in Meat Extracts," by W. B. Smith; "Flotation," by George Belchic; "Heat Value of Gas of the Mid-Continental Field," by Prof. H. C. Allen.

W. B. SMITH, *Secretary*.

#### CHICAGO SECTION.

The regular meeting was held February 18th. Program: "The Present Status of Fertilizer Theory and Practice," by W. D. Richardson.

The regular meeting was held March 17th. Program: "The Chemistry and Metabolism of the Nucleic Acids," by H. Gideon Wells.

D. K. FRENCH, *Secretary*.

#### CINCINNATI SECTION.

The 203d regular meeting was held February 16th. Program: "The Application of Physical Chemistry to Some Geological Problems," by Otto Charles von Schlichten.

The 204th meeting was held March 8th. Program: "Various Aspects of the Smoke Problem," by Osborn Monnett.

ELLERY K. FILES, *Secretary*.

#### PUGET SOUND SECTION.

The Section held an open meeting in coöperation with the Manufacturers' Association February 26th. Program: "The Electrical Fixation of Nitrogen," by J. D. Roso; "Fisheries Products," by Geo. H. Stillson; "Potash from Kelp," by I. F. Laucks and H. Mahschmedt; "Potash from Mineral Resources," by G. A. Newhall; "Phosphate Rocks," by G. E. Weaver.

H. L. TRUMBULL, *Secretary*.

#### NASHVILLE SECTION.

The 38th meeting was held February 18th. Program: "The Utilization of Waste in the Manufacture of Copper," by Prof. J. T. McGill.

The 39th meeting was held March 17th. Program: "Estimation of Extract of Beef," by Prof. E. A. Ruddiman.

VICTOR P. LEE, *Secretary*.

#### NEBRASKA SECTION.

The February meeting was held February 19th. Program: "The Laboratory Examination of Clays," by Prof. George Borrowman.

H. M. PLUM, *Secretary*.

#### LOUISIANA SECTION.

The regular meeting was held February 18th. Program: "The Oxidation of Ethyl Alcohol by Means of Potassium Permanganate" (No. 2), by Jesse E. Day; "The Syrup Precipitate in the Direct Manufacture of White Cane Sugar," by C. E. Coates and L. C. Slater; "Some Notes on the Chemical Control of Petroleum Refineries," by C. E. Coates and M. M. Merritt.

F. W. LIEPMAN, *Secretary*.

#### ROCHESTER SECTION.

The regular meeting was held February 21st. Program: "Sewage Disposal," by C. C. Hopkins.

The regular meeting was held March 6th. Program: "The Photographic Microscope in Analysis," by Fred E. Wright.

H. H. TOZIER, *Secretary*.

#### AMES SECTION.

The fourth regular meeting was held March 2nd.

The Section was addressed by Dr. William D. Harkins, of the University of Chicago, on, "The Evolution of the Elements and the Periodic System."

W. G. GAESSLER, *Secretary*.

#### WASHINGTON SECTION.

The 258th meeting was held March 9th. Program: "The Action of Light on Chlorine with Special Reference to the Formation of Chloracetic Acid," by H. H. Curtis; "The Isolation of Vitamines from Brewers' Yeast," by A. Seidell; "On the Chemical Nature of Vitamines," by R. R. Williams.

E. C. McKELVY, *Secretary*.

#### ST. LOUIS SECTION.

The Section met March 6th. Program: "Activated Sludge," by Edward Bartow.

GEO. LANG, JR., *Secretary*.

#### CLEVELAND SECTION.

A special meeting was held February 23rd. Program: "Glass," by Alexander Silverman.

The March meeting was held March 13th. Program: "The Heat Temperature of Steel," by R. R. Abbott.

A. F. O. GERMANN, *Secretary*.

#### VIRGINIA SECTION.

The March meeting was held March 10th. Program: "The Revolution in Coke Manufacture and Its Relation to Our National Welfare," by Charles H. Herty.

W. A. BURROWS, *Secretary*.

#### UNIVERSITY OF MICHIGAN SECTION.

A meeting was held March 3rd. Program: "Glass Defects," by E. C. Sullivan.

H. H. WILLARD, *Secretary*.

#### CONNECTICUT VALLEY SECTION.

The 39th meeting was held March 11th. Program: "Electrical Precipitation of Flue Dust," by Mr. Egbert of the Research Corporation of New York City; "Manufacture and Testing of Cold Rolled Steel," by Mr. F. W. Shaefer, Stanley Works, New Britain.

R. J. MARSH, *Secretary*.

#### PHILADELPHIA SECTION.

The regular meeting of the Section was held February 24th. Program: "Modern Painting Practices on Structural Material," by George B. Heckel.

The regular meeting was held March 16th. Program: "The Chemistry of Glass Making," by Alexander Silverman.

J. HOWARD GRAHAM, *Secretary*.

## DETROIT SECTION.

The 79th meeting was held March 16th. "The Chemical Composition of Steel in Relation to Its Industrial Uses," by Jos. N. Bourg

EDW. J. GUTACHE, *Secretary*.

## WESTERN NEW YORK SECTION.

A meeting was held February 17th. Program: "Manufacture of Ice-cream," by Harry F. Lichtenberg.

The regular meeting was held March 3rd. Program: "The Chemistry of Photography," by F. C. Frary.

R. H. WHITE, *Secretary*.

## OREGON SECTION.

The 26th regular meeting was held February 26th. Program: "The Synthesis of Metals," by A. A. Knowlton.

NORMAN C. THORNE, *Secretary*.

## NEW HAVEN SECTION.

A meeting was held February 25th. Program: "On the Synthesis of Pyrimidine—Rosaniline Dyes," by T. B. Johnson; "On the Metallic Gallium and Some Gallium Reactions," by P. E. Browning; "The Effect of Freezing Precipitated Inorganic Colloids," by Blair Saxton; "An Apparatus for Determining Freezing-Point Lowering," by R. G. Van Name and F. G. Brown.

GEORGE S. JAMIESON, *Secretary*.

## MARYLAND SECTION.

The 12th regular meeting was held March 11th. Program: "By-Product Coke Oven Operation," by B. W. Winship.

FRANK M. BOYLES, *Secretary*.

## WISCONSIN SECTION.

The March meeting was held March 8th. Program: "The Electron Theory," by M. Mason.

L. F. AUGSPURGER, *Secretary*.

## LEXINGTON SECTION.

The 31st regular meeting was held March 9th. Program: "Investigations on the Abderhalden Test for Pregnancy," by W. S. Anderson; "The Duties of the United States Assay Commission," by F. E. Tuttle; "Some Queer Colloidal Precipitations," by C. A. Nash.

P. L. BLUMENTHAL, *Secretary*.

## MAINE SECTION.

A meeting of the Section was held March 3rd. Program: "Control of Sulfite Digestion by Titration Methods," by A. G. Durgin; "The Purchase Heat," by A. B. Andrews; "The Pulp and Paper Industry," by R. H. McKee.

E. O. WHITTIER, *Secretary*.

## DECEASED.

Martin Dennis, 859 Summer Ave., Newark, N. J., February 3, 1916.

# Proceedings.

## COUNCIL.

### Representatives of the American Chemical Society in the Organization for Industrial Preparedness.

ALABAMA.....	B. B. Ross.....	Auburn, Alabama
ALASKA.....	W. P. Lass.....	Speel River Electrochemical Co., Juneau, Alaska

#### CORPORATION MEMBERS.

Lindsay Light Co., 161 E. Grand Ave., Chicago, Ill.  
 Oliver Chemical Co., Mount Eden, Calif.  
 Westinghouse Lamp Co., Bloomfield, N. J.

### MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505, Washington, D. C.]

#### CHICAGO SECTION.

The regular monthly meeting was held April 14th. Program: "Practical Vapor Pressures and Distillation," by Dr. M. A. Rosanoff, Mellon Institute, Pittsburgh, Pa.

D. K. FRENCH, *Secretary*.

#### LEXINGTON SECTION.

The 32nd regular meeting was held April 13th. Program: "Note on the Occurrence of Gallium," by Dr. R. N. Maxson. "A Recent Discovery with Reference to the Bang Bacillus," by Prof. E. S. Good. "The Separation and Estimation of Polysulfids and Thiosulfate in Lime-Sulfur Solution," by Mr. S. D. Averitt.

P. L. BLUMENTHAL, *Secretary*.

#### WASHINGTON SECTION.

The 259th meeting (special) was held March 21st. Program: Prof. John Uri Lloyd, of Cincinnati, "A Practical Demonstration of Some of the Principles of Colloidal Chemistry."

E. C. McKELVY, *Secretary*.

## MINNESOTA SECTION.

The Section met March 24th. Program: "The Factors Influencing the Occurrence of HCN in Plants," J. J. Willaman; "The Reimer-Tiemann Reaction," W. H. Hunter.

STERLING TEMPLE, *Secretary*.

## SOUTHERN CALIFORNIA SECTION.

The regular monthly meeting was held March 16th. The paper for the evening was presented by Mr. Wilhelm Hirschkind, Ph.D., on "The Bunsen Flame in Old and New Light."

H. L. PAYNE, *Secretary*.

## RHODE ISLAND SECTION.

The March meeting was held March 23rd. The speaker for the evening was Professor F. P. Gorham, of Brown University, who addressed the Section on "The Bacterial Treatment of Textile Fibers."

ROBERT F. CHAMBERS, *Secretary*.

## UNIVERSITY OF ILLINOIS SECTION.

The regular meeting was held March 21st. Program: "The Raw Materials of Varnish," Mr. C. T. Bragg, Chemical Engineer of the Ohio Brass Company.

G. D. BEAL, *Secretary*.

## LOUISIANA SECTION.

The 92nd meeting was held March 17th. Program: Dr. M. A. Schneller, "On the Determination of Diastatic Power in Wheat Flour." Mr. Wm. L. Owen, "The Influence of Phosphates on Alcoholic Fermentation." Mr. F. W. Liepsner, "Discussion of the By-products of Rice Milling."

F. W. LIEPSNER, *Secretary*.

## PUGET SOUND SECTION.

The March meeting was held March 25th. Program: C. E. Bogardus, "Opportunities for Electrochemical Industries." W. R. Hainsworth, "Bleaching Powder Costs." J. Daniels, "Artificial Abrasives." H. L. Trumbull, "The Production of Alkalies and Salts from Sea Water."

H. L. TRUMBULL, *Secretary*.

## SOUTH CAROLINA SECTION.

The 4th regular meeting was held December 10, 1915. Program: Dr. R. N. Brackett, "Abstract, Report of Referee Nitrogen Determination." Prof. C. F. Lipscomb, "Calomel Standard Cell, and the Various Thermodynamic and Thermochemical Relations Occurring in the Cell." Dr. J. E. Mills, "Gravitation." Mr. C. J. King, "A Note upon Methods for Determining Acidity in Soils." Mr. Boyden Nims, "The Relation of the State Laboratories to the Commercial Chemist." The election of officers was then taken up and the following were elected to hold office until the summer meeting of 1917: Dr. R. N. Brackett, *President*; Mr. C. T. Mayes, *Vice-President*; A. C. Summers, *Secretary-Treasurer*; Mr. Boyden Nims, *Councilor*.

A. C. SUMMERS, *Secretary*.

## UNIVERSITY OF MISSOURI SECTION.

The 65th meeting of the Section was held March 10th. Dr. Herman Schlundt gave a report on "The Methods of Radium Extraction from Carnotite Ore Used by the National Radium Institute at Denver, Colo."

A. G. LOOMIS, *Secretary*.

## OREGON SECTION.

The 27th regular meeting was held April 1st. Program: "Sulfur and Soil Acidity, Two Important Factors in the Fertility of Soils," Prof. H. V. Tartar.

NORMAN C. THORNE, *Secretary*.

## CONNECTICUT VALLEY SECTION.

The 40th regular meeting was held April 8th. Program: "Manufacture of Celluloid," Mr. Herbert E. Nims; "Some Analyses of Rocks from the Islands of the Pacific," Dr. E. W. Morley; "Browning of Gun Barrels," Mr. C. F. Wessell.

R. J. MARBE, *Secretary*.

## UNIVERSITY OF MICHIGAN SECTION.

The March meeting was held March 28th. Dr. F. E. Bartell presented a paper on "Negative Osmose."

H. H. WILLARD, *Secretary*.

## MARYLAND SECTION.

The 13th regular meeting was held April 15th. Program: "Coal Gas Residuals" (illustrated), by Dr. Frederick H. Wagner, of the Bartlett, Hayward Co.

FRANK M. BOYLES, *Secretary*.

## CLEVELAND SECTION.

The April meeting was held April 10th. Program: "The Microscope and its Accessories," Mr. L. B. Hall, of the Bausch & Lomb Optical Company, Rochester, N. Y.

A. F. O. GERMANN, *Secretary*.

## CINCINNATI SECTION.

The 205th regular meeting was held April 12th. Program: "The History, Characteristics and Methods of Manufacture of Modern Explosives," by Mr. M. F. Lindsley.

E. K. FILES, *Secretary*.

## IOWA SECTION.

A meeting was held April 8th. Program: "A Plant for the Manufacture of Synthetic Phenol," by Professor Harry McCormack, Head of the Department of Chemical Engineering, Armour Institute of Technology.

P. A. BOND, *Secretary*.

## VIRGINIA SECTION.

The April meeting was held April 14th. Program: "Some Chemical Classics," Dr. Garnett Ryland; "Some Phenomena of Lightning and Lightning Prevention," Dr. R. E. Loving; "The Relation of Research to Everyday Life," Dr. J. B. Weems.

W. A. BURROWS, *Secretary*.

## ROCHESTER SECTION.

The March meeting was held March 20th. Program: "The Character, Cost and Adulteration of Foods," by Prof. A. P. Sy, of the University of Buffalo.

A special meeting of the Section was held April 3rd. Program: "Velocity of Heterogenous Reactions with Especial Reference to Catalysis," by Dr. Irving Langmuir, from the Research Laboratories of the General Electric Co.

The regular meeting was held April 17th. Program: "The Organization of Industrial Research," by Dr. C. E. Kenneth Mees, Director of the Research Laboratories of the Eastman Kodak Company.

H. H. TOZIER, *Secretary*.

## SYRACUSE SECTION.

The 105th regular meeting was held March 24th. G. W. Cavanaugh, Professor of Agricultural Chemistry in Cornell University, spoke on "Some Problems in Agricultural Chemistry."

A special meeting was held April 7th. Mr. G. M. Berry, of the Halcomb Steel Co., spoke on "The Decennial of Electric Steel in America."

R. S. BOEHNER, *Secretary*.

## PITTSBURGH SECTION.

The 124th meeting was held February 17th. Program: "Thermal Reactions among Hydrocarbons at High Temperatures," by W. F. Rittman; "The Corrosion Resistance of Copper Steel," by D. M. Buck and J. O. Handy.

The 125th regular meeting was held March 16th. Program: F. C. Phillips, University of Pittsburgh, "Joseph Priestly;" Charles L. Parsons, Chief Chemist of the U. S. Bureau of Mines and Sec'y of the Amer. Chem. Society, "The Extraction of Radium from its Ores." W. C. COPE, *Secretary*.

## CALIFORNIA SECTION.

The 90th regular meeting was held March 25th. Program: "Some Problems in Paper Manufacture," by Mr. V. P. Edwardes; "A General System of Acids and Bases," by Dr. Merle Randall, Ph.D.

BRYANT S. DRAKE, *Secretary*.

## DECEASED.

Charles G. Carroll, University of Arkansas, Fayetteville, Ark., Feb. 22, 1916.

C. A. Catlin (Councilor A. C. S.), 133 Hope Street, Providence, R. I., April 12, 1916.

Gerald R. Donahoe, 510 Main St., Greensburg, Pa., Feb. 15, 1916.

Elton Fulmer, Agr. Exp. Station, Pullman, Washington, Feb. 20, 1916.

Harry C. Jones, Johns Hopkins University, Baltimore, Md., April, 1916.

Frank Kremer, Box 1608, Milwaukee, Wis., March 9, 1916.

G. E. Patrick, Dept. of Agriculture, Washington, D. C., March, 1916.

# Proceedings.

## GENERAL MEETING.

The 52nd meeting of the American Chemical Society was held at the University of Illinois, Urbana-Champaign, April 18th to 21st. A full account of the meeting will be found published on page 396 of the May issue of the *Journal of Industrial & Engineering Chemistry*. Five hundred and seventy-two members and one hundred and fifty-seven guests registered at the meeting, making it the largest meeting on record, no registration having been taken at the time of the New York meeting in conjunction with the 8th International Congress of Applied Chemistry. Members were present from thirty-two States, from Canada, Canal Zone, China and Japan.

The following Divisions met, titles of papers offered being already printed in the *Journal of Industrial & Engineering Chemistry* for May, page 462:

- Division of Agricultural and Food Chemistry.
- Division of Biological Chemistry.
- Division of Fertilizer Chemistry.
- Division of Industrial Chemists and Chemical Engineers.
- Division of Organic Chemistry.
- Division of Pharmaceutical Chemistry.
- Division of Physical and Inorganic Chemistry.
- Division of Water, Sewage and Sanitation.

The following business was transacted by the Divisions:

Division of Agricultural and Food Chemistry:

The meeting was called to order by Chairman L. M. Tolman on April 19th. Owing to the absence of the Secretary, the Chairman appointed M. B. Porch as acting Secretary. No business was transacted.

### DIVISION OF BIOLOGICAL CHEMISTRY.

In the absence of Chairman Alsberg, Vice-Chairman I. K. Phelps acted as Chairman of the Committee. There was extended discussion, especially on the papers bearing on colloid chemistry.

### DIVISION OF FERTILIZER CHEMISTRY.

The Division met with the regular officers present. No business was transacted. Reports of committees were discussed.

### DIVISION OF INDUSTRIAL CHEMISTS AND CHEMICAL ENGINEERS.

The Industrial Division met April 19, 20, 1916, with Dr. H. E. Howe presiding.

The Secretary reported a balance in the treasury of \$22.22.

It was voted that the Executive Committee be empowered to consider the revising of committees and to report at the New York meeting.

It was voted that the notice prescribed in Article VII of the By-Laws of the Division be sent to members before the New York meeting, as to a proposed amendment of Article IV.

It was voted that a Committee on Analysis of Fats and Oils, appointed by a number of manufacturers and buyers of fats and oils in the middle west and consisting of W. D. Richardson, Swift & Co., *Chairman*; P. Rudnick, Armour & Co.; A. Lowenstein, Morris & Co.; I. Katz, Sulzberger Sons & Co.; J. R. Powell, Armour Soap Works; H. J. Morrison, Proctor and Gamble; Ernst Twitchell, Emery Candle Co., be taken over by the Division and be known as the Committee on the Analysis of Fats and Oils.

It was voted that the Chairman appoint a committee to be known as the Committee on Analysis and Specifications of Cotton Seed Products.

It was voted that the members of the Division be assessed one dollar each for the purpose of defraying Divisional expenses.

#### Executive Committee Meeting:

The Executive Committee of the Division met on the afternoon of April 20th, the following members being present: H. E. Howe, *Chairman*; S. W. Parr, C. H. Herty, J. R. Withrow, S. H. Salisbury, Jr.

The Committee indorsed the Division's action with regard to the amendment of Article IV of the By-Laws so that certain committees need not be appointed.

The Committee indorsed the action of the Division with regard to the taking over of the Committee on the Analysis of Fats and Oils.

The Committee favored the appointment of a Committee on the Analysis and Specifications of Cotton Seed Products; but agreed that any methods made necessary by sudden changes of conditions in the Industry should not have the authorization of the Society until they had passed through the regular channels.

It was voted that the program for the New York meeting consist largely of conferences rather than so many regular papers.

It was voted that an advisory committee be appointed to determine the length of time a paper shall have on the program.

The Committee favored the suggestion that papers, of which an abstract is submitted to the committee before the meeting, be allowed five minutes and that the committee shall allow more time at their discretion.

The Committee favored the suggestion that the author of a paper give, before the Division, the object of his work and a summary of the results and leave the details to be brought out in discussion.

S. H. SALISBURY, JR., *Secretary*.

#### DIVISION OF ORGANIC CHEMISTRY.

The Division met with the regular officers present. No business was transacted.

### DIVISION OF PHARMACEUTICAL CHEMISTRY.

The Division met with the regular officers present. No business was transacted.

### DIVISION OF PHYSICAL AND INORGANIC CHEMISTRY.

The following motion was unanimously passed:

"That a committee of three be appointed by the chair to arrange the program of the Division of Physical and Inorganic Chemistry for the September meeting of the Society. No paper exceeding five minutes in length shall be read before the Division unless an abstract is received by the Committee and approved by them. No member shall present more than one paper before the Division unless an abstract of each paper be received and approved by the Committee."

The Division appointed James Kendall, W. D. Bancroft, and Colin G. Fink as the program committee for the annual meeting.

The Chairman of the Division, Irving Langmuir, was present and presided.

### DIVISION OF WATER, SEWAGE, AND SANITATION.

The Division met with Chairman Edward Bartow in the Chair. R. B. Dole was elected Secretary, *pro tem*.

The following report of the Committee on Standard Methods for the Examination of Water and Sewage was presented and accepted:

The chief methods which have been added to the Second Edition of Standard Methods of Water Analysis published by the American Public Health Association and now being revised by your committee in collaboration with a committee of the American Public Health Association and the Referees of the Association of Official Agricultural Chemists are methods for the examination of sewage sludge and muds, for chemicals used in water treatment, and for available chlorine. The diction of the former edition has been extensively revised in the interest of attaining unity and clearness. The methods have been rearranged in groups and classified in order to make them more logical. The determinations of total acidity by titration with sodium carbonate in the presence of phenolphthalein, of manganese by Knorre's volumetric persulfate method and by the lead peroxide method, of lime and soda value and of caustic alkalinity by the silver nitrate method will be omitted from the third edition. This edition is now in galley proof.

As above indicated, details of the meeting and of the papers offered to the various Divisions will be found in the May issue of the *Journal of Industrial & Engineering Chemistry* and need not be reprinted here.

CHARLES L. PARSONS, *Secretary*.

## DIRECTORS' MEETING.

The Directors of the American Chemical Society met in the Chemistry Building of the University of Illinois on Wednesday morning, April 19, at 11 o'clock, with President Herty in the chair and Directors Bigelow, Bogert, Parsons, Smith and Whitney present.

The payment of \$1,800 by the Finance Committee to The Chemists' Club on account of the Morris Loeb Museum fund was approved by the Directors.

The recommendation of the Council regarding the printing of the ten-year index to *Chemical Abstracts* was considered by the Directors and formally approved by them. It was voted that Mr. Crane be authorized to proceed with the compilation of this index, employing the necessary assistance therefor on the basis of his estimate of \$6,500 for compilation purposes; that he be authorized to obtain bids for the printing of the index and to present these to the Directors for further action at their December meeting.

It was voted that the price for the index to *Chemical Abstracts*, unbound, be \$10.00 to members subscribing up to January, 1917; thereafter the price should be \$12.00 to members. It was voted that the price to all non-members of the Society subscribing after the announcement to be made in the May 10 issue of *Chemical Abstracts* should be \$15.00.

It was voted that the Secretary be authorized to solicit and receive subscriptions from chemical manufacturers toward the cost of publishing the ten-year index to *Chemical Abstracts*, as it was estimated that the cost of publishing would be about \$10,000 in excess of the \$20,000 advance subscriptions already received.

It was voted that such part of \$75.00 as may be necessary to meet the expenses of the Allyn Committee be appropriated.

It was voted to appropriate the usual annual contribution of \$100.00 to the Annual Tables of Physical & Chemical Constants, and an extra \$100.00 owing to the special difficulties which our foreign colleagues have to meet at the present time.

The question of advertising rates in the journals of the American Chemical Society was discussed by the Directors. It was voted to ask Messrs. E. G. Love, M. C. Whitaker, and B. C. Hesse to act as an Advertising Committee for the Directors during the year 1916. The Secretary was directed to request the Advertising Committee to consider at once the question of an advance in the rates of advertising in our journals and take early action thereon, as the Directors considered the matter urgent.

CHARLES L. PARSONS, *Secretary*.

## COUNCIL.

President Herty appointed the following to represent the Society on the occasions noted after their names:

M. T. Bogert, Chas. L. Parsons, George D. Rosengarten, Edward Bartow, H. E. Barnard—Spring Meeting of the National Conservation Congress.

T. W. Richards—Dedication of the New Buildings of the Massachusetts Institute of Technology.

Leroy W. McCay—Celebration of the 150th Anniversary of the Founding of Rutgers College.

### Minutes of the Council Meeting.

The Council of the American Chemical Society met in the Chemical Building of the University of Illinois on Monday, April 17, at 8 P.M., the following councilors being present: Atkinson, F. C.; Bailey, E. H. S.; Bancroft, W. D.; Barton, G. E.; Bartow, Edward; Bigelow, W. D.; Bogert, M. T.; Boyles, F. M.; Bryan, T. J.; Byers, H. G. (substitute); Campbell, A.; Chamot, E. M.; Coover, W. F.; Crane, E. J.; Derick, C. G.; Fischer, Richard; Frankforter, G. B.; French, D. K.; Goldbaum, J. S.; Henderson, W. E.; Hendrixson, W. S.; Hollinshead, W. H.; Howe, H. E.; Hudson, C. S.; Hunter, W. H.; Johnson, T. B.; Johnston, John; Jones, Grinnell; Jones, L. W.; Langmuir, Irving; Lowenstein, Arthur; Mabery, C. F. (substitute); Magruder, E. W.; Nickell, L. F. (substitute); Noyes, W. A.; Parr, S. W.; Phelps, I. K.; Phillips, F. C.; Schlundt, Herman; Smith, Alexander; Sosman, R. B.; Stieglitz, Julius; Talbot, H. P.; Taylor, A. N. (substitute); Tolman, L. M.; Tower, O. F.; Tuttle, F. E.; Washburn, E. W.; Watkins, W. H.; Whitney, W. R.

The appointment of Mr. W. B. Price as representative of the American Chemical Society on the Committee of the Institute of Metals Advisory to the Bureau of Standards was approved.

The appointment of Dr. Charles Baskerville to represent the American Chemical Society on the "Joseph A. Holmes Memorial" Committee was approved.

The death of Mr. Charles A. Catlin, Councilor since 1898, was announced to the Council. A committee consisting of W. R. Whitney, W. A. Noyes, and H. P. Talbot was appointed to draw up suitable resolutions to be transmitted to the family of Mr. Catlin and to be published in the *Journal of Industrial & Engineering Chemistry*.

It was voted to establish a local section with headquarters at Burlington, Vt., with territory covering the State of Vermont, as soon as a waiver of jurisdiction can be obtained from the Northeastern Section.

It was voted to continue the towns of Sewanee and Richard City, Tenn., in the territory of the Nashville Section.

It was voted to establish a local Section with headquarters at Vermilion, S. D., including the territory of the State of South Dakota.

It was voted to refer to the editors, with power, the question of reversing the order of publication of the *Journal of Industrial & Engineering Chemistry* and the *Journal of the American Chemical Society*.

The invitations from the Kansas City Section of the American Chemical Society and from the University of Kansas to hold the Spring meeting of 1917 in Kansas City, Mo., and in Lawrence, Kansas, were accepted.

A communication was presented to the Council by E. J. Crane, Editor of *Chemical Abstracts*, showing that nearly Twenty Thousand Dollars has been raised by subscription from members of the American Chemical Society for the printing of a ten-year index to *Chemical Abstracts*, and that Thirty Thousand Dollars would be required to print the necessary number of copies. After discussion, it was moved that the Council recommend to the Directors that a ten-year index to *Abstracts* be published in 1917.

A letter from Mr. Thomas B. Freas, of Columbia University, New York City, was presented to the Council by Professor Alexander Smith, regarding the question of duty-free importations of chemical apparatus. It was voted to appoint a committee to consider the whole matter and report at the next meeting of the Council. President Herty appointed a committee consisting of Alexander Smith, Chairman, Arthur H. Thomas, and Wm. McPherson.

Upon request of the Bureau of Mines, a committee of the American Chemical Society, of whom President Herty should be chairman, was appointed as an advisory committee to the Bureau of Mines on chemical problems in connection with its investigations. The committee consists of C. H. Herty, L. H. Baekeland and W. R. Whitney.

The Council passed a unanimous vote of thanks to the following organizations and individuals for efficient assistance given by them toward the success of the Urbana meeting:

President Edmund J. James and the Trustees of the University of Illinois, for their interest and coöperation.

Chamber of Commerce, Champaign, Illinois, C. W. Murphy, Managing Secretary, for their part in the complimentary smoker.

Commercial Club, Urbana, Illinois, W. D. Miles, Secretary, for their part in the complimentary smoker.

Professor Isabel Bevier, Woman's Building, University of Illinois, Chairman of the Ladies Committees, and the members of the Committee, for the entertainment of the ladies.

Dr. H. L. Olin, Chemistry Building, University of Illinois, and Mr. A. N. Bennett, of State Water Survey, Urbana, Illinois, for organizing and superintending the exhibit of chemical industries.

Professor J. M. White, Supervising Architect, Administration Building, University of Illinois, for coöperation with the committee in making plans for the meeting and in the efficient services given by himself and his assistants before and during the meeting.

John Glover, Illinois Traction Company, Urbana, Illinois, for coöperation in planning and carrying out the special excursion to Danville.

H. J. Pepper, Superintendent Street Railway Co., Champaign, Illinois, for arrangements for special cars after the council meeting, smoker and banquet.

Danville Chamber of Commerce, Danville, Illinois, P. L. Wills, Secretary, for entertainment of the Society at luncheon.

J. W. Hegeler, President Hegeler Zinc Co., Danville, Illinois, for privilege of visiting the Hegeler plant.

W. G. Hartshorn, President, Two Rivers Coal Co., Danville, Illinois, for arrangements for visit to the strip coal mine and the special trouble he took to have the plant operated for the members of the Society.

F. W. Butterworth, Danville, Illinois, General Manager, Western Brick Company, for permission to visit the plant of the Western Brick Company.

Danville Rotary Club, Thomas J. Corsey, Secretary, Danville, Illinois, for their assistance in entertaining the members of the Society.

Illinois Window Glass Co., Chas. Robasse, Manager, Danville, Illinois, for the privilege of visiting the works of the glass company.

Major R. W. Mearns, 12th Infantry, U. S. A. Commandant, University of Illinois, for the arrangements for the brigade drill.

Professor A. A. Harding, Director of the University of Illinois Band, for the band concert.

McIntosh Stereopticon Co., 30 E. Randolph St., Chicago, Illinois, for furnishing lanterns for all of the sectional meetings and for the courtesy and efficiency of Mr. Price, the manager.

Dean E. Davenport, Agricultural College, University of Illinois, for arrangements for visits to the Agricultural College and especially for the assistance rendered by Professor Rankin and Mr. Checkley in planning the excursion and in carrying it out.

Dean W. F. M. Goss, College of Engineering, University of Illinois, for visit to the Engineering College, especially to B. W. Benedict in arranging the program and carrying it out.

G. D. Worthington, Hotel Beardsley, Champaign, Illinois, for his successful management of the banquet and for his interest and coöperation in caring for the members of the Society.

F. R. Smedley, District Deputy, Grand Master, Order of Masons, Champaign, Illinois, for his kindness in allowing us the use of the banquet room and first floor of the Masonic Temple for an assembly room and for cloak room.

Cosmopolitan Club, Champaign, Illinois, for their part of the entertainment at the smoker.

Mr. H. A. Winkelmann, Chemistry Building, University of Illinois, for his management of the checking arrangements at the banquet and Mr. W. F. Langelier for his management of the checking arrangements at the smoker.

Chairmen and members of the local committees to whom the success of the meeting was chiefly due.

It was voted that the reports of the Committee on Water Analysis and the Committee on Coal Analysis be adopted and approved by the American Chemical Society when these reports have received the approval of the Supervisory Committee on Standard Methods of Analysis.

The committee of the American Chemical Society consisting of Julius Stieglitz, Lauder W. Jones, Lucius P. Brown, A. D. Thorburn, and E. H. S. Bailey, presented the following report, which, after discussion and minor amendment, was unanimously adopted in the following form by the Council:

#### **Report of the Committee on the Westfield Campaign and Mr. Lewis B. Allyn's Connection Therewith.**

Your committee begs to report as follows:

I. After due consideration of the facts and evidence presented we recommend that no further action be taken leading to the expulsion of Mr. Lewis B. Allyn from our Society, and we recommend that the St. Louis Section be so informed.

II. Special pure food movements, of which the so-called Westfield campaign is but one, seem to have originated and received their impetus from the recognition of the fact that the public desires a positive guarantee of the purity of foods and of toilet preparations. This demand is indeed appreciated by public officials but the recognition in a positive sense, of individual articles is as yet the exception and not the rule. The most common form of public service in this field by the national government, the states, the municipalities, consists rather in exposing misbranded or fraudulent preparations, in prosecuting infringements of the law and in assisting manufacturers to comply with legal requirements.

On the other hand, those special movements which have been exploited by magazines and other publications in connection with their advertising columns must be considered *altogether wrong in principle and opposed to the best interests of the public*. The following are the reasons leading to this conclusion. All or part of them apply, we believe, to the various individual forms, which movements of this kind have taken.

(1) Almost without exception, profiting financially by means of advertising is directly connected in one way or another with such campaigns. The movements are therefore not *disinterested*. In the very nature of the case pressure is quite likely to be exerted by advertising departments on the editorial department and on the policy of the publication. A bias may thus be created, which has no proper place in matters demanding purely scientific and judicial decisions. This bias in debatable cases, will often lead men, consciously or unconsciously, to yield to private gain rather than to public interests. Furthermore, for the sake of large financial returns, such a campaign is almost certain to be used by some agent or other, such as the advertising manager, to bring what must be considered an illegitimate kind of pressure to bear on those who advertise food products or toilet preparations, to have their advertisements appear in the publication conducting the campaign. Such a campaign in itself must be considered a form of unfair coercion.

(2) Special campaigns of this character have neither the large means nor the high scientific standing needed to secure a really efficient and reliable guarantee to the public. Any guarantee which they afford may become utterly worthless, and, by inducing a false sense of security, may indeed do positive harm, if it is not supported by *continuous* control, including unexpected examinations, and by persistent official inspection covering all phases of food control, such as the inspection of the places and methods of manufacture, their sanitary surroundings, and the quality and condition of materials used. The public control of the milk supply, as it has developed in recent years in some of our larger municipalities, is an illustration of what adequate control must aim at.

In the light of all experience these special campaigns are likely to be supported by wholly inadequate chemical and bacteriological staffs and by altogether insufficient forces of inspectors, for the indispensable routine work of the thorough-going and continuous control by analysis and inspection. This defect, quite aside from motives of gain underlying a campaign, makes such a propaganda a very questionable value to the public.

(3) In place of developing and adopting standards on the basis of exhaustive and authoritative investigations by men of the highest scientific training and experience and of obviously disinterested motives,

such campaigns as a rule depend on the dictum of some single self-constituted "authority," possibly having little or no scientific standing, often of narrow training and experience. Proper organization of such a movement demands facilities for disinterested scientific investigations by a staff of chemists, bacteriologists, physiologists and physiological chemists, or at least should depend for its final authoritative control on the combined judgment of a group of men of special training and recognized standing in these lines of scientific work.

III. In view of the defects of endorsement of preparations by special food movements, as exploited by magazines and other publications, and in order that the just demand of the public for positive information guaranteeing the purity of food and toilet articles, may be properly satisfied, the committee would urge that the Society consider formulating plans to be laid before governing bodies, which would lead to some kind of direct certification of food and toilet articles, by the national government, by properly organized and equipped departments of the states and larger municipalities, or some other forms of responsible control.

The preparation of a detailed plan involves questions of considerable difficulty, which the short time at the disposal of the committee has not made it possible for its members to study and decide. The committee, therefore, recommends that the formulation of such plans be referred to a special committee of the Council.

(The following paragraph of the report of your committee was proposed and endorsed by the non-official members of the committee:)

These larger plans for public control are so much more justified as the Council of the American Chemical Society, in common with all well informed men, knows that the country has reason to have the highest degree of pride and confidence in the integrity, the disinterestedness and the competent character of the work done in the past and at present by the men engaged in the government food control.

An expression of thanks was unanimously voted to Dr. Stieglitz and the members of his Committee for their efficient handling of this difficult problem.

The following two suggestions of amendments to the By-Laws were presented by the Committee appointed to consider the Allyn matter:

1. The Chairman of the Committee on Membership shall submit a monthly report for publication in the Proceedings of the Society which gives the name, residence, and occupation of each nominee, and the names and residence of his nominators. Final action shall be taken by the Committee on these names only after thirty days have elapsed since the publication in the Proceedings.

2. Any motion for the expulsion of any member of the Society shall

be submitted first in confidence (without further divulging the name of the member) to the President of the Society with a full statement of the *prima facie* evidence on which the motion is based. The President, in conjunction with the two ex-Presidents preceding him most immediately in office, shall form a committee with full power to decide whether the motion shall be dropped without further action and without report to the Council; whether the accused member shall be allowed to resign without report to the Council, or whether the motion shall be referred, without prejudice, to a special committee of the Council for further investigation and report to the Council.

After some discussion the Council voted to refer these two amendments to a committee of three to be appointed by the President to prepare a report and submit same to the Secretary in time to present to the Council for action at the September meeting. The President appointed W. A. Noyes, M. T. Bogert, and F. K. Cameron.

On the motion of Mr. H. E. Howe it was voted that a committee be appointed to consider the formation of a publicity bureau, whose duties shall include the publication of chemical articles to offset objectionable matter so often appearing in the public press. The President appointed H. E. Howe, Ellwood Hendrick, and A. V. H. Mory.

The following committees reported to the Council:

Committee on Patent Legislation:

Report will be printed in full in the *Journal of Industrial and Engineering Chemistry*.

Committee on Inventions by Government Employees presented to the Council a statement of present conditions, but made no recommendations. The report was placed on file.

A statement was received from the Chairman of the Committee on Professional Ethics, but as the matter had not received the approval of the full Committee, it was voted to continue the Committee and request them to complete their report and submit same to the Council in writing in advance of the meeting at which it is to be considered.

The Supervisory Committee on Methods of Analysis reported as follows:

In accordance with the provision of the Constitution, relative to Standing Committees, I submit to you, for presentation to the Council, my report as Chairman of the Supervisory Committee on Methods of Analysis, covering the period since March 17, 1915, the date of my last report (Proceedings, 1915, p. 50).

#### I. COMMITTEES OF THE GENERAL SOCIETY.

##### 1. *Committee on Revision of Methods of Coal Sampling and Analysis.*—

A joint committee representing the American Chemical Society and the American Society for Testing Materials.

A final report of the above named committee was submitted to the American Society for Testing Materials at its meeting last Summer. According to the rules of that Society, such a report must be considered tentative for one year. The report has received the unanimous approval of the committee of our own Society and upon final adoption by the coöperating Society will be submitted to the Supervisory Committee on Methods of Analysis for acceptance on behalf of the American Chemical Society.

There are some important considerations connected with coal analysis still under discussion among the chemists of the country, especially the question of the fusibility of the ash of coal and methods for the analysis of coke, which are now in the hands of another committee with which the Committee on Coal Analysis is coöperating. On this account both societies will be asked to continue the joint committee.

2. *Committee on Methods of Analysis of Potable Waters and Sewage.*—A committee of the American Chemical Society, working in conjunction with one from the American Public Health Association and with representatives of the Association of Official Agricultural Chemists.

The report has been completed, but will be submitted for final criticism before adoption by the Water, Sewage, and Sanitation Division of the American Chemical Society and the Laboratory Section of the American Public Health Association.

## II. DIVISIONAL COMMITTEES.

A. Division of Industrial Chemistry and Chemical Engineers. Chaos still rules with respect to the relation to each other of the Committees of this Division.

1. *Committee on Standard Specifications and Methods of Analysis.*—This committee still lacks a head and has been entirely inactive during the year. Committees supposedly under its control, if active, are acting independently of it.

(a) *Committee on Non-Ferrous Metals and Alloys.*—The reports on copper and spelter from this committee referred to in my report of last year, having received the approval of the Supervisory Committee on Methods of Analysis, were printed in the *Journal of Industrial and Engineering Chemistry*, 7, 546-7. The committee has had to postpone further work for the present.

(b) *Committee on Soap and Soap Products.*—No active work has been done by this committee, but a tentative set of methods will be considered at the Urbana meeting of the Society for trial by the committee and those who may be willing to coöperate. It is proposed that where the methods overlap the work of other committees in and outside of the

Society, they be coördinated. For the better attainment of this result it is suggested that two outside committees be recognized as committees of the Division.

(c) *Committee on Glycerine*.—At present this is a sub-committee of that on Soap and Soap Products, but the latter committee is disposed to recommend to the Division that it be given independent standing. The Chairman of the Glycerine Committee has in preparation an article on the bi-chromate method for the determination of glycerine and a new specific gravity table based on a new method of preparing pure glycerine.

#### B. Division of Fertilizer Chemists.

1. *Committee on Research and Methods of Analysis*.—Nothing has been learned regarding the work of this committee and of its several sub-committees, notwithstanding the efforts made by myself to secure reports.

#### C. Division of Pharmaceutical Chemistry.

1. *Committee on Quantitative Methods*.—No work done during the year.

#### D. Section of Rubber Chemists.

1. *Committee on Analysis of Rubber and Rubber Products*.—This committee has been inactive during the year. The Chairman writes that the committee needs reorganizing in consequence of the resignation of two of its members and the inability of a third to do active work.

W. F. HILLEBRAND, *Chairman*.

The Committee on Occupational Diseases presented the following report:

1. The Committee on Occupational Diseases in Chemical Industry purposes having a symposium on the subject at the New York Meeting of the Society.

2. The unusual development of coal-tar color and explosives industries in the United States, due to the War, has laid some emphasis upon the necessity for improving ventilation and taking more care to destroy certain fumes as precautions against occupational diseases arising from their inhalation. Information as to several such cases has come to hand.

3. A surgeon of the United States Public Health Service has been specially assigned to the study of Occupational Diseases. He is at present carrying on his investigations in the Pittsburgh district.

4. The effort at the enactment of a *uniform* law in all the states in regard to wood alcohol has progressed by its introduction in the Legislatures of Kentucky and New York.

5. Trouble arising from dust of vanadium ores has been overcome at the Denver radium plant by suitable dust removers. The use of sponges over the noses and mouths of the men sampling iron vanadate at the same plant has not proved to be a sufficient protection. After a few

hours' work the men cough and get a feeling of lassitude with a tightness in the chest and throat. If the work be continued, pains follow. The effects wear off after a few days' rest. No permanent injury has been reported.

6. An investigation of the pathological effects of Port Oxford Cedar dust is under way.

Respectfully submitted,

CHAS. BASKERVILLE, *Chairman.*

The Committee on Exchanges reported that fourteen new exchanges had been put into effect during the past year; that three old exchanges had been discontinued, and five offers to exchange had been declined.

The Finance Committee reported as follows:

The Finance Committee begs to report for the fiscal year ending November 30, 1915, that the financial affairs of the Society are in a very satisfactory condition.

The Report and Balance Sheet submitted by the Treasurer have been properly audited by certified Public Accountants, under the direction of the Committee, and the same have already been printed in the Proceedings for February.

During the year New York City Bonds to the amount of \$2,000, at  $3\frac{1}{2}\%$ , which fell due in October, were re-invested in similar bonds at  $4\frac{1}{2}\%$ .

Since the close of the last fiscal year, the Society, as Trustee of the Morris Loeb Museum Fund, has paid to The Chemists' Club \$1,800, making a total of \$2,500 paid to the Club under the Trust.

Respectfully submitted,

E. G. LOVE,

G. C. STONE,

A. E. HILL,

*Finance Committee.*

The Committee on Paper reported that they had carefully followed the quality of the paper used in the Society's publications during the past year; that the quality had not been entirely up to specifications, but that they hoped this could be remedied in the future.

The Committee on Membership reported that during the past year 877 members have been elected, two Corporation Members and one Honorary Member.

The Perkin Medal Committee reported the awarding of the Perkin Medal for 1916 to Dr. Leo H. Baekeland, of Yonkers, N. Y.

The American Chemical Society representative on the Committee on Supervision of the Chemical Engineering Catalog reported progress, and

that the assistance of the Committee had been of value to the publishers. It was reported that they hoped such a Chemical Engineering Catalog would be issued during the coming Fall.

Professor F. C. Phillips presented a communication to the Council regarding a memorial to Joseph Priestley. Professor Phillips' report had been previously presented to the Pittsburgh Section of the American Chemical Society; had been adopted by them and recommended to the Council of the Society. The Council voted that the President should appoint a committee to decide upon a Priestley Memorial, with power to carry out their conclusions and to solicit funds therefor. President Herty appointed the following committee: F. C. Phillips, *Chairman*; M. T. Bogert, E. D. Campbell, F. W. Clarke, E. C. Franklin, J. Lewis Howe, J. H. Long, E. W. Morley, A. A. Noyes, W. A. Noyes, Ira Remsen, Alfred Springer, F. P. Venable, C. F. Chandler.

The following committees have been appointed for 1916-17 by President Herty:

Committee for Annual Report on Atomic Weights: G. P. Baxter.

Committee on Exchanges: E. J. Crane, *Chairman*; W. A. Noyes, M. C. Whitaker.

Finance Committee: E. G. Love, *Chairman*; A. E. Hill, G. C. Stone.

Committee on Methods of Analysis for Potable Waters and Sewage: Edward Bartow, *Chairman*; E. H. S. Bailey, H. E. Jordan, W. P. Mason, W. W. Skinner.

Committee on Nomenclature and Spelling: Editors of the Society's journals.

Committee on Occupational Diseases: Chas. Baskerville, *Chairman*; Geo. P. Adamson, H. K. Benson, Chas. E. Coates, Wm. Lloyd Evans, F. W. Frerichs, H. W. Gillett, Edward Gudeman, Milton I. Hersey, Earle B. Phelps, S. R. Scholes, F. N. Smalley.

Committee on Paper: F. P. Veitch.

Committee on Patent and Related Legislation: L. H. Baekeland, *Chairman*; Carleton Ellis, E. A. Hill, A. D. Little, C. P. Townsend, W. R. Whitney.

Committee on the Revision of Methods of Coal Sampling and Analysis (Joint with the Society for Testing Materials): W. A. Noyes, *Chairman*; Perry Barker, A. C. Fieldner, W. F. Hillebrand, A. H. White.

Committee on Code of Professional Ethics: A. D. Little, *Chairman*; L. H. Baekeland, W. D. Bancroft, Wm. Brady, F. K. Cameron.

Committee on Supervision of Chemical Engineering Catalog: Raymond F. Bacon, American Chemical Society's representative.

Supervisory Committee on Standard Methods of Analysis: W. F. Hillebrand, *Chairman*; Clifford Richardson, Geo. C. Stone, H. P. Talbot.

Membership Committee: Frank K. Cameron, *Chairman*; W. D. Bigelow, Charles L. Parsons.

Committee on Endowment: I. K. Phelps, *Chairman*; A. Lowenstein, F. R. Eldred.

Committee on Inventions by Government Employees: L. H. Baekeland, Wm. M. Grosvenor.

Perkin Medal Committee: J. M. Matthews, *Chairman*; T. B. Wagner, A. M. Comey, E. G. Love, George D. Rosengarten, M. Toch, J. C. Olsen, D. Wesson.

CHARLES L. PARSONS, *Secretary*.

#### MEMBERS ELECTED BETWEEN APRIL 15 AND MAY 15, 1916.

- Acton, Walter, 9 Trees Park Ave., Barrhead, Scotland.  
 Adams, Howard W., 409 W. Willow St., Normal, Ill.  
 Adams, Robert H., 56 Pingree Ave., Detroit, Mich.  
 Anderson, George A., 403 Emerson Ave., Syracuse, N. Y.  
 Backstrom, R., 576 Mission St., San Francisco, Calif.

#### CORPORATION MEMBER.

The Pfaudler Co., 217 Cutler Bldg., Rochester, N. Y.

### MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505, Washington, D. C.]

#### ALABAMA SECTION.

The May meeting was held May 6th. Dr. Clarence N. Wiley read a paper on, "The Role of the Chemist in the Cement Industry." The retiring President, Dr. Stewart J. Lloyd, gave a talk on "Isotopic Elements." Prof. B. B. Ross, who is the Alabama member of the National Committee on Preparedness, told of the purpose of his committee and asked coöperation of every member.

The officers for the ensuing year were elected as follows: *President*, A. H. Olive; *First Vice-President*, J. P. Montgomery; *Second Vice-President*, C. N. Wiley; *Secretary-Treasurer*, Wm. H. Beers, Jr.; *Councilor*, 1916, Stewart J. Lloyd.

WM. H. BEERS, JR., *Secretary*.

#### SOUTH DAKOTA SECTION.

The Section met in its organization meeting on May 6th. The following program was given: "The Free Energy of Dilution of Sulfuric Acid," by Orville E. Cushman and Merle Randall; "A Study of Canned Salmon, A Preliminary Note," by Cecil Clemens and Sylvanna Elliott; "A Modified Scheme for Qualitative Analysis," by O. R. Overman; "The Nitro Phenyl

Ethers," by Hilton Ira Jones and Alfred N. Cook; "Some Subjects under Investigation in The Chemical Laboratories of the University of South Dakota," by Alfred N. Cook.

The following officers were elected: *President*, Alfred N. Cook; *Vice-President*, B. A. Dunbar; *Secretary*, H. I. Jones; *Treasurer*, H. F. Hadley; *Councilor*, O. R. Overman.

HILTON IRA JONES, *Secretary*.

#### MILWAUKEE SECTION.

The April meeting was held the 21st. Mr. C. J. Atkinson, Metallurgical Engineer, gave a lecture, illustrated by lantern slides, on the "Metallography of Iron and Steel."

A meeting was held May 10th. Dr. H. E. Horton of the American Steel & Wire Co., Chicago, gave a lecture entitled: "Through the Furnace to the Farm."

H. T. McALLISTER, *Secretary*.

#### NORTHERN INTERMOUNTAIN SECTION.

The Section held its annual meeting May 6th. Program: "Two Methods for the Separation of the Alkaline Earth Group," by Professor Alice G. Paterson; "Recent Advances in Ore-Dressing," by Dr. R. R. Goodrich; "Composition and Baking Value of Dry Farmed and Irrigated Wheat," by Professor J. S. Jones; "Electric Laboratory Heating Device," by Harry Redekey Rupert.

The following were elected as officers for 1916: Professor Carl M. Brewster, *Chairman*; Dr. John A. Kostalek, *Vice-Chairman*; Professor Geo. A. Olson, *Councilor*; Professor H. A. Holaday, *Secretary-Treasurer*.

GEO. A. OLSON, *Secretary*.

#### INDIANA SECTION.

A meeting was held April 21st. Dr. Chas. H. Herty delivered an address on "Chemistry as an Aid to the Efficiency of Democracy."

The regular meeting was held May 13th. Program: "Detection of Nickel and Cobalt Salts," by A. R. Middleton; "Nonprotein Forms of Nitrogen in Alfalfa," by R. H. Carr; "Electromotive-Force Measurements with Tenth Normal Hydrochloric Acid and Calomel Electrodes," by N. E. Loomis.

H. W. RHODEHAMEL, *Secretary*.

#### COLUMBUS SECTION.

The May meeting was held May 5th. Program: "Rate of Absorption of CO<sub>2</sub> by Soda-lime," by Professor C. W. Foulk; "Determination of Transition Points by Difference of Potential Methods," by Mr. I. M. Geiger.

Review of the Urbana meeting of the American Chemical Society, Mr. E. J. Crane; Professor G. O. Higley, Ohio Wesleyan; Professor Wm. E. Henderson; Professor James E. Withrow.

WM. J. McCaUGHEY, *Secretary*.

## CALIFORNIA SECTION.

The ninety-first regular meeting was held April 15th. Program: "Borax and Its Uses," by Mr. T. M. Cramer, Superintendent, Pacific Coast Borax Company; "The Chemistry of Copper Ore Enrichment," by Professor S. W. Young, of Stanford University.

On May 2nd there was held a joint meeting on military preparedness.

*San Francisco Sections:* American Chemical Society; American Institute of Electrical Engineers; American Society of Mechanical Engineers; American Institute of Mining Engineers; American Society of Civil Engineers.

Three papers were presented: "Methods by Which the Civilian Engineers Can Prepare Themselves to Assist the Engineer Corps of the U. S. Army in Case of War," by Capt. Richard Park, Engineer Corps, U. S. A.; "The Work at the Military Training Camps," by Capt. John Murphy, Coast Artillery, U. S. A.; "An Outline of the Work of the Organization for Industrial Preparedness of the Naval Consulting Board," by A. H. Babcock, Member of the Naval Consulting Board.

BRYANT S. DRAKE, *Secretary*.

## PITTSBURGH SECTION.

The 126th regular meeting of the Section was held April 20th. Program: "Constitution of Porcelains," by A. A. Klein; "Manufacture of Table Glass Ware," by S. R. Scholes.

W. C. COPE, *Secretary*.

## ST. LOUIS SECTION.

The regular meeting was held April 4th. Program: Mr. W. C. Hamilton, Chief Chemist of the American Steel Foundry, addressed the Section on, "Modern Methods in the Manufacture of Steel Castings."

The May meeting was held May 1st. Program: "The Biological Chemistry of the Colon Group," by Dr. Frederick A. Baldwin.

GEO. LANG, JR., *Secretary*.

## NORTH CAROLINA SECTION.

The spring meeting was held April 29th.

The following officers were elected for the ensuing year: *President*, Dr. J. K. Plummer, Raleigh, N. C.; *Vice-President*, Dr. H. B. Arbuckle, Davidson, N. C.; *Secretary-Treasurer*, F. E. Carruth, West Raleigh, N. C.; *Councilor*, Dr. A. S. Wheeler, Chapel Hill, N. C.; *Reporter*, L. B. Rhodes, Raleigh, N. C.

The following papers were presented: "The Action of Ammonia on Arsenic Iodide," by Dr. Chas. H. Herty and C. B. Carter; "Some Properties of the Solutions of Substantive Cotton Dyes," by F. E. Carruth; "Electrolysis of Certain Inorganic Salts in Liquid Ammonia Solution,"

by C. F. Miller; "The Chemistry of Gossypol," by Prof. W. A. Withers and F. E. Carruth.

J. T. DOBBINS, *Secretary*.

#### IOWA SECTION.

The annual meeting was held Saturday April 29. Program: "Electromotive Forces and Electrode Potentials in Pure and Mixed Solvents. II," by F. S. Mortimore and J. N. Pearce; "Barium in Tobacco," by Nicholas Knight; "Pure Sodium Chloride," by Nicholas Knight; "Acid Potassium and Sodium Phthalates as Standards in Acidimetry and Alkalimetry" (Second Paper), by W. S. Hendrixson; "An Improved Method of Solubility Determination," by W. S. Hendrixson; "Auxo-amylases," by E. W. Rockwood; "Conditions Existing in Solutions near the Critical Temperature" (a preliminary paper), by P. A. Bond.

By invitation the following papers were read: "A Comparison of Barbituric Acid, Thiobarbituric Acid and Malonylguanidine as Quantitative Precipitants for Furfural," by A. W. Dox and G. P. Plaisance, Agricultural Experiment Station, State College; "An Accurate Aeration Method for Determining Alcohol in Fermentation Mixtures," by A. W. Dox and A. R. Lamb, Agricultural Experiment Station, State College; "Relative Influence of Bacteria and Enzymes on Silage Fermentation," Preliminary Report, by A. R. Lamb, Agricultural Experiment Station, State College; "Estimation of Calcium in Ash of Forage Plants and Animal Carcasses," by S. B. Kuzirian, Agricultural Experiment Station, State College.

P. A. BOND, *Secretary*.

#### WISCONSIN SECTION.

The April meeting was held April 26th. Professor O. L. Kowalke spoke on "Some Characteristics of Base Metal Thermocouples."

The May meeting was held May 10th. Prof. M. A. Rosanoff, of Mellon Institute, spoke on "The Theory of Distillation."

L. F. AUGSPURGER, *Secretary*.

#### ROCHESTER SECTION.

A meeting was held May 1st. Dr. W. R. White of the Geophysical Laboratory, Washington, D. C., gave a talk on "The Development of Calorimetry."

A meeting was held May 15th. Program: Mr. H. Y. Norwood of the Taylor Instrument Companies gave a talk on "The Mercurial Thermometer and its Adaption to Industrial Arts."

H. H. TOZIER, *Secretary*.

#### LOUISIANA SECTION.

The 94th meeting was held April 21st. Program: "A Preliminary Report on Raw Materials Available for Certain Louisiana Chemical Industries, by the Committee on Resources," by Dr. Chas. E. Coates, *Chairman*.

F. W. LIEPNER, *Secretary*.

## UNIVERSITY OF MICHIGAN SECTION.

The April meeting was held April 27th. Dr. Oliver Kamm gave a paper on "Some Relationships between Ionization and Structure in Unsaturated Acids."

H. H. WILLARD, *Secretary*.

## NEW HAVEN SECTION.

A meeting was held April 14th. Dr. B. C. Hesse addressed the Section on "The Experimental Methods of the Badische Anilin and Soda Fabrik."

GEORGE S. JAMIESON, *Secretary*.

## DETROIT SECTION.

The 80th regular meeting was held April 15th. Program: Dr. H. P. Talbot, Dean of Chemistry and Chemical Engineering of the Mass. Institute of Technology, lectured on "The Rare Gases."

The 81st regular meeting was held May 18th. Program: "Modern Facts on Cider Vinegar," by Floyd W. Robison.

EDWARD J. GUTSCHE, *Secretary*.

## SYRACUSE SECTION.

The 106th regular meeting was held April 21st. Program: "The Flow of Heat through Furnace Walls. Radiation of Heat from Furnaces. Proper Materials to be Used in the Making of Mortar for Use in Furnaces," by Prof. J. W. Richard.

R. S. BOENNER, *Secretary*.

## CHICAGO SECTION.

The regular meeting was held May 19th. At this meeting the Willard Gibbs Medal was presented to Dr. W. R. Whitney. The following officers were elected to serve for the ensuing year: A. V. H. Mory, *Chairman*; C. S. Miner, *First Vice-Chairman*; C. A. Tibbals, Jr., *Second Vice-Chairman*; D. K. French, *Secretary-Treasurer*; A. Lowenstein, L. M. Tolman, A. M. Taylor, W. R. Smith, Wm. Brady, H. N. McCoy, *Councilors* for 1917.

D. K. FRENCH, *Secretary*.

## NEW YORK SECTION.

The 6th regular meeting of the session 1915-16 was held April 7th. Program: "University and Industry," by William H. Nichols, B.S., M.S., LL.D., Sc.D. Discussion by Marston T. Bogert, Columbia University; Elon H. Hooker, Hooker Electrochemical Company; Phoebus A. Levene, The Rockefeller Institute for Medical Research; Benjamin L. Murray, Merck & Company.

C. M. JOYCE, *Secretary*.

## EASTERN NEW YORK SECTION.

The 65th meeting was held April 7th. Dr. H. B. Goodrich lectured on "The Mendelian Theory of Heredity and the Determination of Sex" (illustrated).

The 66th regular meeting was held May 2nd. Program: Subject: "Calorimetry: The Development of Calorimetry," by Dr. W. P. White, Geophysical Laboratory, Washington, D. C. *ALBERT J. SALATHE, Secretary.*

#### WESTERN NEW YORK SECTION.

At the regular meeting, March 23rd, Dr. K. F. Stahl spoke on "Hydrofluoric Acid and Fluorides."

On April 4th a joint meeting was held with Niagara Falls Section, American Electrochemical Society. Dr. Robert B. Sosman, of the Geophysical Laboratory, Carnegie Institution of Washington, spoke on "The Common Refractory Oxides."

*R. H. WHITE, Secretary.*

#### PHILADELPHIA SECTION.

The regular meeting was held May 18th. Program: "The Manufacture of Vaccines and Serums," by C. W. Brown.

*J. HOWARD GRAHAM, Secretary.*

#### LEXINGTON SECTION.

The 33rd regular meeting was held May 11th. Program: "Note on the Occurrence of Gallium," by Dr. R. N. Maxson; "The Growth of Isolated Plant Embryos," by Dr. G. D. Buckner; "On the Reaction between Iodine and Tetrathionate," by Dr. P. L. Blumenthal.

*P. L. BLUMENTHAL, Secretary.*

#### CLEVELAND SECTION.

The May meeting was held in the Chemical Laboratory of Case School of Applied Science May 8th. Prof. C. F. Mabery addressed the Society on "The Relations in Origin and Composition of Coal, Petroleum and the Natural Asphalts."

*A. F. O. GERMANN, Secretary.*

#### WASHINGTON SECTION.

The 261st meeting was held May 11th. Program: "The Preparation of Heavy Metal Salts of Certain Organic Acids," by C. N. Myers, Hygienic Laboratory; "Some Observations upon the Toxicity and Chemotherapy of the Heavy Metals," by G. C. Lake, Hygienic Laboratory; "The Separation and Determination of Small Amounts of Antimony," by Elias Elvove, Hygienic Laboratory.

*E. C. McKEIVY, Secretary.*

#### OREGON SECTION.

The 28th regular meeting was held May 6th. Prof. A. A. Knowlton, of Reed College, presented a paper on "The Synthesis of Metals."

*NORMAN C. THORNE, Secretary.*

## MARYLAND SECTION.

The 14th regular meeting was held May 13th. Program: "Measurement of Osmotic Pressure of Concentrated Sugar Solutions," by R. T. Myrick; "Esterification of Acids by Mercaptans," by J. H. Sachs and J. W. Kimball; "Catalytic Preparation of Nitriles," by G. D. Van Epps; "The Identification of Acids," by J. A. Lyman and E. Emmet Reid; "The Manufacture of Ethyl Alcohol," by H. W. Berger.

FRANK M. BOYLES, *Secretary*.

---

## DECEASED.

Turner, Herbert S., Oglesby, Ill., died April, 1916.

---

# Proceedings.

## COUNCIL.

MEMBERS ELECTED BETWEEN MAY 15 AND JUNE 15, 1916.

- Appel, Maurice, 9 East 38th St., Bayonne, N. J.  
Bashore, E. G., La Tourette Hotel, Bayonne, N. J.  
Belfit, Robert W., 785 North St., Pittsfield, Mass.  
Berger, Emily V., 1602 Louisiana St., Lawrence, Kans.  
Blakemore, Herbert S., Lewiston, Calif.  
Boyce, T. D., Bakersfield, Calif.  
Brede, L. H., 414 N. Morrison Ave., Collinsville, Ill.  
Bridgeman, Oscar C., University of Saskatchewan, Saskatoon, Sask., Canada.  
Brown, Frank E., Jr., 923 So. Jefferson St., Roanoke, Va.  
Buck, Harry C., 3307 N. Broad St., Philadelphia, Pa.  
Clark, O. E., West Middlesex, Pa.  
Cohen, William H., International Correspondence Schools, Scranton, Pa.  
Davies, Emlyn, Nicholson, Pa.  
Delp, Wm. S., 2120 N. Third St., Philadelphia, Pa.  
Drinker, Philip H., South Bethlehem, Pa.  
Essex, Jesse L., 523 Russell St., W. Lafayette, Ind.

## MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505, Washington, D. C.]

### INDIANA SECTION.

The last meeting of this year was held June 9. Program: "Theory and Practice of Making Serums and Vaccines," by Dr. Severance Burgence.

H. W. RHODEHAMEL, *Secretary*.

### ST. LOUIS SECTION.

The Section met June 5. Mr. Edward Mallinckrodt, Jr., read a paper on "The Determination of Water and Alcohol in Ether."

GEO. LANG, JR., *Secretary*.

### KANSAS CITY SECTION.

The 117th meeting of the Kansas City Section was held April 29. An illustrated lecture on "Ancient Chemistry" was given by Professor F. B. Dains.

The 118th meeting was held May 20. Program: "The Chemical Conditions Necessary for Making Alfalfa Silage," C. O. Swanson. "Notes on New and Non-official Remedies and the Propaganda of Reform,"

R. H. Needham. "On the Nutritional Deficiencies of Corn," J. T. Willard.

W. B. SMITH, *Secretary*.

#### EASTERN NEW YORK SECTION.

The 67th regular meeting of the Section was held in Amsterdam June 3. Program: "Manufacture and Uses of Linseed Products," by A. C. Goetz. "The Dye Situation," by Aug. Amrein.

ALBERT J. SALATHE, *Secretary*.

#### NEW YORK SECTION

The 7th regular meeting of the session of 1915-16 was held on May 19 in conjunction with the New York Sections of the American Electrochemical Society and the Society of Chemical Industry, under the auspices of the latter society. Program: "Some Problems in the Petroleum Industry," by Dr. Raymond F. Baker.

The eighth regular meeting of the session of 1915-16 was held June 9. Program: "An Account of Some Experiments Relating to Vapor Pressures, Fractional Distillation, Critical Data and Compressibility of Gases," by George A. Burrell. "The Petrographic Microscope in Analysis," by Frederick E. Wright.

C. M. JOYCE, *Secretary*.

#### NASHVILLE SECTION.

The 41st meeting was held May 19. The program included the following papers: "Studies in Preservation of Diphtherial Toxin, for Schlick's Test," by Dr. Wm. Litterer.

The following officers were elected: J. F. Norris, *Chairman*; W. H. Hollinshead, *Vice-Chairman*; Paul C. Bowers, *Sec.-Treas.*; J. I. D. Hinds, *Councilor*.

PAUL C. BOWERS, *Secretary*.

#### WASHINGTON SECTION.

A joint meeting of the Society of Engineers and this Section was held May 24. Program: "The Machine Shop and the Chemical Laboratory as Related to National Preparedness for Defense," by Mr. Joseph Steinmetz, President of the Aero Club of Pennsylvania.

E. C. MCKELVY, *Secretary*.

#### CINCINNATI SECTION.

The 206th regular meeting was held May 17. Program: "Milk Clarifiers," by Clarence Bahlmann.

E. K. FILES, *Secretary*.

#### UNIVERSITY OF MICHIGAN SECTION.

The May meeting of the Section of the American Chemical Society was held May 23. Mr. C. S. Schoepfle presented a paper on "The Molecular Weights of Free Radicals."

H. H. WILLARD, *Secretary*.

## NEBRASKA SECTION.

The May meeting was held May 27. Program: "Some Substances Essential to Growth," by John W. Calvin. "Life and Work of Professor J. U. Neff," by Dr. F. W. Upson.

H. M. PLUM, *Secretary*.

## PITTSBURGH SECTION.

A special meeting of the Section was held May 25. Program: "Smelter Smoke and Arsenical Poisoning," by W. D. Harkins, Professor of Chemistry, University of Chicago and Chairman of the Chicago Section of the American Chemical Society.

The 128th regular meeting was held June 15. Program: "Chemistry and the Present War: How It May Affect the Future of the Chemical Industries in the United States," by L. H. Baekeland.

W. C. COPE, *Secretary*.

## LOUISIANA SECTION.

The 96th meeting was held June 16. Program: "The Estimation of Minute Quantities of Sulfur Dioxide in the Atmosphere," by C. S. Williamson, Jr. "Notes on the Analysis of Aspirin," by C. L. Clay.

F. W. LIEPNER, *Secretary*.

## CORNELL SECTION.

The regular meeting was held May 23. Program: "Some Topics in Luminescence," by Prof. E. L. Nichols.

J. A. BRIDGMAN, *Secretary*.

## CLEVELAND SECTION.

A special meeting was held June 16, in connection with the eighth semi-annual meeting of the American Institute of Chemical Engineers. The following papers were presented: "Water Powers of the United States," by Herman Stabler, Chemist and Engineer, U. S. Geological Survey; "Acid Resisting Alloys," by W. C. Carnell.

A. F. O. GERMANN, *Secretary*.

## ROCHESTER SECTION.

At the annual meeting, held on May 15, the following officers were elected to serve for the ensuing year: *Chairman*, C. F. Hutchison; *Vice-Chairman*, R. F. Baxter; *Sec.-Treas.*, H. H. Tozier.

H. H. TOZIER, *Secretary*.

## CHICAGO SECTION.

The June meeting was held June 7. Dr. B. C. Hesse addressed the Section on "Our Responsibilities."

D. K. FRENCH, *Secretary*.

## VERMONT SECTION.

At its organization meeting on May 19, the following officers were elected: *Chairman*, S. F. Howard; *Vice-Chairman*, P. C. Voter; *Sec.-Treas.*, C. E. Burke; *Councilor*, 1916, G. H. Burrows.

C. E. BURKE, *Secretary*.

## DETROIT SECTION.

The following officers were elected at the meeting on May 18: Howard T. Graber, *Pres.*; Edw. J. Gutsche, *Vice-Pres.*; James H. Bogart, *Sec.*; E. E. Follin, *Treasurer*.

EDW. J. GUTSCHE, *Secretary*.

## NEW HAVEN SECTION.

The regular meeting was held May 19. Professor Charles A. Kraus, of Clark University, gave a lecture, with demonstrations, on "Some Recent Developments in Glasses and the Art of Glass Blowing."

GEORGE S. JAMIESON, *Secretary*.

## UNIVERSITY OF ILLINOIS SECTION.

The regular meeting was held May 23. Program: "A Theory of the Formation of Smooth Deposits by Electrolysis," by Dr. A. MacInnes and R. W. Morgan. "The Contamination of Precipitates," by G. McP. Smith.

G. D. BRAL, *Secretary*.

## SYRACUSE SECTION.

The 107th regular meeting of the Section was held June 2. Dr. E. C. Sullivan, of the Corning Glass Works, addressed the Section on "Some Phases of Glass Manufacture."

R. S. BORNHNER, *Secretary*.

## PUGET SOUND SECTION.

The May meeting was a joint meeting with the Lumbermen's Association held May 27. Dr. Benson presented a paper on, "By-Products of the Lumber Industry," based upon his work with the Federal Bureau.

H. L. TRUMBULL, *Secretary*.

## VAN'T HOFF FUND.

According to the regulations of the van't Hoff Fund, founded June 28, 1913, interested persons are sent the following information:

The foundation, with headquarters at Amsterdam, is under the supervision of the Royal Academy of Sciences, and grants each year, before the 1st of March, from the income of the fund, certain sums to investigators in the field of pure and applied chemistry who have applied for same before November 1st of the previous year. At the present time the Committee in charge of the fund consists of A. F. Holleman (*President*), S. Hoogewerff, A. Smits, E. H. Buchner (*Secretary*), to whom applications should be addressed. The Committee has the privilege of enlarging its membership by the appointment of others for one-year terms.

The names of grantees will be published. Any individuals who have received a grant are expected to send to the Committee copies of papers relating to the results of their work, but they are otherwise at liberty to choose the manner and place of publication, with the simple requirement

that they mention the fact that the research was made from an endowment received under the van't Hoff Fund. The amount available for 1917 will be approximately \$520.

Application should be sent, registered by post, to: Het Bestuur der Koninklyke Akademie van Wetenschappen; bestemd Voor de Commissie van het "van't Hoff fonds," Trippenhuis, Kloveniersburgwal, te Amsterdam, with a detailed account of the proposed use of the grant, and of the reasons on which the candidates ground their claim. They must be received before November 1, 1916.

In the name of the Committee of the "*van't Hoff Fund*."

A. F. HOLLEMAN, *President*.

E. H. BUCHNER, *Secretary*.

Amsterdam, the month of May, 1916.

### Harry Clary Jones.

Harry Clary Jones, Professor of Physical Chemistry in Johns Hopkins University, died suddenly on April 9th last, in the fifty-first year of his age. He was born at New London, Maryland, where his father was a prosperous farmer. His early life was spent at home where the educational advantages were not of the best. In spite of the handicap he prepared himself for higher work and in 1885, when he was 20 years old, he was admitted to the Johns Hopkins University as a "special student," his preparation not having been sufficient to enable him to pass all the entrance examinations. In a short time, however, he was received as a regular candidate for the degree of bachelor of arts and this degree was conferred upon him in 1889. The traits which became so conspicuous in his later years were clearly exhibited in his undergraduate life—untiring industry, intellectual alertness, and the power of acquisition. He was a marked man from the beginning of his career as a student.

His interest in physical science was awakened by reading one of Tyndall's books that were so popular a generation ago, and it was in this way that he was led to college doors. He had to work hard before they were opened wide enough to permit of his entrance, but hard work was his specialty.

After receiving the bachelor's degree he continued his studies, devoting himself largely to chemistry, physics, and mathematics. In the third year of his graduate work he was selected as one of the Fellows of the university, which is good evidence of the esteem in which he was held by his teachers. His introduction to research was made under Professor H. N. Morse with whom he carried out two pieces of work, one "On the Action of Metallic Cadmium on the Halogen Salts of Cadmium and on the Sub-hydroxide and Sub-oxide of Cadmium" and the other on "A Redetermination of the Atomic Weight of Cadmium."

In 1892 he received the degree of Doctor of Philosophy from the Johns Hopkins University. At that time the subject of physical chemistry had come into great prominence in consequence of the work of van't Hoff, of Ostwald, and of Arrhenius. Jones was attracted to this field and determined to go abroad for the purpose of studying with these three leaders. He went first to Leipsic where he came under the influence of Ostwald; then to Stockholm to be with Arrhenius; and then to Amsterdam to sit at the feet of that genius, the genial van't Hoff. Two years were spent in this way and during this time Jones became an out-and-out physical chemist. His intense way of doing things and of looking at things led him to certain scientific excesses which jarred somewhat on the feelings of conservatives, but his tremendous enthusiasm and energy offset these defects.

The year after his return from Europe he held the position of Fellow by Courtesy in the Johns Hopkins University. This was a purely honorary position. He taught a little and carried on investigations. The next year, 1895, he was appointed Instructor in Physical Chemistry and began his career as a regular teacher of his favorite subject in his *Alma Mater*. In 1898 he was promoted to the position of Associate. In 1900 he became Associate Professor; and in 1903 Professor, which position he held at the time of his death.

During his entire career research was a passion with him and few chemists in a period of twenty years have contributed a larger number of memoirs to the literature of their subject. But this was not enough for him. He also wrote a number of books—text-books of inorganic chemistry and of physical chemistry, and treatises on special chapters of physical chemistry, some of these of a semi-popular nature.

His researches had their inception in the laboratory of Arrhenius where he began the work on the hydrates of sulfuric acid. Shortly after his return to this country he took up a systematic inquiry into the reasons for the failure of other than ideal solutions to conform to the laws of gas pressure and the theory of electrolytic dissociation, and in 1903 he was enabled to enlarge the scope of his work by the aid of generous grants from the Carnegie Institution of Washington which were continued up to the time of his death.

His earlier work was devoted to a study of the abnormalities in the molecular depression of the freezing point shown by certain substances having water of crystallization. In 1900 he offered the following tentative explanation: "In concentrated solutions these substances must take up a part of the water forming complex compounds with it and thus removing it from the field of action as far as freezing-point lowering is concerned. . . . . The lowering of the freezing point is thus abnormally great, because a part of the water is no longer present as solvent. . . . .

We do not put forward the above suggestion as the final statement of a theory, but only as a tentative explanation which, however, seems to account for the experimental facts which have been brought to light." This is the first appearance of his hydrate theory which was the guiding thought in all his subsequent experimental work.

About 1901 another line of investigation was opened up—the study of the conductivity and dissociation of electrolytes and their temperature coefficients; and, a little later, work on the absorption spectra of solutions was begun.

Using the conductivity method, a study of a large number of inorganic compounds and of organic acids was made in water alone. This work was soon extended to non-aqueous and mixed solvents and, in this connection, parallel investigations on the viscosity of the solutions were carried out and the important bearing of this property upon conductance established, as well as the explanation of certain phenomena, *e. g.*, negative viscosity coefficients.

The last phase of his work was the study of the absorption spectra of solutions and their bearing on solvation. This involved observations on thousands of solutions. Four of the ten monographs embodying the results of his investigations carried out under the auspices of the Carnegie Institution of Washington were devoted to a discussion of the results obtained both in aqueous and non-aqueous solutions. The most recent work was carried out with a fine grating spectroscope and radiomicrometer combined. With this not only were the phenomena of solvation investigated, but the ionization constants of indicators and the light absorption coefficients of solutions as well.

Space will not permit a discussion of the wide application of the results obtained from these various lines of investigation followed by Professor Jones and his students, but fortunately we have such a discussion in his own words in Chapter VII, *Publication 210*, Carnegie Institution of Washington as well as a complete bibliography up to 1915 of all his publications on the solvate theory. A quotation from his writings may be employed to give his own estimate of the place of the theory in chemistry. He says: "The theory of electrolytic dissociation, supplemented by the theory of solvation, is then not simply a theory of dilute or ideal solutions, but a theory of solutions in general."

Chemistry has lost one of her most industrious, most energetic, and most enthusiastic devotees.

IRA REMSEN.

# Proceedings.

## COUNCIL.

President Herty has appointed the following to represent the Society in coöperating with the National Academy of Sciences on Nitrate Supply for the United States Government: Chas. H. Herty, W. R. Whitney, Leo H. Baekeland, and W. K. Lewis.

### MEMBERS ELECTED BETWEEN JUNE 15 AND JULY 15, 1916.

- Babcock, J. H., Institute of Industrial Research, Washington, D. C.  
Bantrell, M. A., 206 Meigs St., Rochester, N. Y.  
Bauer, Edward A., 2034 N. Crawford Ave., Chicago, Ill.  
Bayliss, William, Y. M. C. A., Muncie, Ind.  
Bower, Leibert W., Eagle Mills, Arkansas.  
Breese, Kenneth E., Grand Mere, P. Q., Canada.  
Brodsky, Israel J., 5118 Parkside Ave., Philadelphia, Pa.  
Broggini, Mario J., 1475 Coutant St., Lakewood, Ohio.  
Brown, Norman B., Shawinigan Falls, Quebec, Canada.  
Buchanan, Ruth, 423 S. Graham St., Pittsburgh, Pa.  
Birmingham, Foster A., 1118 Burns Ave., St. Paul, Minn.  
Coolidge, Albert Sprague, Pittsfield, Mass.  
Davis, N. W., 3820 Fifth St., Des Moines, Iowa.  
Findley, Park A., 617 Walnut St., Des Moines, Iowa.  
Fulton, Robert R., 413 Bellefontain, Kansas City, Mo.  
Harpster, W. C., 1151 Wightman St., Pittsburgh, Pa.  
Harris, Robt. W., c/o British American Chem. Co., Ltd., 371 Aqueduct St., Montreal, P. Q., Canada.  
Hartmann, Bernhard G., 4404 Magnolia Ave., Chicago, Ill.  
Hicks, Russell E., Yale & Towne Mfg. Co., Stamford, Conn.

Young, Alexander B., 1001 Livingston Hall, Columbia University, New York City.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505, Washington, D. C.]

## MEETINGS OF THE SECTIONS.

### WESTERN NEW YORK SECTION.

The annual meeting was held May 27. The following officers were elected for the ensuing year: *President*, J. G. Melendy; *1st Vice-President*, Dr. J. A. Miller; *2nd Vice-President*, Dr. Albert Sy; *Secretary*, David H. Childs; *Treasurer*, Leslie E. Chamberlain; *Ex. Comm.*, Ray W. Lindsay, Dr. W. H. Stanton, R. H. White. *Councilors*, W. J. Watkins, Walter Wallace.

R. H. WHITE, *Secretary*.

### PUGET SOUND SECTION.

The regular meeting was held June 22. Dr. Horace G. Deming, head of the department of chemistry in the University of the Philippines, gave an illustrated lecture on "The Resources and Industries of the Philippines."

H. L. TRUMBULL, *Secretary*.

# Proceedings.

## COUNCIL.

President Herty appointed L. H. Baekeland to represent the Society on the Committee on General Lines of Coöperation between the National Academy of Sciences and Four Engineering Societies.

MEMBERS ELECTED BETWEEN JULY 15 AND AUGUST 15, 1916.

Blanchetiere, Alexandre, Bur. Hygiene, Boulogne-sur-mer, France.  
Borgstrom, Parry, Y. M. C. A., Berkeley, Calif.  
Brunkow, H. E., San Diego Cons. Gas & Elec. Co., San Diego, Calif.  
Campbell, Chas. L., 75 Pitts St., Boston, Mass.  
Cleary, David F., 319 Traphagen St., West Hoboken, N. J.  
Coombs, Richard H., Forest Grove, Waltham, Mass.  
Currier, Richard J., Box 178, Fulton, N. Y.  
Dorrance, Roy L., Chem. Div., Experimental Farm, Ottawa, Canada.  
Fischer, Alfred, Box 1597, Milwaukee, Wisc.  
Francis, Parker, Oxygen Gas Co., Kansas City, Mo.  
Freeman, H. A., Central Expt. Farm, Ottawa, Canada.  
Friedman, Elisha M., 14 Wall St., New York City.  
Hanzelin, Frank C., 24535 Central Park Ave., Chicago, Ill.

### MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons, Box 505, Washington, D. C.]

#### CHICAGO SECTION.

The regular meeting was held September 15. Program: "The Manufacture of Synthetic Phenol," by Prof. Harry McCormack; "Synthetic Phenol Resins for Printing Plates—A Special Application of Anhydrous Resins," by L. V. Redman, A. J. Weith and F. P. Brock.

D. K. FRANCE, *Secretary*.

#### ROCHESTER SECTION.

The following officers were elected and served during the term 1915-16, but inadvertently they have not been published heretofore: *Chairman*, Harry A. Carpenter; *Vice-Chairman*, Chas. F. Hutchison; *Secretary*, H. H. Tozier; *Treasurer*, J. E. Woodland; *Councilor*, H. E. Howe.

H. H. TOZIER, *Secretary*.

#### DECEASED.

Charles S. Champion, Savona, N. Y. Died July 31, 1916.

Francis Wyatt, 402 W. 23rd St., New York City. Died September, 1916.

Charles C. Steere, 3320 Reading Road, Cincinnati, Ohio. Died September, 1916.

# Proceedings.

## GENERAL MEETING.

The 53rd meeting of the American Chemical Society was held in New York City from Monday, September 25, to Saturday, September 30, 1916. The meeting opened with a Council meeting at 4.00 P.M. at The Chemists' Club, with sixty-eight Councilors present, dinner being served to the Council two hours later as guests of the New York Section.

On Tuesday morning, September 26, at Columbia University, the meeting was opened by Chairman J. Merritt Matthews, of the New York Section of the Society, followed by addresses of welcome from Health Commissioner Dr Haden Emerson, of the City of New York, and President Butler, of Columbia University. Charles H. Herty, President of the American Chemical Society, made a fitting response. There was then presented a communication from Dr. J. McKeen Cattell, Chairman of the Committee on Policy of the American Association for the Advancement of Science, requesting the American Chemical Society to hold an adjourned meeting in New York City with Section C of the American Association for the Advancement of Science during Convocation Week, 1916-1917, this being the intent of the vote passed by the Council of the American Chemical Society at Cincinnati. It was unanimously voted by the chemists assembled that this meeting be adjourned to Convocation Week, 1916-1917, for the purpose of participating in the sessions of Section C of the American Association for the Advancement of Science to be held in New York City during that week. It was voted that the Secretary be instructed to give notice of this adjourned meeting to all members of the Society not later than November 1, and that it also be announced in the *Journal of Industrial and Engineering Chemistry* for December. Two papers were then read in general meeting as follows: Wilder D. Bancroft, "Outline of Colloid Chemistry;" Horace C. Porter, "Coal and Coke By-Products as a Source of Fixed Nitrogen" (illustrated).

On Tuesday afternoon a public meeting was held in the Horace Mann Auditorium of Columbia University with papers as follows: "Chemistry and the National Welfare," Gen. William Crozier, Chief of Ordnance, War Department; "Chemistry and Banking," John E. Gardin, Vice-President National City Bank; "Expanding Relations of Chemistry in America," Charles H. Herty, President American Chemical Society.

At 8.00 P.M., a reception to the visiting members of the Society, guests, members of the American Electrochemical Society and members of the Technical Association of the Pulp and Paper Industry was given by the New York Section at Hotel Astor. Refreshments were served, and dancing was in order during the latter part of the evening.

Meetings of Divisions were held on Wednesday, Thursday, Friday and Saturday mornings, and two special industrial conferences were held on Wednesday, Thursday, and Friday afternoons and Saturday morning. These industrial conferences were a feature of the meeting and were largely attended. The subjects of the conferences were as follows: "American Dye-Stuff Manufacture," Chas. H. Herty, Presiding; "Electric Furnace Steels and Alloy Steels," John A. Mathews, Presiding; "American-Made Chemical Glass and Porcelain," Arthur H. Thomas, Presiding; "Industrial Alcohol, Acetone, and Acetic Acid," Arthur D. Little, Presiding; "Manufacture of Paper Pulp and By-Products," Robert B. Wolf, Presiding; "Medicinal Chemicals," Harold Hibbert, Presiding; "Miscellaneous Chemical Industries: Convertibility of Plant," William H. Grosvenor, Presiding; "Oils and Motor Fuels," Raymond F. Bacon, Presiding.

A very successful symposium on colloids, both theoretical and applied, was a feature of the general session of the Biochemical, Physical and Inorganic, and Industrial Divisions. On Friday morning the Division of Industrial Chemists and Chemical Engineers held a symposium on occupational diseases in chemical trades.

The Rubber Section again met, after some two years' inactivity, with over one hundred members present, and held a very successful meeting.

On Friday evening, members and guests sat down to a banquet at the Waldorf Astoria with over four hundred present. The banquet was one which will be long and pleasantly remembered by those present.

The Second National Exposition of Chemical Industries afforded members a wonderful opportunity to come in touch with the advance which has taken place in chemical industries during the last two or three years and to familiarize themselves with the materials available for the chemists' use in both the laboratory and plant.

The meeting was the largest ever held by the American Chemical Society where registration was taken, nineteen hundred and five members and guests registering for the meeting. The meeting was a success in every particular, and great credit is due to the management of the local New York Section for the way the details were handled and the care with which the comfort of every member attending the meeting was considered.

Full details of the meeting with titles of papers read will be found in the October issue of the *Journal of Industrial and Engineering Chemistry*. The minutes of the Divisions will be found on the pages following.

CHAS. L. PARSONS, *Secretary*.

#### **DIVISION OF AGRICULTURAL AND FOOD CHEMISTRY.**

The meeting was called to order at 9.30 A.M., September 26, by

T. J. Bryan, who was acting chairman on account of the absence of Chairman Tolman.

The following officers were elected for the ensuing year: *Chairman*, T. J. Bryan; *Vice-Chairman*, L. P. Brown; *Secretary*, G. F. Mason. Executive Committee: L. M. Tolman, W. D. Bigelow, A. V. H. Mory.

The meeting adjourned at 12.30 noon.

G. F. MASON, *Secretary*.

#### DIVISION OF BIOLOGICAL CHEMISTRY.

The joint meetings of the Divisions of Biological Chemistry, Physical and Inorganic Chemistry, and Industrial Chemists and Chemical Engineers were attended by a large audience and much interest was evident. The following sessions on Friday and Saturday were devoted to the general program of the Division and were again attended by an interested and enthusiastic audience. At the annual meeting held at the close of the sessions, the following officers were elected for the ensuing year: *Chairman*, C. L. Alsberg; *Vice-Chairman* and *Secretary*, I. K. Phelps. Executive Committee: W. D. Bancroft, *Chairman*, E. Kremers, A. W. Dox, W. R. Bloor, R. E. Swain.

It was also voted that the Executive Committee be requested to consider the advisability of amending the By-Laws to make the annual meeting of the Division the special order of business at the opening of the second session of the September meeting rather than at the close of the sessions.

ISAAC KING PHELPS, *Secretary*.

#### FERTILIZER DIVISION.

The meeting, held in Rumford Hall, The Chemists' Club, was called to order Wednesday morning, September 27, by Chairman Breckenridge, in accordance with the official program.

On motion, the minutes of the previous meeting were dispensed with.

Reports of the following committees were read and accepted: Committee on Fertilizer Legislation, *Chairman*, F. B. Carpenter; Committee on Research and Methods of Analysis, *Chairman*, Paul Rudnick.

On motion, the following Special Committee on Methods of Analysis was appointed by the Chairman: F. S. Lodge, *Chairman*, W. J. Jones, C. H. Jones, F. B. Carpenter, S. W. Wiley.

The following officers were elected: *Chairman*, J. E. Breckenridge; *Vice-Chairman*, L. L. Van Slyke; *Secretary*, F. B. Carpenter. Executive Committee: Paul Rudnick, R. N. Brackett, C. H. Jones, H. J. Wheeler.

No other business appearing, the meeting was adjourned.

F. B. CARPENTER, *Secretary*.

### DIVISION OF INDUSTRIAL CHEMISTS AND CHEMICAL ENGINEERS.

The Division of Industrial Chemists and Chemical Engineers met in Schermerhorn Hall, Columbia University, September 25, 26 and 27, 1916, with H. E. Howe as Chairman and S. H. Salisbury, Jr., Secretary. The Secretary had no report.

The Division voted to amend Article IV of the By-Laws so that it shall consist of the first sentence only.

The Committee on the Analysis of Fats and Oils, through its Chairman, W. D. Richardson, handed in a report upon its work since the Urbana meeting.

The Thursday meeting was taken up with a symposium on Colloids in conjunction with the Division of Biological Chemistry and the Division of Physical and Inorganic Chemistry.

The Friday meeting consisted of a symposium on Occupational Diseases in the Chemical Trades.

The nominating Committee reported the following names for officers, who were duly elected: *Chairman*, H. E. Howe; *Vice-Chairman*, R. F. Bacon; *Secretary*, S. H. Salisbury, Jr. Executive Committee: W. F. Hillebrand, C. H. Herty, H. K. Benson, J. R. Withrow, S. W. Parr. S. H. SALISBURY, JR., *Secretary*.

### DIVISION OF ORGANIC CHEMISTRY.

The Organic Division held its meeting in the gymnasium at Columbia University during the mornings of September 27 and 28. A committee, consisting of Messrs. Frankforter, Hudson, and Nicolet, was re-appointed to make arrangements for a joint meeting with the Division of Physical and Inorganic Chemistry at the next general session.

The following officers were elected for the coming year: *Chairman*, J. R. Bailey; *Vice-Chairman* and *Secretary*, H. L. Fisher. Executive Committee: F. B. Allan, C. G. Derick, E. E. Reid.

H. L. FISHER, *Secretary*.

### DIVISION OF PHARMACEUTICAL CHEMISTRY.

Chairman Long was present and presided. L. F. Kebler was appointed to act as secretary in the absence of Secretary Beal.

The following officers were elected for the ensuing year: *Chairman*, L. F. Kebler; *Secretary*, Geo. D. Beal.

L. F. KEBLER, *Acting Secretary*.

### DIVISION OF PHYSICAL AND INORGANIC CHEMISTRY.

Meetings were held on Wednesday, September 27, and Thursday, September 28, in conjunction with the Division of Biological Chemistry and the Division of Industrial Chemists and Chemical Engineers, the subject under general discussion being Pure and Applied Colloid Chemistry. On Friday, September 29, after the conclusion of the Colloid

Symposium, the Division proceeded to its own program and the election of officers.

The following nominees for officers of the Division for the year 1916-1917 were unanimously elected: *Chairman*, T. W. Richards; *Vice-Chairman*, H. P. Cady; *Secretary*, Earl B. Millard. Executive Committee: A. W. Browne, F. K. Cameron, W. E. Henderson, A. B. Lamb, I. Langmuir.

JAMES KENDALL, *Secretary*.

#### DIVISION OF WATER, SEWAGE, AND SANITATION.

The minutes of the last previous meeting were read and approved.

The following officers were elected for the ensuing year: *Chairman*, R. B. Dole; *Vice-Chairman*, E. H. S. Bailey; *Secretary*, H. P. Corson. Executive Committee: The above officers, *ex officio*, E. B. Phelps, Edward Bartow.

The meeting then adjourned.

H. P. CORSON, *Secretary*.

#### RUBBER SECTION.

The Rubber Section met on Thursday morning in Rumford Hall, The Chemists' Club, with L. E. Weber in the chair and J. B. Tuttle, secretary. About seventy-five persons were present at the opening, which increased to one hundred later. An active discussion followed on "The Accelerated Life Test of Rubber Compounds." The papers presented will be found in the October issue of the *Journal of Industrial and Engineering Chemistry*. It was voted to leave the arrangements for further meetings with the chairman and secretary, who are to consult with the proper officers of the Society in this regard. A stenographer was present, who took down a large portion of the discussion on the topic above-mentioned, which, in revised form, will be printed for the benefit of the rubber industry in the *India Rubber World*.

J. B. TUTTLE, *Secretary*.

---

#### DIRECTORS' MEETING MINUTES.

The Directors met at The Chemists' Club at 9.30 A.M., September 27, 1916. Messrs. Herty, Bogert, Bigelow, Little, Love, Smith and Parsons were present.

It was voted that the secretary be directed to accept subscriptions to the journals on a basis of full volumes only.

It was voted that the secretary be authorized to turn over to the Eschenbach Printing Company the waste paper from excess journals recently taken from stock in consideration of their reprinting, without other recompensation, THIS JOURNAL, Volume 29, Number 5.

It was voted to appropriate the sum of \$50.00 for the expenses of the Chairman of the Priestley Memorial Committee, covering clerical, stationery, and similar expenses.

It was voted that \$150.00 be added to the Secretary's clerical account budget and \$250.00 to his budget for general expenses.

It was voted that necessary expenses under incidental account be appropriated and the amount be paid from general funds or transferred from other appropriations not otherwise used.

It was voted that the communication of the Advertising Committee regarding the *Industrial Journal* be adopted in principle and that the Directors unanimously recommend to the Council the election of Charles H. Herty as Editor.

In view of the fact that the Directors are the responsible trustees of the Society it was voted to recommend that the power of the Council be and hereby is delegated to the Directors to elect the Treasurer of the Society.

It was voted that in the opinion of the Directors it is very desirable that the American Chemical Society undertake as soon as possible the publication of a journal of popular chemistry along lines similar to those outlined in the report of Director A. D. Little upon this subject. With this in view it was recommended that the Council request the President to appoint a Committee of three, of whom A. D. Little shall be Chairman and C. H. Herty one of the members, to secure a guarantee fund of not less than \$50,000; to recommend an editor and a business manager to be employed by the Directors; and to take such other preliminary steps as in their judgment it deems wise.

An adjourned meeting of the Directors was held at The Chemists' Club, Thursday, September 27, at 10.30 A.M. Directors Herty, Love, Smith, Bigelow, Bogert and Parsons were present.

Mr. E. J. Crane appeared before the Directors with certain inquiries regarding the issuance of the Decennial Index to *Chemical Abstracts*.

It was voted that the Index to *Chemical Abstracts* should contain no advertisements.

Besides the regular paper binding offer of the Decennial Index to *Chemical Abstracts*, it was voted to offer one form of binding and one form only at a price sufficient to cover all costs involved, the binding to be a dark brown buckram.

It was voted that payment for the Index to *Chemical Abstracts* be asked for when the first volume is ready for delivery.

It was voted that Charles H. Herty be added to the Advertising Committee, and that the Committee be asked to formulate a plan for the future conduct of the advertising office, and, after obtaining the consent of the Directors, that they be authorized to put it into force.

It was voted that the Editor of the *Journal of Industrial and Engineering Chemistry* shall receive a salary of \$6,000 per annum, beginning with the fiscal year December 1st next.

By authorization of the Council, the Directors elected E. G. Love Treasurer of the Society with the purpose of consolidating the offices of the Treasurer and the Chairman of the Finance Committee.

The Directors passed a vote of thanks to A. P. Hallock and directed the Secretary to express to him their appreciation of his long service as Treasurer of the Society.

The directors voted that the salary of A. P. Hallock be continued in the form of an honorarium for the fiscal year beginning December 1, 1916.

### COUNCIL.

President Herty has appointed M. T. Bogert, W. R. Whitney and C. L. Alsberg, to represent the Society on the General Committee of Chemical Research of the National Research Council and the American Chemical Society.

President Herty has appointed Dr. Eugene F. Smith as a member of the Priestley Memorial Committee.

### Council Minutes, New York Meeting.

The Council of the American Chemical Society met on Monday, September 25, at 4.00 P.M., in Rumford Hall, 'The Chemists' Club, New York City, with the following Councilors present: F. C. Atkinson, L. H. Baekeland, J. T. Baker, G. F. Barton, Edward Bartow, Chas. Baskerville, H. D. Batchelor (sub.), W. D. Bigelow, M. T. Bogert, R. N. Brackett (sub.), W. P. Bradley, J. E. Breckenridge, T. J. Bryan, S. R. Church, C. E. Coates, W. F. Coover, E. J. Crane, A. L. Day, C. G. Derick, A. C. Fieldner, G. B. Frankforter, J. S. Goldbaum, W. J. Hale, B. C. Hesse, E. F. Hicks, J. I. D. Hinds, H. E. Howe, C. S. Hudson, W. L. Jennings, E. S. Johnson (sub.), T. B. Johnson, John Johnston, C. M. Joyce, A. C. Langmuir, Irving Langmuir, A. D. Little, J. H. Long, E. G. Love, A. Lowenstein, W. J. McCaughey (sub.), H. McCormack, H. N. McCoy (sub.), D. F. McFarland (sub.), R. H. McKee, K. G. MacKenzie, E. W. Magruder, J. M. Matthews, A. V. H. Mory (sub.), W. A. Noyes, T. J. Parker, S. W. Parr, I. K. Phelps (sub.), F. C. Phillips, Ira Remsen, W. K. Robbins, W. P. Schuck (sub.), Alexander Smith, Julius Stieglitz, W. T. Taggart, A. N. Taylor, J. E. Teeple, F. E. Tuttle, W. H. Watkins, R. C. Wells, David Wesson, A. S. Wheeler, M. C. Whitaker, W. A. Whitaker (sub.), H. W. Wiley, J. L. Wills (sub.).

A communication from the Conference Committee on National Preparedness, asking the support of the American Chemical Society for national preparedness, was read. The communication was referred to the President, Secretary, and Charles Baskerville, for report.

A communication was received from the New York Section of the American Chemical Society, requesting the President of the Society to appoint

a central committee from representatives of the universities and the industries to study opportunities and to make recommendations for co-operation along the lines laid down in the conclusions arrived at as a result of the activities of the committee of the New York Section. (See page 658, July, 1916, issue *Journal of Industrial and Engineering Chemistry*.) The President was authorized to appoint such committee, the number to be left to his discretion, and to be added to at will.

A communication was presented from the Chairman of the National Vigilance Committee of the Associated Advertising Clubs, asking the assistance of the American Chemical Society in passing upon questionable advertisements relating to chemical subjects. It was voted to refer the communication to the Committee on Government Specifications of Food and Toilet Articles.

A communication was received from the Committee on Publicity regarding the desirability of the proper dissemination of chemical information to the public, which was referred to the Directors with the approval of the Council for such action as they deem wise.

Invitations from the Cleveland Section and from the Northeastern Section to hold the next annual meeting of the Society in Cleveland and Boston, were read. After careful consideration of the subject, it was voted that the invitation of the Northeastern Section be given preference over the Cleveland Section, for geographical reasons, as the Spring meeting is to be held in Kansas City.

It was voted that the next annual meeting be held between September 1 and September 10, 1917, in Boston, Mass. The Secretary was instructed to express the thanks and appreciation of the Council to the Cleveland Section for their kind invitation to meet with them next year.

The Committee on Professional Ethics submitted the following report:

### **Majority Report of the Committee on Professional Ethics.**

#### **I.**

The first obligation upon the chemist is a scrupulous regard for truth.

#### **II.**

Chemistry has become a science through the coöperative effort of tens of thousands of earnest seekers after truth. The chemists should recognize their obligation to these workers and to the community which has provided opportunities for study and research. They should give due credit to the one and loyal service to the other.

#### **III.**

As good citizens it is the duty of chemists to be ever vigilant for the welfare of the community and to bear their part in sustaining its institutions and its burdens. They should welcome and make use of op-

portunities to educate the public to a true appreciation of the dignity and usefulness of their profession.

## IV.

Chemists should endeavor to inculcate sound ideas in the public mind regarding chemical facts and theories, and from the nature of their work and training should be uncompromising enemies of fraud in every form. In its suppression they should not be content with passive resistance and a merely personal honesty but should take an active and aggressive part.

## V.

In their relations to each other chemists should strive to promote mutual helpfulness, mutual understanding, mutual encouragement in scientific work and in all good endeavor. They should cultivate mutual forbearance, fraternal courtesy and a broad and generous fellowship.

## VI.

In their relations to their employers chemists should constantly remember that they are practising a profession of honor and dignity which places service before gain. They should undertake no work for which they are not qualified by training, but should refer their client to a properly qualified specialist in such work.

## VII.

Self respect and a due regard for their obligations to each other require chemists to make proper charges for work done, information furnished or opinions rendered in the course of business or professional practice. In the estimation of such charges consideration should be given to the various factors entering into the cost and value of the service, as the responsibility involved, the time and equipment required, the general custom of the profession in the locality concerned and the special value of the service.

## VIII.

The chemist stands in a fiduciary relation to his employer and should in no case accept financial or other compensation from more than one party in interest without the knowledge and consent of all parties. He should not disclose to others the contents of certificates or reports to clients without the written consent of the client concerned. The chemist should treat as confidential all communications of his client, and should guard, more carefully than his own, his client's interests in all matters entrusted to him.

## IX.

The chemist should not accept conflicting retainers or represent conflicting interests or identify himself with other than legitimate and well considered enterprises. He should endeavor to protect all reputable chemists from misrepresentation.

## X.

The client is entitled to painstaking and accurate work by recognized and accepted methods, and to the best information and advice which it is within the power of the chemist to give. Reports should be dignified in form and substance, careful and conservative in statement, and as definite in their conclusions as the facts permit.

Clients should recognize that inconsistencies in results sometimes secured by different chemists are often due to actual differences in the samples submitted by the client and are thus in fact an evidence of careful work. They should be slow to attribute these inconsistencies to incompetency or unworthy motives.

## XI.

It is desirable for the public welfare and prosperity that chemical investigations be conducted without undue restriction in institutions which maintain courses for the education and training of chemists and that the instructing staff in such institutions be permitted to turn their special knowledge and experience to the direct service of individual clients and to charge therefor a proper compensation, but it is prejudicial to the best interests of chemistry for such service to be rendered in unfair competition with the profession at large at charges which ignore the usual costs of equipment and conduct of the work.

## XII.

The obligations of the chemist and the community are reciprocal. To the community the chemist owes his training and his opportunity for service, and in this service he should expend his best endeavor. To chemists the community owes in far larger measure than it yet appreciates, its comfort, protection, prosperity and breadth of intellectual view. The well-being of the community requires due provision for the teaching of chemistry and the promotion of research and such encouragement of the study and practice of chemistry as may be derived from adequate compensation and the recognition which is based on understanding.

Respectfully submitted,

(Signed) ARTHUR D. LITTLE, *Chairman*,  
L. H. BAEKELAND,  
WILLIAM BRADY,  
F. K. CAMERON.

**Minority Report.**

The chemists of this country may be classified roughly as consulting chemists, works chemists, government chemists, and teaching chemists, though any one man may belong in several groups or even in all at once. The interests of the groups diverge so much that it seems impossible to devise a single code unless we limit it to platitudes.

While the American Chemical Society does not in any way encourage the betrayal of professional secrets, it has always stood hitherto for the freest discussion possible under existing circumstances. It would be a distinct step backwards to adopt officially a rule that no chemist should discuss professional matters unless he has received written permission from his employer. In a great many cases this rule or something similar is enforced by employers; but the American Chemical Society should encourage and not discourage the belief that a chemist is a person of discretion. The rule, as worded, would require a college chemist to obtain written permission of the president or trustees before publishing any paper. This will not be done and it is not the intention of the committee that it should be done; but a code that requires interpretation and that is not to be lived up to, is worse than no code at all because it makes us a laughing-stock.

The proposed code was written by a consulting chemist for consulting chemists. It is an admirable one for that purpose; but it should not be adopted by the American Chemical Society as a general code applicable to all members.

WILDER D. BANCROFT.

After discussion, the Minority Report, which referred to Section VIII of the Majority Report, was voted down, it being considered by the majority of the members that the word "client" in Section VIII of the Majority Report, to which it referred, was distinctive.

After discussion of the Majority Report, it was voted to refer this Report to the local sections of the Society for discussion, and that it be taken up again at the annual meeting of the Society in September, 1917.

The Council then adjourned for dinner, and re-assembled at 8.30 P.M., when the Report of the Committee on Business Management, presented first to the Council at the Cincinnati meeting and made a special order for this meeting, was taken up.

After several hours' discussion, it was voted to lay both the Majority and the Minority Report of the Committee on Business Management on the table, and to discharge the Committee.

The following communication, prepared at the request of the Advertising Committee, who had for some weeks been considering the question of the business arrangements of the *Industrial Journal*, was read to the Council, the Council also being informed at the same time that Dr. Whitaker could under no condition continue as Editor of the *Industrial Journal* on account of pressure of other duties.

### **The Future of the Industrial Journal.**

Six years of daily contact with the numerous problems of building up and developing the *Journal of Industrial and Engineering Chemistry* would naturally bring out some observations which I have been urged to place, briefly, before the Directors for their consideration and discussion.

The *Industrial Journal*, as the organ of the American Chemical Society, should occupy a commanding position among technical publications of this country, instead of being as it is now, simply a medium for the publication of original papers of and for members of the Society, with the added opportunity for impressing personal views and opinions of members upon each other.

The Journal should be in a position to cement and unify the interests of the chemical profession, to develop and improve the ethical standards of chemists, to collect and distribute all knowledge which will make for higher chemical engineering achievements, to draw us to—not to separate us from—other engineering professions, to take and to hold a position squarely representing the profession before the public, and to be a real factor in moulding and directing national policies in which the chemical profession has a right to be heard.

The very fact that the Journal has the backing of a great technical society should give it a position of strength for enhancing its influence and for bestowing substantial benefits on the profession which supports it. Its policy and outlook should be big and broad enough to make its influence felt not only inside the society, but outside; not only on purely chemical matters, but matters of general technical and engineering value; not only in scientific matters, but the relations of the chemical profession to great public or national problems.

The *Industrial Journal* is essentially a product of evolution. It had to begin in a small way, due to lack of resources of the Society and the absence of editorial experience. The management of the publication up to the present has been, as a matter of necessity, amateurish. Heretofore the resources of the Society and the earning power of the publication did not justify the employment of an adequate organization to develop the Journal along its lines of greatest opportunity.

Have we not now reached the turning point? Is this not the time and place to accept an obvious opportunity—almost an obligation—and put the *Industrial Journal* upon a sound permanent footing, and give it the means to do its best?

The *Industrial Journal* is now more than self-supporting. The income from advertising has been increasing steadily as a result of the most strenuous work in overcoming handicaps imposed by our lack of experience and adequate facilities. The present advertising income plus a reasonable allowance from the membership dues of the Society, for subscription price, places to the credit of the Journal operating account a handsome profit which is now commandeered by the Society and used for other purposes. This surplus alone, reinvested in the *Industrial Journal*, would supply ample funds for the reorganization of the publication upon a new and sound basis.

Inadequate funds and lack of experience cannot now, therefore, be urged

as a reason for our failure to take advantage of the opportunity and the obvious need of the publication.

### **The Remedy.**

*First.* Develop comprehensive editorial policies.

The power and influence of any publication is developed through the soundness and consistency of its editorial utterances. The *Industrial Journal* has at present no editorial policy. In the past such articles as have been published as editorials have been of a hit-and-miss character, representing the expression of individual views, summaries of industrial developments, descriptive articles covering Society meetings, and now and then an effusion on some particular hobby of a chemist, by a chemist, for a chemist. It is obvious that such a variety of matter, which flows more or less irregularly, cannot be characterized as an editorial policy. A system of shopping around among the associate editors and various members of the Society for editorial articles could not possibly achieve the needed consistent editorial policy.

A comprehensive editorial policy would result from the selection of a *real editor* who would devote his entire time (1) to the study of the Society's problems, (2) to the consistent editorial development and discussion of its needs, (3) to the editorial treatment of questions of public and national interest in which the Society is concerned, and (4) to the general development of an editorial policy which would make the Journal known both at home and abroad as the authoritative representative of the views, aims, ethics and sphere of influence of the chemical profession in America.

*Second.* Provide adequate and well equipped editorial and business quarters for the Journal.

At the present time the editorial headquarters are squeezed into a bottle storage room (see photographs and plan attached) with a single window, where four or five people struggle with the innumerable editorial duties, under conditions of congestion which would not be permitted in many factories.

Quarters befitting the dignity of the Society and the chemical profession should be provided in New York City for both the editorial headquarters and the advertising department.

*Third.* Editorial assistance, proof-readers and clerical help should be provided in sufficient quantity, and of such quality that the routine work of the office might proceed regularly and methodically, without periods of excessive strain. Furthermore, this arrangement should provide reasonable vacation allowances, without doubling the burdens of co-workers.

*Fourth.* The news gathering facilities of the Journal should be developed at once, by providing staff reporters to cover all technical and engineering society and convention meetings.

*Fifth.* Foreign and domestic engineering and industrial news should be reviewed promptly and regularly, for the benefit of the readers of the Journal. The trend of industrial progress should be forecasted from a close study of foreign and domestic patent literature.

*Sixth.* Competent staff writers should be provided to investigate and report upon important plant, process, and equipment improvements. The Journal should publish each month, at least one good illustrated article by such a staff representative, describing some of the new plants or processes constantly being developed in this country. Such articles should include engineering, power, labor, organization, costs, insurance, industrial hazard, market, competitive and other conditions affecting manufacturing success.

To continue the *Industrial Journal* along its present lines, with a make-shift part-time editor, with no fixed editorial policy or aim, with no headquarters nor adequate staff for its operation and development, with no coördination of its interests and no controlling hand for its future, will in my humble opinion lead to its ultimate failure.

On the other hand, the time is ripe, and the way is now clear, to take the Journal from its present state of development, which has been attained at such cost in labor and effort, and place it upon a foundation from which it can develop into an influence and power both within and outside of the chemical profession.

M. C. WHITAKER,

*Editor, Journal of Industrial and Engineering Chemistry.*

After a short discussion, it was moved and voted that the above communication be referred to the Directors, with the request that they consider it and report their opinion of its advisability to the Council at an adjourned meeting to be held Wednesday evening, September 27.

The Council then adjourned.

An adjourned meeting of the Council was held in Rumford Hall, The Chemists' Club, September 27, at 8.00 P.M., with the following Councilors present: F. C. Atkinson, L. H. Baekeland, W. D. Bancroft, G. E. Barton, Edward Bartow, Charles Baskerville, W. D. Bigelow, F. M. Boyles, R. N. Brackett (sub.), T. J. Bryan, C. E. Coates, E. J. Crane, C. G. Derick, A. C. Fieldner, G. B. Frankforter, A. P. Hallock, B. C. Hesse, E. F. Hicks, W. H. Hollingshead, H. E. Howe, W. L. Jennings, E. S. Johnson (sub.), A. C. Langmuir, A. D. Little, J. H. Long, A. Lowenstein, H. N. McCoy (sub.), R. H. McKee, K. G. MacKenzie, E. W. Magruder, J. M. Matthews, A. V. H. Mory (sub.), W. A. Noyes, T. J. Parker, I. K. Phelps (sub.), F. C. Phillips, W. P. Schuck (sub.), Alexander Smith, F. E. Tuttle, J. E. Teeple, R. C. Wells, David Wesson, A. S. Wheeler, M. C. Whitaker, W. A. Whitaker (sub.), H. W. Wiley, J. L. Wills (sub.).

The following two proposed amendments to the By-Laws suggested

at the Urbana Meeting of the Society, as noted on page 74 of the Proceedings for June, were considered:

1. The Chairman of the Committee on Membership shall submit a monthly report for publication in the Proceedings of the Society which gives the name, residence, and occupation of each nominee, and the names and residence of his nominators. Final action shall be taken by the Committee on these names only after thirty days have elapsed since the publication in the Proceedings.

2. Any motion for the expulsion of any member of the Society shall be submitted first in confidence (without further divulging the name of the member) to the President of the Society with a full statement of the *prima facie* evidence on which the motion is based. The President, in conjunction with the two ex-Presidents preceding him most immediately in office, shall form a Committee with full power to decide whether the motion shall be dropped without further action and without report to the Council; whether the accused member shall be allowed to resign without report to the Council, or whether the motion shall be referred, without prejudice, to a special committee of the Council for further investigation and report to the Council.

The report of the Committee appointed by President Herty to report on this matter is as follows:

"The Committee on the By-Laws proposed at the Urbana meeting, respectfully report that we consider the first By-Law proposed (see p. 74 of the Proceedings for June) unnecessary and undesirable. The second By-Law proposed seems to us suitable and we recommend its adoption.

W. A. NOYES,  
M. T. BOGERT,  
F. K. CAMERON."

The Council voted unanimously to reject the first proposed By-Law, printed above, and to adopt the second, amended to strike out the words "without prejudice," so that the By-Law adopted by the Society reads as follows:

"Any motion for the expulsion of any member of the Society shall be submitted first in confidence (without further divulging the name of the member) to the President of the Society with a full statement of the *prima facie* evidence on which the motion is based. The President, in conjunction with the two ex-Presidents preceding him most immediately in office, shall form a committee with full power to decide whether the motion shall be dropped without further action and without report to the Council; whether the accused member shall be allowed to resign without report to the Council, or whether the motion shall be referred to a special committee of the Council for further investigation and report to the Council."

The Committee appointed at the previous Council meeting to pass resolutions regarding national preparedness, offered the following resolution, which was unanimously adopted:

"Resolved, that the Council of the American Chemical Society declares itself to be in favor of an adequate system of national defense. Such a system involving our Army, Navy, coast defences, natural resources, and industrial development should be so designed as to maintain our liberty and preserve our peaceful pursuit of happiness. The system should also be designed with such reserve power as to maintain our honor and integrity, should the same be menaced by foes within or without. To that end we hold ourselves in readiness to serve Our Country in any capacity, but especially in such ways as our abilities best qualify us.

CHAS. H. HERTY,  
CHAS. L. PARSONS,  
CHAS. BASKERVILLE."

The following recommendation of the Directors was presented to the Council:

"In the opinion of the Directors it is very desirable that the American Chemical Society undertake as soon as possible the publication of a journal of popular chemistry along lines similar to those outlined in the report of Director A. D. Little upon this subject. With this in view it was recommended that the Council request the President to appoint a committee of three, of whom A. D. Little shall be Chairman, and Chas. H. Herty one of the members, to secure a guarantee fund not less than \$50,000; to recommend an editor and a business manager to be employed by the Directors, and to take such other preliminary steps as in their judgment it deems wise."

Mr. A. D. Little presented the plan in detail, and it was unanimously voted that the recommendation be adopted, and that the President be authorized to appoint the third member of the committee.

The Directors reported back to the Council, recommending that the plan outlined by M. C. Whitaker, and presented through the Advertising Committee, be adopted in principle, and that Chas. H. Herty be elected Editor. The Council unanimously adopted this recommendation of the Directors, and Chas. H. Herty was elected Editor of the *Journal of Industrial and Engineering Chemistry* to succeed M. C. Whitaker, resigned.

It was voted that Chas. H. Herty be authorized to recommend his Board of Associate Editors, decreasing the number, if he deemed it advisable, and that the Directors be authorized to elect them.

The Council passed a unanimous vote of thanks, expressing to M. C. Whitaker, Editor of the *Journal of Industrial and Engineering Chemistry*, their sincere appreciation of the splendid and efficient work that he has done as Editor of the *Industrial Journal* during the last six years. The vote was sincere and unanimous.

W. A. Noyes was re-elected Editor of *THIS JOURNAL*, and the following Board of Associate Editors, recommended by him, was also elected: G. P. Baxter, M. T. Bogert, C. A. Browne, Edward Hart, W. F. Hillebrand, John Johnston, J. H. Long, W. Lash Miller, Julius Stieglitz, H. W. Wiley.

E. J. Crane was re-elected Editor of *Chemical Abstracts*.

Chas. L. Parsons was re-elected Secretary.

The following recommendation of the Directors, regarding the Treasurer of the Society, was read:

"Recommended that since the Directors are the responsible trustees of the Society that the power of the Council be and hereby is delegated to the Directors to elect the Treasurer of the Society."

This recommendation was unanimously adopted.

B. C. Hesse made a statement to the Council regarding the work of the "Committee to Cooperate with the United States Government to Obtain the Regular Collation and Publication of Complete and Uniform Statistics in Regard to Foreign Commerce in Chemicals," and asked the help of all local sections to obtain information on imports.

Charles Baskerville called attention of the Council to certain phases of the work on occupational diseases. The whole matter was referred to the Directors of the Society.

Professor Francis C. Phillips made a preliminary report to the Council regarding the Priestley Memorial.

The Council arose and remained standing as a tribute to the memory of Sir William Ramsay and Joseph H. Kastle.

A vote of thanks was passed to the Chairman and members of the New York Section of the Society, and to the chairmen and members of the Committees having in charge arrangements for the New York meeting; to the Chairmen of the Industrial Conferences, to The Chemists' Club, to the officials of Columbia University, to Dean Goetze, Superintendent Norris, and Professor Army, of Columbia University; to Mr. C. I. Fischer, to the management of the Second National Exposition of Chemical Industries, to General Wm. Crozier, to Mr. John E. Gardin, and to those members of the Society and citizens of New York who contributed their automobiles for the entertainment of the ladies, and to the individuals, firms, and corporations who contributed funds and thereby made the meeting a possibility.

The Council then adjourned.

CHARLES L. PARSONS, *Secretary*.

#### MEMBERS ELECTED BETWEEN SEPTEMBER 15 AND OCTOBER 15, 1916.

Allen, A. Holmes, 316 West Grace St., Richmond, Va.

Allen, Henry E., 32 Exchange Place, Providence, R. I.

Allen, Oliver F., Room 1712, 30 Church St., New York City.

Altman, C. A., 1220 Riverview Ave., Kansas City, Kans.

Bailey, Ralph H., 52 Grays Hall, Cambridge, Mass.  
 Bailey, R. J., Du Bois, Pa.  
 Baker, John Shortt, 1409 Jackson St., Wilmington, Del.  
 Beath, O. A., Laramie, Wyo.  
 Beatley, Chas. A., 30 Empedrado, Havana, Cuba.  
 Beers, William H., 2114 First Ave., Birmingham, Ala.  
 Bell, Richard D., 26 Bow St., Somerville, Mass.  
 Blass, Talmadge, Lackawanna Steel Co., Lackawanna, N. Y.  
 Bosworth, H. O., Box 28, Five Corners Station, Jersey City, N. J.  
 Bradley, Charles S., 41 Park Row, New York City.  
 Brennan, J. J., 76 West Third St., St. Paul, Minn.  
 Breth, F. W., 450 High St., Newark, N. J.  
 Britton, Harry C., R. F. D. No. 2, Station A, Syracuse, N. Y.

## MEETINGS OF THE SECTIONS.

[Full accounts of all meetings should be sent to Secretary Charles L. Parsons Box 505, Washington, D. C.]

### CALIFORNIA SECTION.

The 92nd regular meeting was held September 19th. Program: "Colloids and Biology," by Dr. Martin H. Fischer, Professor of Physiology, University of Cincinnati. "The Use of Petroleum in Smelting Iron Ore," by Mr. A. E. Bourcoud.

BRYANT S. DRAKE, *Secretary*

### CHICAGO SECTION.

The regular monthly meeting was held October 13th. The paper of the evening was on "The Evolution of the Elements and Structure of Atoms," by Dr. W. D. Harkins, of the University of Chicago.

D. K. FRENCH, *Secretary*.

### CINCINNATI SECTION.

The 207th regular meeting was held October 11th. Program: "Exfoliation and Carbon Concentration in the Case-Hardening of Steel," by Edwin P. Stenger.

E. K. FILMS, *Secretary*.

### CLEVELAND SECTION.

The opening meeting of the year 1916-17 was held October 9th. Dr. Harry N. Holmes, head of the Chemistry Department of Oberlin College, spoke on "Some Recent Researches in Colloid Chemistry."

A. F. O. GERMANN, *Secretary*.

### CONNECTICUT VALLEY SECTION.

The 42nd regular meeting was held October 7th. Program: "Cooperation between the College and Industry," by Dr. M. L. Crossley.

R. J. MARSH, *Secretary*.

### DETROIT SECTION.

The 82nd regular meeting was held September 21st. Program: "Agricultural Chemistry: Its Present Status in the United States, and its Relation to the National Food Problem," by Dr. H. J.

Wheeler, of Boston, Mass., Manager of the American Agricultural Chemical Co.

JAMES H. BOGART, *Secretary*.

#### EASTERN NEW YORK SECTION.

The 68th meeting was held at Saratoga Springs, September 23rd. Dr. J. H. Stoller, Professor of Geology at Union College, spoke on "Geology and Geochemistry of the Saratoga Quadrangle."

ALBERT J. SALATHE, *Secretary*.

#### INDIANA SECTION.

The first fall meeting was held October 13th. Dr. R. H. Ransom addressed the section on "Chemical Science in Indiana." Officers were elected for the ensuing year as follows: F. C. Atkinson, *President*; C. M. Hargrave, *Vice-President*; H. W. Rhodehamel, *Secretary-Treasurer*.

H. W. RHODEHAMEL, *Secretary*.

#### LEXINGTON SECTION.

The Section held its 34th regular meeting October 12th. Program: "The Chemistry of Bread-Baking," by Mr. R. C. Dabney.

P. L. BLUMENTHAL, *Secretary*.

#### MARYLAND SECTION.

The 15th meeting was held October 21st. Dr. W. W. Randall, of the Maryland State Board of Health, presented a paper on "The Hydrolysis of Ethyl Sulfuric Acid."

FRANK M. BOYLES, *Secretary*.

#### NEW YORK SECTION.

The 1st regular meeting of the session 1916-17 was held October 13th, in conjunction with the New York Sections of the American Electrochemical Society, and the Society of Chemical Industry. Program: "Why Our Chemical Import Statistics Should be Overhauled," by Bernhard C. Hesse.

CHAS. F. ROTH, *Secretary*.

#### PHILADELPHIA SECTION.

The regular meeting was held October 19th. Program: "Early History of Chemical Industry in Philadelphia," by Dr. Samuel P. Sadtler.

J. HOWARD GRAHAM, *Secretary*.

#### PITTSBURGH SECTION.

The 129th regular meeting was held September 21st. Program: W. C. Cope, (a) "Revision of Our Chemical Import Statistics," (b) "Ten-Year Index to Chemical Abstracts;" A. V. Bleininger, "The Properties of Some European Bonding Clays."

The 130th meeting was held October 19th. Program: "The Viscosity of Blast Furnace Slags," by A. L. Field; "The Extraction of Cerium and Preparation of Some of its Salts," by C. T. Vogt.

W. C. COPE, *Secretary*.

# PUGET SOUND SECTION.

The Section met September 25th. Illustrated Lecture: "The Genesis of the Elements," by Prof. W. D. Harkins. Chairman of the Chicago Section.

H. L. TRUMBULL, *Secretary*.

# RHODE ISLAND SECTION.

The October meeting was held October 11th. Mr. C. F. Quaintance, of the Herold China and Pottery Co., of Golden, Colorado, spoke on "Made in America Porcelain," and Mr. W. W. Case, of Denver, Colorado, spoke on "Denver Fire Clay Products."

ROBERT F. CHAMBERS, *Secretary*.

# ROCHESTER SECTION.

A meeting was held October 2nd. Program: "Photo-Engraving," by A. J. Newman.

The regular meeting was held October 16th. Mr. H. A. Carpenter, of West High School, spoke on "The Teaching of Elementary Chemistry."

H. H. TOZIER, *Secretary*.

# ST. LOUIS SECTION.

A meeting was held October 2nd. Program: "The New United States Pharmacopoeia," by Dr. C. E. Caspari.

GEO. LANG, JR., *Secretary*.

# SYRACUSE SECTION.

The following have been elected as officers of the section for the ensuing year: G. M. Berry, *President*; E. J. Wall, *Vice-President*; R. S. Boehner, *Secretary*; R. S. Fleming, *Treasurer*; E. S. Johnson, *Councilor*.

R. S. BOEHNER, *Secretary*.

# UNIVERSITY OF ILLINOIS SECTION.

A joint meeting was held with the Chemical Club of the University of Illinois, October 3rd. Miss Marian E. Sparks spoke on "Chemical Literature and its Use."

G. D. BEAL, *Secretary*.

# WISCONSIN SECTION.

The October meeting was held October 10th. Prof. Bradley Stoughton, Secretary of the American Institute of Mining Engineers, spoke on "The Constitution of Steel."

L. F. AUGSPURGER, *Secretary*.

# Proceedings.

## COUNCIL.

President Herty appointed the following as members of the Committee on Dyestuffs for the U. S. Bureau of Printing and Engraving: J. Merritt Matthews, *Chairman*, Allen Rogers, E. F. Roeber.

MEMBERS ELECTED BETWEEN OCTOBER 15 AND NOVEMBER 15, 1916.

- Acheson, John L., 743 Hill Ave., Wilkinsburg, Pa.  
Allen, E. J., Defiance, Ohio.  
Anderson, Arthur K., 307 Manitou St., Northfield, Minn.  
Bache-Wiig, John, 507 Cumberland Ave., Portland, Maine.  
Benjamin, Edward O., 177 Hillside Ave., Newark, N. J.  
Berg, Eysten, Room 659, 200 Fifth Ave., New York City.  
Berk, Paul Felix, 1 Fenchurch Ave., London, E. C., England.  
Bicknell, Richard S., 65 Prospect St., East Orange, N. J.  
Blodgett, W. A., 34 Hickok Place, Burlington, Vt.  
Blue, Thos. G., Prescott, Ariz.  
Bock, John E., 3322 Walnut St., Milwaukee, Wis.  
Booraem, J. Francis, 52 Vanderbilt Ave., New York City.  
Bronfenbrenner, Jacob, Western Pennsylvania Hospital, Pittsburgh, Pa.
